SEVENTH EDITION

**VOLUME ONE**

EDITOR IN CHIEF

## Arnold G. Coran, MD

Emeritus Professor of Surgery
Section of Pediatric Surgery
University of Michigan Medical School and C. S. Mott Children's Hospital
Ann Arbor, Michigan
Professor of Surgery
Division of Pediatric Surgery
New York University Medical School
New York, New York

ASSOCIATE EDITORS

## N. Scott Adzick, MD

Surgeon-in-Chief
The Children's Hospital of Philadelphia
C. Everett Koop Professor of Pediatric Surgery
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

## Thomas M. Krummel, MD

Emile Holman Professor and Chair
Department of Surgery
Stanford University School of Medicine
Susan B. Ford Surgeon-in-Chief
Lucile Packard Children's Hospital
Stanford, California

## Jean-Martin Laberge, MD

Professor of Surgery
McGill University
Attending Pediatric Surgeon
Montreal Children's Hospital of the McGill University Health Centre
Montreal, Quebec, Canada

## Robert C. Shamberger, MD

Chief of Surgery
Children's Hospital Boston
Robert E. Gross Professor of Surgery
Harvard Medical School
Boston, Massachusetts

## Anthony A. Caldamone, MD

Professor of Surgery (Urology) and Pediatrics
Brown University School of Medicine
Chief of Pediatric Urology
Hasbro Children's Hospital
Providence, Rhode Island

EMERITUS EDITORS

## Jay L. Grosfeld, MD

Lafayette Page Professor of Pediatric Surgery and Chair, Emeritus
Section of Pediatric Surgery
Indiana University School of Medicine
Surgeon-in-Chief, Emeritus
Pediatric Surgery
Riley Children's Hospital
Indianapolis, Indiana

## James A. O'Neill, Jr., MD

J. C. Foshee Distinguished Professor and Chairman, Emeritus
Section of Surgical Sciences
Vanderbilt University School of Medicine
Nashville, Tennessee

## Eric W. Fonkalsrud, MD

Emeritus Professor of Surgery and Chief of Pediatric Surgery
University of California, Los Angeles
Los Angeles, California

# About the Editors

**ARNOLD G. CORAN, MD,** is Emeritus Professor of Surgery at the C. S. Mott Children's Hospital and the University of Michigan Medical School. He was the Chief of Pediatric Surgery and the Surgeon-in-Chief at the C. S. Mott Children's Hospital and Professor of Pediatric Surgery at the University of Michigan Medical School from 1974 to 2006. He is also currently Professor of Surgery in the Division of Pediatric Surgery at New York University School of Medicine. He was one of the editors of the fifth and sixth editions of *Pediatric Surgery* and is the current Editor in Chief of this seventh edition. His expertise in pediatric surgery centers on complex esophageal and colorectal diseases in infants and children. He is the past President of the American Pediatric Surgical Association and the past Chairman of the Surgical Section of the American Academy of Pediatrics. He has been married to Susan Coran for 50 years and has three children and nine grandchildren.

**N. SCOTT ADZICK, MD,** has served as the Surgeon-in-Chief and Director of The Center for Fetal Diagnosis and Treatment at The Children's Hospital of Philadelphia since 1995. He is the C. Everett Koop Professor of Pediatric Surgery at the University of Pennsylvania School of Medicine. Dr. Adzick was raised in St. Louis, received his undergraduate and medical degrees from Harvard, and has a Master of Medical Management degree from Carnegie Mellon University. He was a surgical resident at the Massachusetts General Hospital and a pediatric surgery fellow at Boston Children's Hospital. His pediatric surgical expertise is centered on neonatal general and thoracic surgery, with a particular focus on clinical applications of fetal diagnosis and therapy. He has received grant support from the National Institutes of Health for more than 20 years and has authored more than 550 publications. He was elected to the Institute of Medicine of the National Academy of Science in 1998. Scott and Sandy Adzick have one son.

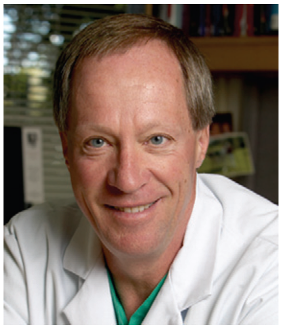
**ANTHONY A. CALDAMONE, MD,** graduated from Brown University and Brown School of Medicine. He was the first graduate of the medical school to become full professor at the institution. He did his residency at the University of Rochester and completed his fellowship under Dr. John W. Duckett at The Children's Hospital of Philadelphia. He is currently Professor of Surgery (Urology) and Pediatrics and Program Director for the Urology Residency at Brown University School of Medicine and Chief of Pediatric Urology at Hasbro Children's Hospital in Providence.

Dr. Caldamone has served as President of the New England Section of the American Urological Association (AUA). He has also served as Secretary-Treasurer and President of the Society for Pediatric Urology. He has been on several committees of the AUA including the Socio-Economic Committee, Publications Committee, and Nominating Committee. He is currently Executive Secretary of the Pediatric Urology Advisory Council. Locally he has served as President of the Rhode Island Urological Society, as President of the Brown Medical Alumni Association, as Chairman of the Board of Directors of Komedyplast Foundation, and as a member of the Board of Regents of La Salle Academy.

Dr. Caldamone has been on several medical missions to the Middle East, South America, and Bangladesh and has been on the Board of Directors of Physicians for Peace.

He was one of the editors of the sixth edition of *Pediatric Surgery*. He is currently an Editor for the *Journal of Pediatric Urology* and is Editor in Chief of the *Dialogues in Pediatric Urology*.

Dr. Caldamone is married to Barbara Caldamone and has two children, Amy and Matthew.



**THOMAS M. KRUMMEL, MD,** is the Emile Holman Professor and Chair of the Department of Surgery at Stanford University and the Susan B. Ford Surgeon-in-Chief at Lucile Packard Children's Hospital. Dr. Krummel has served in leadership positions in the American College of Surgeons, the American Pediatric Surgical Association, the American Surgical Association, the American Board of Surgery, and the American Board of Pediatric Surgery. He has mentored more than 150 students, residents, and postdoctoral scholars. He and his wife, Susie, have three children.

**JEAN-MARTIN LABERGE, MD**, is Professor of Surgery at McGill University and surgeon at the Montreal Children's Hospital of the McGill University Health Centre. He was the Director of Pediatric Surgery at the Montreal Children's Hospital from 1996 to 2008 and Program Director from 1994 to 2008. He is editorial consultant for the *Journal of Pediatric Surgery* and *Pediatric Surgery International* and was guest editor of two issues of *Seminars in Pediatric Surgery.* He has contributed chapters to several textbooks, including previous editions of *Pediatric Surgery,* Holcomb and Murphy's *Ashcraft's Pediatric Surgery,* Taussig and Landau's *Pediatric Respiratory Medicine,* and *Paediatric Surgery: A Comprehensive Text for Africa.* His research has focused on the effects of fetal tracheal occlusion to promote lung growth. His clinical interests include fetal diagnosis and treatment, congenital lung lesions, and anorectal malformations. He was President of the International Fetal Medicine and Surgery Society and is the immediate past President of the Canadian Association of Paediatric Surgeons (2009–2011). He has been married to Louise Caouette-Laberge, a pediatric plastic surgeon, for 34 years and has four children and three grandchildren.

**ROBERT C. SHAMBERGER, MD**, is the Robert E. Gross Professor of Surgery at Harvard Medical School and is Chief of Surgery at Children's Hospital in Boston.

Dr. Shamberger's expertise in pediatric surgery centers on oncology, inflammatory bowel disease, and chest wall deformities. He was Chair of the Surgical Committee for the Pediatric Oncology Group and Children's Oncology Group, as well as a member of the National Wilms' Tumor Study Group. He is the current President of the American Pediatric Surgical Association and Chairman of the Section on Surgery of the American Academy of Pediatrics. He has been married to Kathy Shamberger for 39 years and has three children and one grandchild.

# Contributors

**Mark C. Adams, MD, FAAP**
Professor of Urology and Pediatrics
Vanderbilt University School of Medicine
Pediatric Urologist
Monroe Carell Jr. Children's Hospital at Vanderbilt
Nashville, Tennesee

**Obinna O. Adibe, MD**
Assistant Professor of Surgery
Assistant Professor in Pediatrics
Duke University School of Medicine
Durham, North Carolina

**Jeremy Adler, MD, MSc**
Assistant Professor
Pediatrics and Communicable Diseases
University of Michigan
C. S. Mott Children's Hospital
Ann Arbor, Michigan

**N. Scott Adzick, MD**
Surgeon-in-Chief
The Children's Hospital of Philadelphia
C. Everett Koop Professor of Pediatric Surgery
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

**Craig T. Albanese, MD**
Professor of Surgery
Pediatrics and Obstetrics and Gynecology
Chief, Division of Pediatric Surgery
Department of Surgery
Stanford Hospital and Clinics, Stanford Medicine
John A. and Cynthia Fry Gunn Director of Surgical Services
Lucile Packard Children's Hospital at Stanford
Palo Alto, California

**Walter S. Andrews, MD**
Professor of Pediatric Surgery
Department of Surgery
University of Missouri at Kansas City
Director of Renal Liver Intestinal Pediatric Transplantation Programs
Department of General Surgery
Children's Mercy Hospital
Kansas City, Missouri

**Harry Applebaum, MD**
Attending Pediatric Surgeon
Southern California Permanente Medical Group
Clinical Professor of Surgery
David Geffen School of Medicine
University of California, Los Angeles
Los Angeles, California

**Marjorie J. Arca, MD**
Associate Professor
Division of Pediatric Surgery
Medical College of Wisconsin
Clinical Director
Pediatric Surgical Critical Care
Children's Hospital of Wisconsin
Milwaukee, Wisconsin

**Daniel C. Aronson, MD, PhD**
President
International Society of Paediatric Surgical Oncology
Department of Surgery/Pediatric Surgery
Radboud University Nijmegen Medical Center
Nijmegen, The Netherlands

**Richard G. Azizkhan, MD, PhD**
Surgeon-in-Chief
Lester Martin Chair of Pediatric Surgery
Pediatric Surgical Services
Cincinnati Children's Hospital Medical Center
Professor of Surgery and Pediatrics
University of Cincinnati College of Medicine
Cincinnati, Ohio

**Robert Baird, MD CM, MSc, FRCSC**
Assistant Professor of Surgery
Pediatric General Surgery
Montreal Children's Hospital
McGill University
Montreal, Quebec, Canada

**Sean Barnett, MD, MS**
Assistant Professor of Surgery
Division of Pediatric General and Thoracic Surgery
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

**Douglas C. Barnhart, MD, MSPH**
Associate Professor
Department of Surgery and Pediatrics
University of Utah
Attending Surgeon
Primary Children's Medical Center
Salt Lake City, Utah

**Katherine A. Barsness, MD**
Assistant Professor of Surgery
Division of Pediatric Surgery
Northwestern University
Feinberg School of Medicine
Attending Physician
Division of Pediatric Surgery
Children's Memorial Hospital
Chicago, Illinois

**Robert H. Bartlett, MD**
Professor Emeritus of Surgery
University of Michigan Medical School
Ann Arbor, Michigan

**Laurence S. Baskin, MD**
Professor and Chief, Pediatric Urology
Departments of Urology and Pediatrics
University of California, San Francisco
San Francisco, California

**Spencer W. Beasley, MB ChB, MS, FRACS**
Professor and Clinical Director
Department of Pediatric Surgery
Christchurch Hospital
Professor
Department of Surgery
Christchurch School of Medicine and Health Sciences
University of Otago
Christchurch, New Zealand

**Michael L. Bentz, MD**
Professor and Chairman
University of Wisconsin Plastic Surgery
University of Wisconsin-Madison
Madison, Wisconsin

**Deborah F. Billmire, MD**
Professor
Department of Surgery
Section of Pediatric Surgery
Indiana University
Indianapolis, Indiana

**Scott C. Boulanger, MD, PhD**
Assistant Professor of Surgery
Division of Pediatric Surgery
Case Western Reserve University School of Medicine
Cleveland, Ohio

**Mary L. Brandt, MD**
Professor and Vice Chair
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Houston, Texas

**John W. Brock III, MD**
Professor and Director
Division of Pediatric Urology
Vanderbilt University
Surgeon-in-Chief
Monroe Carell Jr. Children's Hospital at Vanderbilt
Nashville, Tennesee

**Rebeccah L. Brown, MD**
Associate Professor of Clincal Surgery and Pediatrics
Department of Pediatric Surgery
Cincinnati Children's Hospital Medical Center
Associate Director of Trauma Services
Department of Trauma Services
Associate Professor of Surgery
Department of Surgery
University of Cincinnati Hospital
Cincinnati, Ohio

**Imad F. Btaiche, PhD, BCNSP**
Clinical Associate Professor
Department of Clinical Social and Administrative Sciences
University of Michigan College of Pharmacy
Clinical Pharmacist, Surgery and Nutrition Support
Program Director, Critical Care Residency
University of Michigan Hospitals and Health Centers
Ann Arbor, Michigan

**Ronald W. Busuttil, MD, PhD**
Distinguished Professor and Executive Chairman
UCLA Department of Surgery
David Geffen School of Medicine
University of California, Los Angeles
Los Angeles, California

**Anthony A. Caldamone, MD**
Professor of Surgery (Urology) and Pediatrics
Brown University School of Medicine
Chief of Pediatric Urology
Hasbro Children's Hospital
Providence, Rhode Island

**Donna A. Caniano, MD**
Professor of Surgery and Pediatrics
Department of Surgery
Ohio State University College of Medicine
Surgeon-in-Chief
Nationwide Children's Hospital
Columbus, Ohio

**Michael G. Caty, MD**
John E. Fisher Professor of Pediatric Surgery
Department of Pediatric Surgical Services
Women and Children's Hospital of Buffalo
Professor of Surgery and Pediatrics
Department of Surgery
State University of New York at Buffalo
Buffalo, New York

**Christophe Chardot, MD, PhD**
Professor
Universite Rene Descartes
Pediatric Surgery Unit
Hopital Necker Enfants Malades
Paris, France

**Dai H. Chung, MD**
Professor and Chairman
Janie Robinson and John Moore Lee Endowed Chair
Pediatric Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

**Robert E. Cilley, MD**
Professor of Surgery and Pediatrics
Department of Surgery
Penn State College of Medicine
Hershey, Pennsylvania

**Nadja C. Colon, MD**
Surgical Research Fellow
Pediatric Surgery
Vanderbilt University Medical Center
Nashville, Tenesee

**Paul M. Columbani, MD**
Robert Garrett Professor of Surgery
Department of Surgery
The Johns Hopkins University School of Medicine
Pediatric Surgeon in Charge
The Johns Hopkins Hospital
Baltimore, Maryland

**Arnold G. Coran, MD**
Emeritus Professor of Surgery
Section of Pediatric Surgery
University of Michigan Medical School and C. S. Mott Children's Hospital
Ann Arbor, Michigan
Professor of Surgery
Division of Pediatric Surgery
New York University Medical School
New York, New York

**Robin T. Cotton, MD, FACS, FRCS(C)**
Director
Pediatric Otolaryngology–Head and Neck Surgery
Cincinnati Children's Hospital
Professor
Department of Otolaryngology
University of Cincinnati College of Medicine
Cincinnati, Ohio

**Robert A. Cowles, MD**
Assistant Professor
Department of Surgery
Columbia University College of Physicians and Surgeons
Assistant Attending Surgeon
Department of Surgery
Morgan Stanley Children's Hospital of New York–Presbyterian
New York, New York

**Charles S. Cox, Jr., MD**
The Children's Fund Distinguished Professor of Pediatric Surgery
Pediatric Surgery
University of Texas Medical School at Houston
Houston, Texas

**Melvin S. Dassinger III, MD**
Assistant Professor of Surgery
Department of Pediatric Surgery
University of Arkansas for Medical Sciences
Little Rock, Arkansas

**Andrew M. Davidoff, MD**
Chairman
Department of Surgery
St. Jude Children's Research Hospital
Memphis, Tennessee

**Richard S. Davidson, MD**
Division of Orthopedics
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

**Paolo De Coppi, MD, PhD**
Clinical Senior Lecturer
Surgery Unit
University College of London Institute of Child Health
London, United Kingdom

**Bryan J. Dicken, MD, MSc, FRCSC**
Assistant Professor of Surgery
Pediatric Surgery
University of Alberta
Stollery Children's Hospital
Alberta, British Columbia, Canada

**William Didelot, MD**
Vice Chairman, Orthopedic Section
Pediatric Orthopedics
Peyton Manning Children's Hospital
Indianapolis, Indiana

**John W. DiFiore, MD**
Clinical Assistant Professor of Surgery
Case School of Medicine
Staff Pediatric Surgeon
Children's Hospital at Cleveland Clinic
Cleveland, Ohio

**Patrick A. Dillon, MD**
Associate Professor of Surgery
Department of Surgery
Division of Pediatric Surgery
Washington University School of Medicine
St. Louis, Missouri

**Peter W. Dillon, MD**
Chair, Department of Surgery
John A. and Marian T. Waldhausen Professor of Surgery
The Pennsylvania State University College of Medicine
Hershey, Pennsylvania

**Patricia K. Donahoe, MD**
Marshall K. Bartlett Professor of Surgery
Harvard Medical School
Director, Pediatric Surgical Research Laboratories
Massachusetts General Hospital
Boston, Massachusettes

**Gina P. Duchossois, MS**
Injury Prevention Coordinator
Trauma Program
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

**James C. Y. Dunn, MD, PhD**
Associate Professor
Surgery
University of California, Los Angeles School of Medicine
Los Angeles, California

**Sanjeev Dutta, MD, MA**
Associate Professor of Surgery and Pediatrics
Department of Surgery
Stanford University
Surgical Director
Multidisciplinary Initiative for Surgical Technology Research
Stanford University
SRI International
Stanford, California

**Simon Eaton, BSc, PhD**
Senior Lecturer
Surgery Unit
University College London Institute of Child Health
London, United Kingdom

**Peter F. Ehrlich, MD, MSc**
Associate Professor
Pediatric Surgery
University of Michigan C. S. Mott Children's Hospital
Ann Arbor, Michigan

**Martin R. Eichelberger, MD**
Professor of Surgery and Pediatrics
George Washington University
Children's National Medical Center
Washington, District of Columbia

**Lisa M. Elden, MD, MS**
Assistant Professor
Otorhinolaryngology
Head and Neck Surgery
University of Pennsylvania School of Medicine
Attending
Division of Otolaryngology
Department of Surgery
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

**Jonathan L. Eliason, MD**
Assistant Professor of Vascular Surgery
Department of Surgery
University of Michigan
Ann Arbor, Michigan

**Sherif Emil, MD, CM**
Associate Professor and Director
Division of Pediatric General Surgery
Department of Surgery
Montreal Children's Hospital
McGill University Health Centre
Montreal, Quebec, Canada

**Mauricio A. Escobar, Jr., MD**
Pediatric Surgeon
Pediatric Surgical Services
Mary Bridge Children's Hospital and Health Center
Clinical Instructor
Department of Surgery
University of Washington
Tacoma, Washington

**Richard A. Falcone, Jr., MD, MPH**
Associate Professor of Surgery
Division of Pediatric and Thoracic Surgery
Department of Surgery
Cincinnati Children's Hospital Medical Center
University of Cincinnati College of Medicine
Cincinnati, Ohio

**Mary E. Fallat, MD, FACS, FAAP**
Hirikati S. Nagaraj Professor and Chief, Pediatric Surgery
Division Director, Pediatric Surgery
University of Louisville
Surgeon-in-Chief
Kosair Children's Hospital
Louisville, Kentucky

**Diana L. Farmer, MD**
Professor and Chair
Surgery School of Medicine
University of California Davis
Surgeon-in-Chief
University of California Davis Children's Hospital
Sacramento, California

**Douglas G. Farmer, MD, FACS**
Director, Intestinal Transplant Program
Co-Director, Intestinal Failure Center
University of California Los Angeles Medical Center
Los Angeles, California

**Albert Faro, MD**
Associate Professor of Pediatrics
Associate Medical Director
Pediatric Transplant Program
Pediatrics
Washington University
St. Louis Children's Hospital
St. Louis, Missouri

**Michael J. Fisher, MD**
Assistant Professor of Pediatrics
Department of Pediatrics
University of Pennsylvania School of Medicine
Attending Physician
Division of Oncology and Center for
Childhood Cancer Research
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

**Steven J. Fishman, MD**
Associate Professor of Surgery
Children's Hospital Boston
Boston, Massachusettes

**Tamara N. Fitzgerald, MD, PhD**
Senior Resident, Department of Surgery
Yale University
New Haven, Connecticuit

**Alan W. Flake, MD**
Professor of Surgery
Director, Children's Center for Fetal Research
General, Thoracic, and Fetal Surgery
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

**Robert P. Foglia, MD**
Professor, Division Chief, Pediatric Surgery
Hellen J. and Robert S. Strauss and Diana K. and Richard
C. Strauss Chair in Pediatric Surgery
Department of Surgery

Bern, Switzerland

# Preface

In June 1959, a group of five distinguished pediatric surgeons from the United States and Canada formed an editorial board to investigate the possibility of writing an authoritative, comprehensive textbook of pediatric surgery. The five individuals assembled were Kenneth Welch, who served as chairman of the board from Boston Children's Hospital (the original name); Mark Ravitch from The Johns Hopkins Hospital; Clifford Benson from Detroit Children's Hospital (the original name); William Snyder from Los Angeles Children's Hospital; and William Mustard from The Hospital for Sick Children in Toronto, Canada. From 1953 to 1962, the most comprehensive textbook of pediatric surgery was *The Surgery of Infancy and Childhood* by Robert E. Gross. At that time, Dr. Gross had no plans to write a second edition of his book. He was the sole author of the first edition of his book and did not wish to carry out such a monumental task with a second edition. The five editors thought that an updated textbook of pediatric surgery was needed. The first edition was published in 1962 and quickly became recognized as the most definitive and comprehensive textbook in the field. Between 1962 and 2006, six editions of the book were published. During this period, this textbook has been considered the bible of pediatric surgery. The editors and authors have changed during the 44 years that elapsed from the first to the sixth editions. In most cases, the editorial board changed gradually with the deletion and addition of two to three pediatric surgeons with each edition. The editors of the fifth edition also continued as the editors of the sixth edition. In the current seventh edition, the editorial board has been replaced except for Arnold Coran, who has functioned as the Chief Editor of this edition, and Anthony Caldamone, who continues to be the editor for the urology section. A new generation of pediatric surgical leaders has emerged since the last edition, and the editorial board reflects that change. Robert Shamberger from Children's Hospital Boston, Scott Adzick from The Children's Hospital of Philadelphia, Thomas Krummel from the Lucile Packard Children's Hospital and Stanford University Medical Center, and Jean-Martin Laberge from the Montreal Children's Hospital of the McGill University Health Centre represent the new members of the editorial board.

The seventh edition continues its international representation, with authors from several countries contributing chapters. Most of the previous chapters have been retained, but, in several cases, new authors have been assigned to these chapters. Of special interest is the addition of a new chapter (Chapter 16) on patient- and family-centered pediatric surgical care, a relatively new concept in the management of the pediatric surgical patient. Two chapters from the sixth edition, "Bone and Joint Infections" and "Congenital Defects of Skin, Connective Tissues, Muscles, Tendons, and Joints," have been deleted because currently, most pediatric surgeons do not deal with these problems. A few of the urology chapters have been merged, but all the material from the previous edition is included in these chapters. The chapter "Congenital Heart Disease and Anomalies of the Great Vessels" (Chapter 127) was kept comprehensive because so many of these patients have co-existent pediatric surgical problems or have surgical problems after cardiac surgery. Overall, there are 131 chapters in this edition, all of which are written by experts in the field and represent a comprehensive treatise of the subject with an exhaustive bibliography. In addition, each chapter provides a complete discussion of both open and closed techniques, when appropriate, for the management of the surgical problem.

One of the remarkable things about this edition is that not a single sheet of paper was used by the authors or editors in the creation of the book. Everything from the writing of the chapter to its editing was done electronically. This entire process was overseen by Lisa Barnes, the developmental editor at Elsevier. All the editors wish to thank her for her patience, availability, and efficiency in completing this textbook. Finally, we want to thank all the authors for their outstanding chapters, which will provide definitive and comprehensive information on the various pediatric surgical problems to pediatric surgeons throughout the world and thus improve the surgical care of infants and children worldwide.

CHAPTER 1

# History of Pediatric Surgery: A Brief Overview

Jay L. Grosfeld and James A. O'Neill, Jr.

The history of pediatric surgery is rich, but only the major contributions and accounts of the leaders in the field can be summarized here.

## Early Years

The development of pediatric surgery has been tightly bound to that of surgery in adults, and in general, surgical information was based on simple observations of obvious deformities, such as cleft lip and palate, skeletal deformities, and imperforate anus. The only basic science of the 2nd through 16th centuries, until the 19th, was anatomy, mostly developed by surgeons; so, technical care was based on this, regardless of the patient's age. The fate of affected infants with a defect was frequently related to the cultural and societal attitudes of the time, and most did not survive long. A better understanding of the human body was influenced by Galen's study of muscles, nerves, and blood vessels in the 2nd century.[1] Albucacis described circumcision, use of urethral sounds, and cleft lip in Cordoba in the 9th century.[2] Little progress was made during the Middle Ages. In the 15th and 16th centuries, Da Vinci provided anatomic drawings; Vesalius touched on physiology; and Ambrose Paré, better known for his expertise in war injuries, wrote about club foot and described an omphalocele and conjoined twins.[3] The 17th and 18th centuries were the era of the barber surgeon. Johannes Fatio, a surgeon in Basel, was the first to systematically study and treat surgical conditions in children, and he attempted separation of conjoined twins in 1689.[4] Other congenital malformations were identified as a result of autopsy studies, including descriptions of esophageal atresia in one of thoracopagus conjoined twins by Durston in 1670,[5] intestinal atresia by Goeller in 1674,[6] an instance of probable megacolon by Ruysch in 1691,[7] and a more precise description of esophageal atresia by Gibson in 1697,[8] but there were no attempts at operative correction. Surgery for children was usually limited to orthopedic procedures, management of wounds, ritual circumcision, and drainage of superficial abscesses. In 1793, Calder[9] was the first to describe duodenal atresia. In France, Duret[10] performed the initial colostomy for a baby with imperforate anus in 1793, Amussat[11] performed the first formal perineal anoplasty in 1834, and in the United States, Jacobi[12] performed the first colostomy for probable megacolon in 1869. Up to this point, no surgeon devoted his practice exclusively to children. Despite this fact, a movement began to develop hospitals for children, led mainly by women in various communities, who felt that adult hospitals were inappropriate environments for children.

In Europe, the major landmark in the development of children's hospitals was the establishment of the Hôpital des Enfants Malades in Paris in 1802, which provided treatment for children with both medical and surgical disorders.[13] Children younger than 7 years of age were not admitted to other hospitals in Paris. Subsequently, similar children's hospitals were established in major European cities, including Princess Lovisa Hospital in Stockholm in 1854, and other facilities followed in St. Petersburg, Budapest, East London, and Great Ormond Street, London.[14] Children's hospitals in the United States opened in Philadelphia (1855), Boston (1869), Washington, DC (1870), Chicago (1882), and Columbus, Ohio (1892).[15] The Hospital for Sick Children in Toronto was established in 1885. Some of these facilities started out as foundling homes and then mainly cared for orthopedic problems and medical illnesses. Few had full-time staff, because it was difficult to earn a living caring for children exclusively.

Major advances in the 19th century that would eventually influence surgical care were William T.G. Morton's introduction of anesthesia in 1864, antisepsis using carbolic acid championed by Joseph Lister and Ignaz Semelweiss in 1865, and Wilhelm Roentgen's discovery of the x-ray in 1895. Harald Hirschsprung of Copenhagen wrote a classical treatise on two infants with congenital megacolon in 1886,[16] and Max Wilms, then in Leipzig, described eight children with renal tumors in 1899.[17] Fockens accomplished the first successful anastomosis for intestinal atresia in 1911[18]; Pierre Fredet (1907)[19] and Conrad Ramstedt (1912)[20] documented effective operative procedures (pyloromyotomy) for hypertrophic pyloric stenosis; and N.P. Ernst did the first successful repair of duodenal atresia in 1914, which was published 2 years later.[21]

# 20th Century: The Formative Years

## UNITED STATES

There was little further progress in the early 20th century because of World War I and the Great Depression. It was during this time that a few individuals emerged who would devote their total attention to the surgical care of children. William E. Ladd of Boston, Herbert Coe of Seattle, and Oswald S. Wyatt of Minneapolis, the pioneers, set the stage for the future of pediatric surgery in the United States.[14,15,22]

Ladd, a Harvard medical graduate in 1906, trained in general surgery and gynecology and was on the visiting staff at the Boston Children's Hospital. After World War I, he spent more time there and subsequently devoted his career to the surgical care of infants and children and became surgeon-in-chief in 1927. His staff included Thomas Lanman, who attempted repair of esophageal atresia in more than 30 patients unsuccessfully, but the report of his experience set the stage for further success. Ladd recruited Robert E. Gross, first as a resident and then as a colleague. Ladd developed techniques for management of intussusception, pyloric stenosis, and bowel atresia; did the first successful repair of a correctable form of biliary atresia in 1928; and described the Ladd procedure for intestinal malrotation in 1936 (Fig. 1-1, *A* and *B*).[23–26] While Ladd was out of Boston, and against his wishes, Gross, then 33 years old and still a resident, performed the first ligation of a patent ductus arteriosus in 1938. One can imagine how this influenced their relationship. Nonetheless, in 1941, Ladd and Gross published their seminal textbook, *Abdominal Surgery of Infants and Children.*[27] 1941 was of importance not only because of the entry of the United States into WW II, but that was the year that Cameron Haight,[28] a thoracic surgeon in Ann Arbor, Michigan, and Rollin Daniel, in Nashville, Tennessee, independently performed the first successful primary repairs of esophageal atresia.

In addition to his landmark ductus procedure, Gross' surgical innovations, involving the great vessels around the heart, coarctation of the aorta, management of vascular ring deformities, and early use of allografts for aortic replacement, were major contributions to the development of vascular surgery (Fig. 1-2).[14] The training program in Boston grew and recruited future standouts in the field, such as Alexander Bill, Orvar Swenson, Tague Chisholm, and H. William Clatworthy. Ladd retired in 1945 and was succeeded by Gross as surgeon-in-chief. Gross was a very skillful pediatric surgeon and cardiovascular surgical pioneer who continued to attract bright young trainees to his department. In 1946, C. Everett Koop and Willis Potts spent a few months observing at the Boston Children's Hospital and then returned to the Children's Hospital of Philadelphia and Children's Memorial Hospital in Chicago, respectively. Luther Longino, Judson Randolph, Morton Wooley, Daniel Hays, Thomas Holder, W. Hardy Hendren, Lester Martin, Theodore Jewett, Ide Smith, Samuel Schuster, Arnold Colodny, Robert Filler, Arvin Phillipart, and Arnold Coran were just a few of the outstanding individuals attracted to the Boston program. Many became leaders in the field, developed their own training programs and, like disciples, spread the new gospel of pediatric surgery across the country. After Gross retired, Judah Folkman, a brilliant surgeon-scientist, became the third surgeon-in-chief in Boston in 1968. W. Hardy Hendren, Moritz Ziegler, and, currently, Robert Shamberger followed in the leadership role at the Children's Hospital, Boston.[15,25]

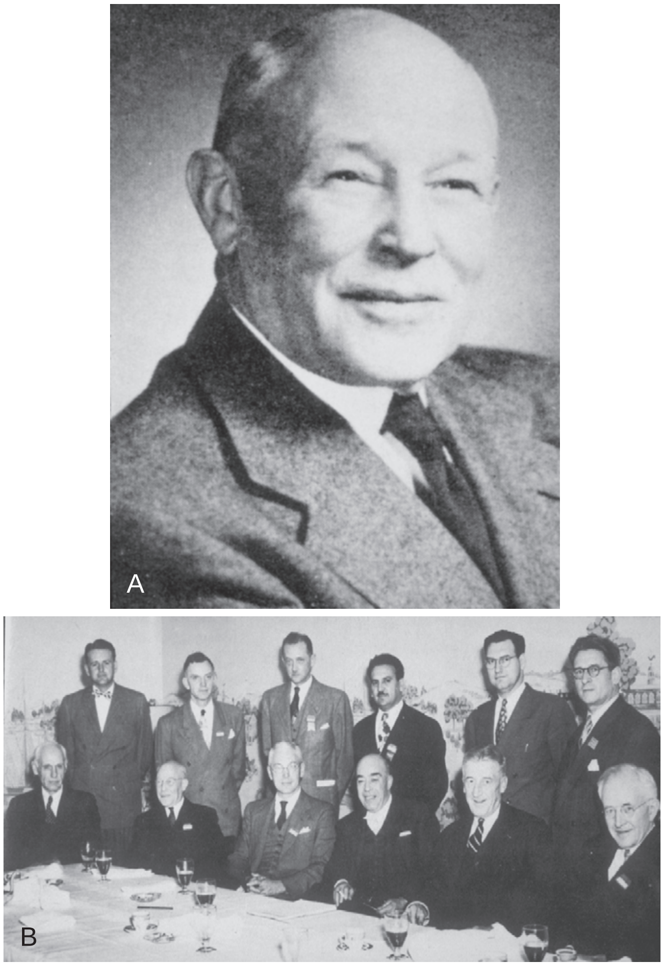

**FIGURE 1-3** **A,** Herbert Coe, Seattle, Washington. **B,** Photograph of the first meeting of the Section on Surgery, American Academy of Pediatrics, November 12, 1948. Seated, from *left to right,* are Drs. William E. Ladd, Herbert Coe, Frank Ingraham, Oswald Wyatt, Thomas Lanman, and Clifford Sweet. Standing, from *left to right,* are Drs. Henry Swan, J. Robert Bowman, Willis Potts, Jesus Lozoya-Solis (of Mexico), C. Everett Koop, and Professor Fontana.

Herbert Coe was raised in Seattle, Washington, and attended medical school at the University of Michigan. After training in general surgery, he returned to Seattle in 1908 and was on staff at the Children's Orthopedic Hospital. After WWI, he spent time at the Boston Children's Hospital as an observer, gaining experience in pediatric surgical care. When he returned to Seattle in 1919, he was the first to exclusively limit his practice to pediatric surgery. He initiated the first children's outpatient surgical program in the country. He was a strong advocate for children and, in 1948, helped to persuade the leadership of the American Academy of Pediatrics (AAP) to form its surgery section, which he saw as a forum for pediatric surgeons to gather, share knowledge, and gain recognition for their new specialty (Fig. 1-3). Alexander Bill joined Coe in practice following his training in Boston and subsequently became surgeon-in-chief at the Children's Orthopedic Hospital.[14,15]

Oswald Wyatt, a Canadian by birth, attended both undergraduate school and medical school at the University of Minnesota. He trained in general surgery in Minneapolis. After serving in the military in WWI, Wyatt returned to Minneapolis and entered surgical practice. In 1927, he spent time with Edwin Miller at the Children's Memorial Hospital in Chicago. When he returned to Minneapolis, he then limited his surgical practice to children. When Tague Chishom completed his training with Ladd and Gross in 1946, he joined Wyatt's practice. Together they developed one of the largest and most successful pediatric surgery community practice groups in the country.[14,15]

In 1948, C. Everett Koop became the first surgeon-in-chief at the Children's Hospital in Philadelphia and served until 1981. He was followed by James A. O'Neill and subsequently Scott Adzick. Prominent trainees from this program include William Kiesewetter, Louise Schnaufer, Dale Johnson, John Campbell, Hugh Lynn, Judah Folkman, Howard Filston, John Templeton, Moritz Ziegler, Don Nakayama, Ron Hirschl, and others. Dr. Koop was the second president of the American Pediatric Surgical Association (APSA) and also served as Surgeon General of the United States from 1981 to 1989 (Fig. 1-4).

Also in 1948, Orvar Swenson performed the first successful rectosigmoidectomy operation for Hirschsprung disease at Boston Children's Hospital (Fig. 1-5).[29] In 1950, he became surgeon-in-chief of the Boston Floating Hospital and subsequently succeeded Potts as surgeon-in-chief at the Children's Memorial Hospital in Chicago.

H. William Clatworthy, the last resident trained by Ladd and Gross' first resident, continued his distinguished career as surgeon-in-chief at the Columbus Children's Hospital, (now Nationwide Children's Hospital) at Ohio State University in 1950 (Fig. 1-6). Clatworthy was a gifted teacher and developed a high-quality training program that produced numerous graduates who became leaders in the field and professors of pediatric surgery at major universities, including

**FIGURE 1-6** H. William Clatworthy, Jr.

Peter Kottmeier (Brooklyn), Jacques Ducharme (Montreal,) Lloyd Schulz (Omaha), James Allen (Buffalo), Beimann Othersen (Charleston), Dick Ellis (Ft. Worth), Alfred de Lorimier (San Francisco), Eric Fonkalsrud (Los Angeles), Marc Rowe (Miami and Pittsburgh), James A. O'Neill (New Orleans, Nashville, and Philadelphia), Jay Grosfeld (Indianapolis), Neil Feins (Boston), Arnold Leonard (Minneapolis), and Medad Schiller (Jerusalem).[25] E. Thomas Boles succeeded Dr. Clatworthy as surgeon-in-chief in 1970.

## EDUCATION, ORGANIZATIONAL CHANGES, AND RELATED ACTIVITIES

Following World War II, a glut of military physicians returned to civilian life and sought specialty training. A spirit of academic renewal and adventure then pervaded an environment influenced by the advent of antibiotics, designation of anesthesia as a specialty, and the start of structured residency training programs in general surgery across the country. By 1950, one could acquire training in children's surgery as a preceptor or as a 1- or 2-year fellow at Boston Children's Hospital (Gross), Children's Memorial Hospital in Chicago (Potts), Children's Hospital of Philadelphia (Koop), Boston Floating Hospital (Swenson), Babies' Hospital in New York (Thomas Santulli), or the Children's Hospital of Los Angeles (William Snyder). There were two established Canadian programs in Toronto and Montreal. The training program at the Columbus Children's Hospital (Clatworthy) started in 1952. Other programs followed in Detroit (C. Benson), Cincinnati (L. Martin), Pittsburgh (Kiesewetter), and Washington, DC (Randolph). The output of training programs was sporadic, and some graduates had varied experience in cardiac surgery and urology, but all had broad experience in general and thoracic pediatric surgery. Gross published his renowned textbook, *The Surgery of Infancy and Childhood*, in 1953.[30] This extraordinary text, the "Bible" of the fledgling field, described in detail the experience at Boston Children's Hospital in general pediatric surgery, cardiothoracic

surgery, and urology and became the major reference source for all involved in the care of children. The successor to this book, *Pediatric Surgery,* originally edited by Clifford Benson, William Mustard, Mark Ravitch, William Snyder, and Kenneth Welch was first published in two volumes in 1962 and has now gone through seven editions. It continues to be international and encyclopedic in scope, covering virtually every aspect of children's surgery. Over time, Judson Randolph, E. Aberdeen, James O'Neill, Marc Rowe, Eric Fonkalsrud, Jay Grosfeld, and Arnold Coran were added as editors through the sixth edition. As the field has grown, several other excellent texts have been published, adding to the rich literature in pediatric surgery and its subspecialties.

The 1950s saw an increasing number of children's surgeons graduating from a variety of training programs in the United States and Canada. Many entered community practice. A number of children's hospitals sought trained pediatric surgeons to direct their surgical departments, and medical schools began to recognize the importance of adding trained pediatric surgeons to their faculties. In 1965, Clatworthy requested that the surgical section of the AAP form an education committee whose mandate was to evaluate existing training programs and make recommendations for the essential requirements for educating pediatric surgeons. Originally, 11 programs in the United States and 2 in Canada met the standards set forth by the Clatworthy committee. In short order, additional training programs, which had been carefully evaluated by the committee, implemented a standard curriculum for pediatric surgical education.[14,15,31,32]

In the 1960s, a number of important events occurred that influenced the recognition of pediatric surgery as a bona fide specialty in North America.[33] Lawrence Pickett, then secretary of the AAP Surgical Section, and Stephen Gans were strong proponents of the concept that the specialty needed its own journal. Gans was instrumental in starting the *Journal of Pediatric Surgery* in 1966, with Koop serving as the first editor-in-chief.[34] Eleven years later, Gans succeeded Koop as editor-in-chief, a position he held until his death in 1994. Jay Grosfeld then assumed the role and continues to serve as editor-in-chief of the *Journal of Pediatric Surgery* and the *Seminars of Pediatric Surgery,* which was started in 1992.

Lucian Leape, Thomas Boles, and Robert Izant promoted the concept of a new independent surgical society, in addition to the surgical section of the AAP. The idea was quickly embraced by the pediatric surgical community, and the American Pediatric Surgical Association (APSA) was launched in 1970, with Gross serving as its first president.[35,36]

In the 1950s and 1960s, three requests to the American Board of Surgery (ABS) to establish a separate board in Pediatric Surgery were unsuccessful. However, with the backing of a new independent surgical organization, established training programs, a journal devoted to the specialty, and inclusion of children's surgery into the curricula of medical schools and general surgical residency programs, another attempt was made to approach the Board for certification.[35] Harvey Beardmore of Montreal (Fig. 1-7), a congenial, diplomatic, and persuasive individual, was chosen as spokesperson. He succeeded where others had failed. In 1973, the ABS approved a new Certificate of Special Competence in Pediatric Surgery to be awarded to all qualified applicants. There was no grandfathering of certification, because all applicants for the certificate had to pass a secured examination administered by the ABS. The first examination was given in 1975 and, for the first time in any specialty, diplomats were required to recertify every 10 years. The accreditation of training programs was moved from the Clatworthy Committee of the AAP, initially, to the APSA Education Committee, and, following Board approval of certification for the specialty, to the Accreditation Council for Graduate Medical Education (ACGME) Residency Review Committee (RRC) for Surgery in 1977.

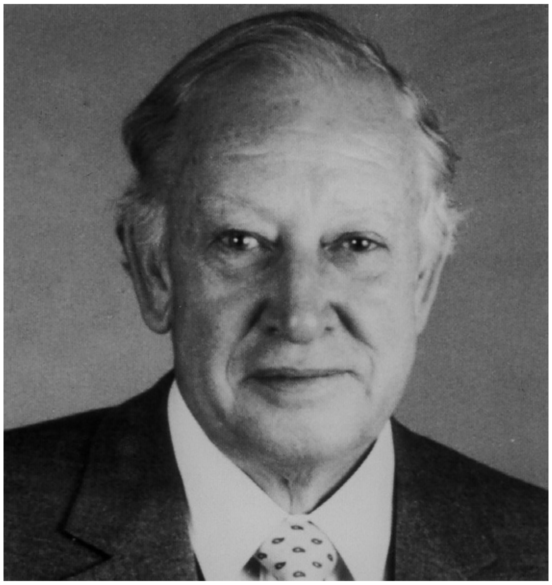

**FIGURE 1-7** Harvey Beardmore, distinguished Canadian pediatric surgeon from Montreal.

In 1989, the Association of Pediatric Surgery Training Program Directors was formed and developed as a liaison group with the RRC. Prospective residents applied for postgraduate training in pediatric surgery, initially through a matching process overseen by APSA and, in 1992, through the National Residency Matching Program (NRMP). In 1992, the ABS developed an in-training examination to be given annually to all pediatric surgical residents. In 2000, the ABS approved a separate pediatric surgery sub-board to govern the certification process. By 2010, there were 49 accredited training programs in the United States and Canada. The American College of Surgeons (ACS) recognized pediatric surgery as a separate specialty and developed focused programs at its annual congress devoted to the specialty, including a pediatric surgery research forum. Pediatric surgeons have an advisory committee at the College and have served in leadership positions on numerous committees, the Board of Governors, Board of Regents and as vice-president and president of the College (Kathryn Anderson). At this point pediatric surgery had come of age in North America and the world.

## Research

Early research in pediatric surgery was clinical in nature and involved clinical advances in the 1930s and 1940s.[14] Ladd's operation for malrotation in 1936 was a signal event based on anatomical studies.[26] In addition to Gross' work on patent ductus arteriosus and coarctation, Alfred Blalock's systemic-to-pulmonary shunt for babies with tetralogy of Fallot was another landmark. Potts' direct aortic-to-pulmonary artery shunt accomplished similar physiologic results but required

a special clamp. When Potts and Smith developed a clamp with many delicate teeth to gently hold a pulsatile vessel securely, they implemented a major technical advance that enabled the development of vascular surgery.[14] To bridge the gap in long, narrow coarctations of the aorta, Gross devised the use of freeze-dried, radiated aortic allografts and demonstrated their initial effectiveness, further promoting the use of interposition grafts in vascular surgery.[14]

Research in surgical physiology affecting adult surgical patients began to be integrated with research adapted to children. Studies of body composition in injured and postoperative patients by Francis D. Moore in adults were adapted to infants by Rowe in the United States, Peter Rickham and Andrew Wilkinson in the United Kingdom, and Ola Knutrud in Norway. Curtis Artz, John Moncrief, and Basil Pruitt were leaders in adult burn care management, and they stimulated O'Neill's interest in burn and injury research, in children.[14] In 1965, Stanley Dudrick and Douglas Wilmore, working with Jonathan Rhodes in Philadelphia, introduced the use of total parenteral nutrition, first studied in dogs, to sustain surgical patients chronically unable to tolerate enteral feedings, saving countless patients of all ages.[37] Shortly thereafter, Ola Knutrud and colleagues in Norway introduced the use of intravenous lipids. In the 1960s following extensive laboratory studies, Robert Bartlett and Alan Gazzaniga instituted extracorporeal membrane oxygenation (ECMO) for infants with temporarily inadequate heart and lung function, including those with congenital diaphragmatic hernia, certain congenital heart anomalies, meconium aspiration, and sepsis.[38] The technique was subsequently expanded for use in older children and adults. ECMO has been used successfully in thousands of infants and children worldwide.

The field of organ transplantation led by Joseph Murray, Thomas E. Starzl, and Norman Shumway in the United States, Peter Morris and Roy Y. Calne in the United Kingdom, Henri Bismuth and Yann Revillion in France, Jean-Bernard Otte in Belgium, as well as others, provided new options for the treatment of end-stage organ failure in patients of all ages. Renal, liver, and bowel transplantation have significantly altered the outcomes of infants with uncorrectable biliary atresia, end-stage renal disease, short bowel syndrome, and intestinal pseudo-obstruction. The use of split liver grafts and living-related donors to offset the problems with organ shortage, has added to the availability of kidneys, liver, and bowel for transplantation, but shortages still exist. Joseph Vacanti and colleagues in Boston and Anthony Atala in Winston Salem have laid the preliminary groundwork for the development of the field of tissue engineering. Using a matrix for select stem cells to grow into various organs, these investigators have successfully grown skin, bone, bladder, and some other tubular organs.

Ben Jackson of Richmond, J. Alex Haller in Baltimore, and Alfred de Lorimier in San Francisco, began experimenting with fetal surgery in the late 1960s and early 1970s.[15] De Lorimier's young associate, Michael Harrison and his colleagues (Scott Adzick, Alan Flake, and others) have provided new insights into fetal physiology and prenatal diagnosis and pursued clinical investigations into the practicalities of intrauterine surgery. Fetal intervention has been attempted for obstructive uropathy related to urethral valves, repair of congenital diaphragmatic hernia, twin–twin transfusion syndrome, arteriovenous shunting for sacrococcygeal teratoma, cystic lung disease, a few cardiac defects, large tumors of the neck, and myelomeningocele repair. Some of these initiatives have been abandoned, but limited protocol-driven investigation continues for fetal myelomeningocele repair in Nashville, Philadelphia, and San Francisco, and fetoscopically placed balloon tracheal occlusion in selected fetuses with diaphragmatic hernia in San Francisco, Providence, and Leuven, Belgium in an attempt to avoid pulmonary hypoplasia.

Patricia Donohoe has carried out fundamental fetal research investigating growth factors that influence embryologic development. Her seminal work defined müllerian inhibitory substance, which influences sexual development and tumor induction. Judah Folkman's discovery of the new field of angiogenesis and antiangiogenesis led him to postulate and search for antiangiogenic agents for use as cancer inhibitors. Antiangiogenic agents are currently being used clinically in a number of cancer protocols for breast and colon cancer, neuroblastoma, gastrointestinal stromal tumors, and others.

### Clinical Advances Related to Research

Although many clinical and research accomplishments have occurred in the United States, many related ones have occurred in other parts of the world as more collaborations have developed. However, the United States got a head start on many of these researches, because medical developments were not as hampered during WWII in the United States as in Europe and Asia.

In the late 1960s and early 1970s, the advent of neonatal intensive care units (NICUs) and the evolving subspecialty of neonatology had a major impact on the survival of premature infants and the activities of pediatric surgeons. The first pediatric surgical ICU was established at Children's Hospital of Philadelphia in 1962. Prior to the availability of infant ventilators, monitoring systems, other life support technologies, and microtechniques, most premature infants succumbed. Most infants weighing greater than 1000 g and 75% to 80% weighing greater than 750 g now survive with satisfactory outcomes. With these advances came new challenges in dealing with premature and micropremature surgical patients with immature physiology and conditions previously rarely encountered, such as necrotizing enterocolitis. This led to a universal emphasis on pediatric surgical critical care.

Sophisticated advances in imaging, including computerized tomography (CT), and use of prenatal ultrasound and magnetic resonance imaging to detect anomalies prior to birth and portable sonography for evaluation of cardiac defects, renal abnormalities, and intracranial hemorrhage in the NICU advanced patient care and survival.

The introduction of nitric oxide, surfactant, and newer ventilator technologies, such as oscillating and jet ventilators, have markedly diminished complications and improved outcomes for infants with respiratory distress. Exogenous administration of indomethacin to induce ductus closure and reduce the need for operative intervention has also enhanced survival.

The evolution of comprehensive children's hospitals capable of providing tertiary care to high-risk patients enabled the activities of pediatric surgeons, and this was further amplified by the expansion of specialists in the critical support services of pediatric anesthesia, pathology, and radiology. Other surgical disciplines began to focus their efforts on children, which eventually led to pediatric subspecialization in orthopedics, urology, plastic surgery, otolaryngology, ophthalmology, cardiac surgery, and neurosurgery.

Because it was recognized that trauma was the leading cause of death in children, trauma systems, including prehospital care, emergency transport, and development of assessment and management protocols, were developed by J. Alex Haller, Martin Eichelberger, James O'Neill, Joseph Tepas, and others, dramatically improving the survival of injured children. The implementation of the Glasgow Coma and Pediatric Injury Severity scores aided in triage and outcome research studies. After the initial favorable experience with nonoperative management of splenic injury in children reported by James Simpson and colleagues in Toronto in the 1970s,[39] nonoperative management protocols were applied to blunt injuries of other solid organs, and the availability of modern ultrasound and CT imaging dramatically changed the paradigm of clinical care. A national pediatric trauma database was subsequently developed, which has provided a vital data research base that has influenced trauma care. Criteria for accreditation of level 1 pediatric trauma centers were established through the Committee on Trauma of the ACS to standardize trauma systems and ideal methods of management.

Pediatric surgeons have been intimately involved in collaborative multidisciplinary cancer care for children with solid tumors since the early 1960s. Cooperative cancer studies in children antedated similar efforts in adults by more than 2 decades. In the United States, the National Wilms' Tumor Study, Intergroup Rhabdomyosarcoma Study, Children's Cancer Group, Pediatric Oncology Group and, more recently, Children's Oncology Group are examples. Tremendous strides have been achieved by having access to many children with a specific tumor managed with a standard protocol on a national basis. C. Everett Koop, Judson Randolph, H. William Clatworthy, Alfred de Lorimier, Daniel Hays, Phillip Exelby, Robert Filler, Jay Grosfeld, Gerald Haase, Beimann Othersen, Eugene Weiner, Richard Andrassy, and others represented pediatric surgery on many of the early solid tumor committees. They influenced the concepts of delayed primary resection, second-look procedures, primary reexcision, selective metastectomy, staging procedures, and organ-sparing procedures. Antonio Gentils-Martins in Portugal and Denis Cozzi in Rome have been the leading proponents of renal-sparing surgery for Wilms' tumors.[40] Currently, 80% of children with cancer now survive. The elucidation of the human genome has led to an understanding of genetic alterations in cancer cells and has changed the paradigm of care. Individualized risk-based management, depending on the molecular biology and genetic information obtained from tumor tissue, often determines the treatment protocol and the intensity of treatment for children with cancer.

In addition to the accomplishments noted above, major advances in clinical pediatric surgery, education, and research continue to unfold, and some of these contributions have been extended to adult surgery as well. Examples include the nonoperative management of blunt abdominal trauma, Clatwothy's mesocaval (Clatworthy-Marion) shunt for portal hypertension, and Lester Martin's successful sphincter-saving pull-through procedures for children with ulcerative colitis and polyposis in 1978, all techniques which have been adapted to adults. Jan Louw of Cape Town clarified the etiology of jejunoileal atresia and its management in 1955, and Morio Kasai of Sendai revolutionized the care of babies with biliary atresia by implementing hepatoportoenterostomy in 1955. The latter procedure was implemented in the United States by John Lilly and Peter Altman and in the United Kingdom by Edward Howard, Mark Davenport, and Mark Stringer. Samuel Schuster's introduction of temporary prosthetic coverage for abdominal wall defects; Donald Nuss' minimally invasive repair of pectus excavatum; Hardy Hendren's contributions in managing obstructive uropathy and repair of patients with complex cloaca; Barry O'Donnell and Prem Puri's endoscopic treatment (sting procedure) for vesicoureteral reflux; Mitrofanoff's use of the appendix as a continent catheterizable stoma for the bladder; Joseph Cohen's ureteral reimplantation technique; Malone's institution of the antegrade continent enema (MACE procedure) for fecal incontinence; Douglas Stephen's introduction of the sacroabdominal perineal pull-through for imperforate anus in 1953; Alberto Peña and DeVries' posterior sagittal anorectoplasty in the 1970s; Luis de la Torre's introduction of the transanal pull-through for Hirschsprung disease in the 1990s; laparoscopic-assisted pull-through for Hirschsprung disease and anorectal malformations by Keith Georgeson, Jacob Langer, Craig Albanese, Atsayuki Yamataka, and others; the longitudinal intestinal lengthening procedure by Adrian Bianchi and introduction of the serial transverse enteroplasty (STEP) procedure by H. B. Kim and Tom Jaksic for infants with short bowel syndrome; and use of the gastric pull up for esophageal replacement by Spitz and later Arnold Coran all represent some of the innovative advances in the specialty that have improved the care of children. Early use of peritoneoscopy by Stephen Gans and thoracoscopy by Bradley Rodgers in the 1970s influenced the development of minimally invasive surgery (MIS) in children. Bax, George Holcomb, Craig Albanese, Thom Lobe, Frederick Rescorla, Azad Najmaldin, Gordon MacKinlay, Keith Georgeson, Steven Rothenberg, C. K. Yeung, Jean-Luc Alain, Jean-Stephane Valla, Nguyen Thanh Liem, Felix Schier, Benno Ure, Marcelo Martinez-Ferro, and others have been the early international leaders in pediatric MIS.

## CANADA

As events in children's surgery were unfolding in the United States, Canadian pediatric surgery was experiencing a parallel evolution. References have already been made above to some of the clinical and research contributions made in Canada. Alexander Forbes, an orthopedic surgeon, played a leading role at the Montreal Children's Hospital from 1904 to 1929. Dudley Ross was chief-of-surgery at Montreal Children's Hospital from 1937 to 1954 and established the first modern children's surgical unit in Quebec. In 1948, he performed the first successful repair of esophageal atresia in Canada.[41] David Murphy served as chief of pediatric surgery and director of the pediatric surgical training program from 1954 to 1974. He was assisted by Herbert Owen and Gordon Karn, and his first trainee in 1954 was Harvey Beardmore.[42] Beardmore served as chief-of-surgery from 1974 to 1981 and was followed by Frank Guttman from 1981 to 1994 and Jean-Martin Laberge after that. The Sainte-Justine Hospital in Montreal, was founded in 1907. The hospital was combined with the Francophone Obstetrical Unit of Montreal, creating one of the largest maternal/child care centers in North America. Pierre-Paul Collin arrived at the hospital in 1954 after training in thoracic surgery in St. Louis, bringing a commitment to child care. He recruited Jacques Ducharme, who had trained in pediatric surgery in Columbus, Ohio, to join him in 1960. They trained a number of leaders in pediatric surgery in

Canada, including Frank Guttman, Hervé Blanchard, Salam Yazbeck, Jean-Martin Laberge, and Dickens St.-Vil. Jean Desjardins became chief in 1986.

The Hospital for Sick Children in Toronto was established in 1875 by Mrs. Samuel McMaster, whose husband founded McMaster University in Ontario.[42] As was the case in the United States, adult surgeons operated on children in Toronto at the end of the 19th and beginning of the 20th centuries. Clarence Starr, an orthopedic surgeon, was the first chief-of-surgery from 1913 to 1921. W. Edward Gallie served as chief surgeon at the Hospital for Sick Children from 1921 to 1929 and was named chair of surgery at the University of Toronto, where he established the Gallie surgical training program. The Gallie School of Surgery in Canada was compared with that of Halsted at Johns Hopkins in the United States.[42] Because of increasing responsibilities as chair, Gallie relinquished his role as chief of pediatric surgery to Donald Robertson, a thoracic surgeon who held the post until 1944. Arthur Lemesurer, a plastic and orthopedic surgeon became chief and in 1949 began a general pediatric surgical training program that produced Clinton Stephens, James Simpson, Robert Salter, Phillip Ashmore, Donald Marshall, and Stanley Mercer, to name some of the illustrious graduates who became leaders in the field of pediatric surgery in Canada.[14,42] In 1956, Alfred Farmer became surgeon-in-chief at the Hospital for Sick Children and developed several specialty surgical divisions, including one for general pediatric surgery. This allowed for separate specialty leadership under direction of Stewart Thomson from 1956 to 1966. Clinton Stephens was chief from 1966 to 1976 and was ably supported by James Simpson and Barry Shandling. During these 2 decades there was an impressive roster of graduates, including Phillip Ashmore, Gordon Cameron, Samuel Kling, Russell Marshall, Geoffrey Seagram, and Sigmund Ein. The tradition of excellence in pediatric surgery was continued with the appointment of Robert Filler, who arrived from Boston in 1977. Jacob Langer is the current chief of pediatric surgery in Toronto. From the latter three key surgical centers, leadership and progress in pediatric surgery spread across the Canadian provinces with the same comprehensive effect seen in the United States. Colin Ferguson, who trained with Gross in Boston, became chief-of-surgery in Winnipeg. Stanley Mercer began the pediatric surgery effort in Ottawa; there was also Samuel Kling, in Edmonton, where he was joined by Gordon Lees and James Fischer, and Geoffrey Seagram in Calgary. In 1957, Phillip Ashmore was the first trained pediatric surgeon in Vancouver, and he was joined by Marshall and Kliman, who trained at Great Ormond Street. In 1967, Graham Fraser, who also trained at Great Ormond Street joined the Vancouver group and became director of the training program. He was succeeded by Geoffrey Blair. Alexander Gillis trained with Potts and Swenson in Chicago and, in 1961, was the first pediatric surgeon in Halifax, Nova Scotia. He started the training program there in 1988. Gordon Cameron, a Toronto graduate, was the first chief of pediatric surgery at McMasters University in Hamilton. Currently, Peter Fitzgerald is head of the training program in Hamilton, which was approved in 2008.[42] The Canadian Association of Pediatric Surgeons (CAPS) was formed in 1967, three years before APSA, with Beardmore serving as the first president and Barry Shandling as secretary.[43] There are currently eight accredited pediatric surgery training programs in Canada: Halifax, Montreal Children's Hospital, Sainte-Justine Hospital in Montreal, Children's Hospital of Eastern Ontario in Ottawa, Hospital for Sick Children in Toronto, Hamilton, Calgary, Alberta, and Vancouver. All these programs are approved by the Royal College of Surgeons of Canada, and candidates for training match along with the U.S. programs through the NRMP.

## UNITED KINGDOM AND IRELAND

In 1852, the Hospital for Sick Children at Great Ormond Street (HSC) opened its doors in a converted house in London.[44] The hospital was the brainchild of Charles West, whose philosophy was that children with medical diseases required special facilities and attention, but those with surgical disorders at the time, mostly trauma related, could be treated in general hospitals.[44] West opposed the appointment of a surgeon to the staff, but the board disagreed and appointed G.D. Pollock. Pollock soon resigned and was replaced by Athol Johnson in 1853. T. Holmes, who followed Johnson, published his 37-chapter book, *Surgical Treatment of the Diseases of Infancy and Childhood,* in 1868.[45] Pediatric care in the 19th century either followed the pattern established in Paris, where all children were treated in hospitals specially oriented toward child care, or the Charles West approach, common in Britain,[46] such as those in Birmingham and Edinburgh, established to provide medical treatment but not surgery for children. In contrast, the Board at the Royal Hospital for Sick Children in Glasgow (RHSC) appointed equal numbers of medical and surgical specialists.[14,47] A major expansion in children's surgery in the latter part of the 19th century followed the development of ether and chloroform anesthesia and the gradual acceptance of antiseptic surgery. Joseph Lister provided the main impetus for antiseptic surgery, which he developed in Glasgow before moving to Edinburgh and then to King's College, London. One of Lister's young assistants in Glasgow was William Macewen, known as the father of neurosurgery, and one of the original surgeons appointed to the RHSC.[14] In Scotland, where pediatric care was generally ahead of the rest of Britain, the Royal Edinburgh Hospital for Sick Children (REHSC) opened in 1860 but did not provide a surgical unit until 1887. The sewing room was used as an operating theater.[48] Joseph Bell, President of the Royal College of Surgeons of Edinburgh, Harold Styles, John Fraser, and James J. Mason Brown, also a president of the Royal College of Surgeons of Edinburgh were the senior surgeons from 1887 to 1964. Gertrude Hertzfeld held a surgical appointment at the REHSC from 1919 to 1947, one of the few women surgeons of that era.[46] In the 19th century, training in pediatric surgery, independent of general surgery in the United Kingdom, occurred in Glasgow. Soon after these hospitals opened, their boards recognized the need for developing dispensaries or outpatient departments. In Manchester, the dispensary actually preceded the hospital. Dispensaries handled many surgical patients, and much of the pediatric surgery of the day was done there. One of the outstanding surgeons of that generation was James Nicoll, who reported 10 years of his work in 1909,[49] one of more than 100 of his publications. He was the "father of day surgery," although only part of his time was devoted to children's surgery because he had a substantial adult practice.[50] He performed pyloromyotomy with success in the late 19th century in a somewhat different fashion from Ramstedt. The Board of the RHSC decided that both physicians or surgeons appointed to the hospital must devote all their professional time to the

treatment of children. In 1919, the University of Glasgow received funding to establish both medical and surgical lectureships, the first academic appointments in Britain. Alex MacLennan was appointed Barclay lecturer in surgical and orthopedic diseases of children at the University of Glasgow from 1919 to 1938. His successor, Matthew White, the Barclay lecturer in 1938, was a thoracic and abdominal surgeon. Mr. Wallace Dennison and Dan Young were among the other surgeons who later filled these posts. In Edinburgh, the children's surgical services and the adult services remained closely associated until Mason Brown became the chief.[14]

Modern pediatric surgery was a development that had to wait until after World War II. Introduction of the National Health Service in Britain, which provided access to care for all citizens, the development of the plastics industry, and many other technical innovations in the mid-20th century, allowed great strides, particularly in neonatal surgery and critical care.[14] In London, and elsewhere in England, general surgeons who were interested in pediatric surgery carried on their pediatric practices in conjunction with their adult practices. Financial considerations influenced their activities, because few were able to earn a living in pediatric surgical practice alone. However, further developments in the specialty were closely related to committed individuals.

Denis Browne, an Australian who stayed in London after serving in WWI, was appointed to the HSC in London in 1924. Browne was the first surgeon in London to confine his practice to pediatric surgery, and he is recognized as the pioneer of the specialty in the United Kingdom.[51–53] He was a tall impressive figure with a somewhat domineering, authoritative manner (Fig. 1-8). Browne's longtime colleague James Crooks called him an "intellectual adventurer, a rebel and a cynic."[51] After World War II, many surgeons from overseas spent time in the United Kingdom; the majority visited the HSC, where they were influenced by Browne. Some subsequently established internationally recognized centers such as Louw in South Africa, and Stephens and Smith in Australia. Browne's major interest was structural orthopedic anomalies, and as an original thinker, he achieved widespread recognition for promoting intrauterine position and pressure as a cause of these deformities.[53] He developed instruments, retractors, and splints to assist in his work, all named after himself. His early contemporaries were L. Barrington-Ward and T. Twistington Higgins, surgeons of considerable stature. It was Higgins who initially held discussions in London that led to the formation of the British Association of Pediatric Surgeons (BAPS) in 1953. Browne became the association's first and longest-serving president. The Denis Browne Gold Medal, an award given by the BAPS, remains a symbol of his presence and demonstrates his views (Fig. 1-9). In his later years in the National Health Service, his colleagues included George McNab, introducer of the Holter valve for hydrocephalus; David Waterston, an early pediatric cardiothoracic surgeon; and David Innes Williams, doyen pediatric urologist of Britain.[14] Each of these outstanding men made major contributions to the development of pediatric surgery. Many young surgeons continued to flock to HSC in London for training in pediatric surgery, including Nate Myers, Barry O'Donnell, H.H. Nixon and others. Andrew Wilkinson replaced Browne as surgeon-in-chief. Many other developments were also taking place. Wilkinson in London and Knutrud in Oslo were studying infant metabolism. Isabella Forshall, later joined by Peter Rickham, established an excellent clinical service in Liverpool. She was one of the few female pediatric surgeons of the time and was president of the BAPS in 1959. Pediatric surgery services were established in Sheffield by Robert Zachary, and in Manchester, Newcastle, Birmingham, Southampton, Bristol, Nottingham, and Leeds. Lewis Spitz from South Africa trained at Alder Hey Hospital in Liverpool with Peter Rickham in 1970. After a brief stay in Johannesburg, he immigrated to the United Kingdom to work with Zachary in Sheffield in 1974. He was then named the Nuffield Professor and head at Great Ormond Street, London and provided excellent leadership and strong surgical discipline at the HSC, leading by example for many years, until 2004 when he retired. His main areas of expertise included esophageal surgery, congenital hyperinsulinism, and separation of conjoined twins.[54,55] His colleagues included Kiely, Brereton, Drake, and Pierro. The latter established a strong research base at the institution and succeeded Spitz as the Nuffield Professor.

## IRELAND

In 1922, Ireland was divided into six northern counties under British rule and 26 southern counties that became the Republic of Ireland. The first children's hospital in Ireland was in the south, the National Children's Hospital, opening on Harcourt Street in Dublin in 1821.[56] The Children's University Hospital in Dublin was founded on Temple Street in 1872. John Shanley, a general surgeon, was appointed to the Temple Street facility and devoted all his surgical activities to children. Another general surgeon, Stanley McCollum, worked at the National Hospital and did pediatric surgery at the Rotunda at the Maternity Hospital. A third children's hospital, Our Lady's Hospital for

**FIGURE 1-9** Denis Browne Gold Medal. **A,** Front of the medal. **B,** Back of the medal, which reads, "The aim of paediatric surgery is to set a standard not to seek a monopoly."

Sick Children, managed by the Daughters of Charity of St. Vincent De Paul, opened in 1956 in Crumlin. Barry O'Donnell was the first full-time, fully trained pediatric surgeon at this facility. Each of the children's hospitals had an academic affiliation, the National Hospital with Trinity College, and Temple Street and Our Lady's with The Royal College of Surgeons University College. Edward Guiney was added to the consultant staff of Our Lady's in 1966 and also was appointed to Temple Street and assisted McCollum at the National Children's Hospital, Dublin. From 1979 to 1993, Ray Fitzgerald, Prem Puri, and Martin Corbally were added as consultant pediatric surgeons. Following Barry O'Donnell's retirement in 1991 and Guiney stepping down in 1993, Fergal Quinn was eventually named to replace him. The Children's Research Center was developed in 1971, with Guiney appointed as director in 1976. He was replaced by Prem Puri, who has mentored numerous overseas research fellows and provided outstanding research concerning many neonatal and childhood conditions. O'Donnell conceived and Puri developed the innovative sting procedure to endoscopically treat vesicoureteral reflux, initially by Teflon injection and subsequently with Deflux. O'Donnell, Guiney, and Fitzgerald have served as presidents of the BAPS. Both O'Donnell and Puri are Denis Browne Gold Medal recipients and achieved international stature. Fitzgerald was president of European Pediatric Surgeons Association (EUPSA) and IPSO, and O'Donnell was president of the Royal College of Surgeons of Ireland. Puri served as president of EUPSA and the WOFAPS (World Federation of Associations of Pediatric Surgeons)

Pediatric surgery in Northern Ireland developed more slowly. Brian Smyth, who trained at Great Ormond Street and Alder Hey Hospitals, was appointed the first specialist pediatric surgeon consultant in 1959. He was joined by a Scotsman, William Cochran, who trained in Edinburgh. Following training in Newcastle and Cape Town, Victor Boston was added as a pediatric surgery consultant in 1975. Political unrest and economic constraints placed some limitations on growth in the north. Cochran returned to Scotland, and in 1995, McCallion was added as a consultant. Today they have similar standards to the southern centers in Ireland.

## EUROPE

Europe served as the cradle of pediatric surgery, but because of space limitations, only the major developments and leading figures can be discussed. In France, the Hôpital des Enfants Malades has a long and storied history, starting with the contributions of Guersant, Giraldes, and de Saint-Germain from 1840 to 1898.[57] Most of their work involved orthopedic conditions and the management of infectious problems. Kirmisson, also well-versed in orthopedic disorders, was appointed the first professor of pediatric surgery in 1899 and published a pediatric surgical textbook in 1906 that contained radiologic information and discussed osteomyelitis and some congenital anomalies. In 1914, Broca described the management of intussusception, instances of megacolon, and experience with Ramstedt's operation for pyloric stenosis. He was succeeded by Ombredanne, a self-taught pediatric surgeon whose works were published by Fevre in 1944.[58] Petit performed the first successful repair of type C esophageal atresia in France in 1949. Because of two world wars, intervals of foreign occupation, and long periods of recovery in all of Europe, it was some time after WWII before modern pediatric surgery could develop in this part of the world. Following WWII, Bernard Duhamel was at the Hôpital des Enfantes Malades but moved to St. Denis, where he devised the retrorectal pull-through for Hirschsprung disease, an alternative procedure to the Swenson operation in 1956 (Fig. 1-10).[59] He was the first editor of *Chirurgie Pediatrique,* started in 1960. Denys Pellerin became chief-of-surgery at the Hôpital des Enfantes Malades and developed a strong department at the institution until he retired in 1990. His successor was Claire Nihoul-Fekete, the first female professor of pediatric surgery in France. Fekete was recognized for her stylish demeanor and expertise in intersex surgery, esophageal anomalies, and congenital hyperinsulinism. She was succeeded by Yann Revillion, an international leader in intestinal transplantation. Yves Aigran plays a leadership role as well. Elsewhere, Michel Carcassone, who developed pediatric surgery in Marseille, had expertise in treating portal hypertension and was an early advocate of a primary pull-through procedure for Hirschsprung disease. He also served as the

**FIGURE 1-10** Bernard Duhamel, Paris, France.

editor-for-Europe for the *Journal of Pediatric Surgery*. J.M. Guys is currently chief in Marseilles. Prevot was the first leader in Nancy. The Société Francaise de Chirurgie Infantile was established in 1959, with Fevre as the first president. The group changed its name to the French Society of Pediatric Surgery in 1983. A strong pediatric oncology presence has existed in Villejuif for many years, initially under the direction of Mme. Odile Schwiesgut.

Pediatric surgical development in Scandinavia also has a rich history. In Sweden, The Princess Lovisa Hospital in Stockholm opened in 1854, but it was not until 1885 that a surgical unit was added under the direction of a general surgeon.[60,61] The first pediatric surgery unit was actually started at the Karolinska Hospital in 1952 and was transferred to St. Gorans Hospital in 1982. In 1998, all pediatric surgery in Stockholm was moved to the newly constructed Astrid Lindgren Children's Hospital at Karolinska University. Three other major pediatric surgery centers were developed in Gothenberg, Uppsala, and Lund. Philip Sandblom was appointed chief-of-surgery at Lovisa from 1945 to 1950, and then he moved to Lund and, later, Lausanne as chief-of-surgery. He was succeeded by Theodor Ehrenpreis, who moved to the Karolinska Pediatric Clinic in 1952. He had a strong interest in research in Hirschsprung disease. Gunnar Ekstrom took his place, and he was succeeded by Nils Ericsson, whose major interest was pediatric urology. Bjorn Thomasson became chief at St. Gorans in 1976. Tomas Wester is the current chief in Stockholm. Gustav Peterson was the initial chief of pediatric surgery in Gothenberg. Ludvig Okmian became the chief of pediatric surgery in Lund in 1969 and helped develop the infant variant of the Engstrom ventilator, and along with Livaditis, employed circular myotomy for long gap esophageal atresia. In 1960, Gunnar Grotte was appointed the first chief of pediatric surgery in Uppsala. He was joined by Leif Olsen, and their major interests included pediatric urology, Hirschsprung disease, and metabolism. The Swedish Pediatric Surgical Association was formed in 1952, and Swedes also participate in the Scandinavian Association of Pediatric Surgeons, founded in 1964.

In Finland, pediatric surgery developed after WWII. Mattie Sulamaa, the pioneer in Finland, was the first to work in the new children's hospital in Helsinki, which opened in 1946. He was instrumental in introducing pediatric anesthesiology. He trained young students, who later started programs at children's hospitals in Turku and Oulu, and university centers in Tampere and Kuopio. He retired in 1973 and was succeeded by Ilmo Louhimo, who specialized in cardiothoracic surgery. He trained Harry Lindahl and Risto Rintala. Rintala is the current chief at Helsinki Children's Hospital and is well recognized for his expertise in pediatric colorectal surgery. Lindahl is a leader in upper gastrointestinal surgery, endoscopy, and the management of esophageal atresia.

There were no children's hospitals in Norway. However, pediatric surgery was strongly influenced by Ola Knutrud of Oslo, beginning in 1962 when he was appointed chief of pediatric surgery at the University Rikshospital. He was an early leader in the field, with interest in pediatric fluid and electrolyte balance, metabolism, fat nutrition, and congenital diaphragmatic hernia. In 1975, Torbjorn Kufaas was named chief of pediatric surgery at the University Hospital in Trondheim.

In Denmark, the first children's hospital opened in1850 and moved to a new facility named after Queen Louise in 1879, with Harald Hirschsprung, a pediatrician appointed as chief physician. Hirschsprung's interests centered on surgical problems, including esophageal atresia, intussusception, ileal atresia, pyloric stenosis, and congenital megacolon.[62] C. Winkel Smith and Tyge Gertz initiated pediatric surgery at University Hospital in Copenhagen, with the latter performing the first successful repair of esophageal atresia in Denmark in 1949. Smith mysteriously disappeared in 1962 but was not declared deceased until 1968.[63] Knud Mauritzen was named his successor as director of pediatric surgery in Copenhagen. Ole Nielsen, a urologic surgeon, succeeded him. Carl Madsen became consultant surgeon at Odense University Hospital; however, there is no department of pediatric surgery there or in Arhus, where pediatric urology and children's surgery are performed in the Department of Urology or Surgery. The only Danish department of pediatric surgery exists in Copenhagen. Although the Danish governmental specialty rules listed pediatric surgery as a specialty in 1958, this was rescinded in 1971 and has not been restored.[63]

Modern pediatric surgery in Switzerland starts with the pioneer in that country, Max Grob. A native of Zurich, he trained in general surgery with Clairmont in Zurich in 1936 and then spent 6 months in Paris at the Hôpital des Enfantes Malades under Ombredanne. He returned to Zurich and entered private practice. It was during WWII that he was appointed to replace Monnier, a general surgeon in charge at the Children's Hospital, whom he met during training. His pediatric surgical practice was quite varied and included plastic surgery and cardiac surgery.[64] He modified Duhamel's operation for Hirschsprung disease and did the first hiatal hernia repair in a child in Switzerland. He trained a new generation of pediatric surgeons in Zurich, including Marcel Bettex, Noel Genton, and Margrit Stockman. The Swiss Society of Pediatric Surgery was formed in 1969, with Grob as its first president.[65] Peter Paul Rickham moved from Liverpool to succeed Grob in Zurich in 1971. Marcel Bettex

developed a separate department of pediatric surgery in Bern, as did Noel Genton in Lausanne, Alois Scharli in Luzern, Anton Cuendet in Geneva, and Nicole in Basel. Urs Stauffer replaced Professor Rickham as chief in Zurich in 1983. Martin Meuli is the current chief in Zurich. Claude Lecoutre succeeded Cuendet in Geneva. The current chief there is Barbara Wildhaber. Peter Herzog is presently chief in Basel, Marcus Schwoebel in Lausanne, and Zachariah Zachariou in Bern. Alois Scharli began the journal *Pediatric Surgery International* in 1985 and served as editor-in-chief for 18 years, followed by Puri and Coran as the current co–editors-in-chief.

In Germany, pediatric care began with the development of children's hospital facilities in various cities across the country, most notably, in Munich, Cologne, and Berlin. Early contributions from Max Wilms in Liepzig and Conrad Ramstedt in Münster have been previously noted.[17,20] Progress was somewhat hampered by war, political and social unrest, and the separation of the country into East Germany and West Germany during the occupation following WW II. Children's surgical units developed either in university settings within adult hospitals or in independent children's hospitals. The contributions of Anton Oberniedermayr and Waldemar Hecker in Munich, who was the first professor of pediatric surgery in the Federal Republic of Germany, Fritz Rehbein in Bremen, and Wolfgang Maier in Kahrlsruhe are well recognized.[66] Fritz Rehbein's clinic in Bremen attracted many young men to train there. He was a thoughtful and resourceful pediatric surgical leader who contributed much to patient care, including the Rehbein strut for pectus excavatum, modifications in esophageal surgery, low pelvic anterior resection for Hirschsprung disease (the Rehbein procedure),[67,68] and a sacral approach with rectomucosectomy of the atretic rectum with abdominoperineal pull-through for high imperforate anus (Fig. 1-11). He was a founding editor of *Zeitschrift Kinderchirurgie* in 1964, which was the precursor of the *European Journal of Pediatric Surgery* following merger with the French journal *Chirurgie Pedaitrique* in 1990. Alex Holschneider was editor from 1980 to 2007, and Benno Ure of Hannover has been the editor-in-chief since 2007. Many of Rehbein's trainees went on to leadership roles in other European cities, including Michael Hoellwarth (Graz), Alex Holschneider (Cologne), Pepe Boix-Ochoa (Barcelona), and others. He was recognized throughout Europe as a leader in the field and was a recipient of the Denis Browne Gold Medal from the BAPS and many other awards. His contributions to European pediatric surgery are recognized by the establishment of the Rehbein Medal, awarded each year by the EUPSA, representing 28 countries in Europe. In West Germany, pediatric surgery was not recognized as an independent specialty until 1984. Following the fall of the Berlin Wall and the reunification of Germany in 1990, the 33 East German pediatric surgery programs joined those of the West from the Federal Republic of Germany and formed a joint German Society of Pediatric Surgery.

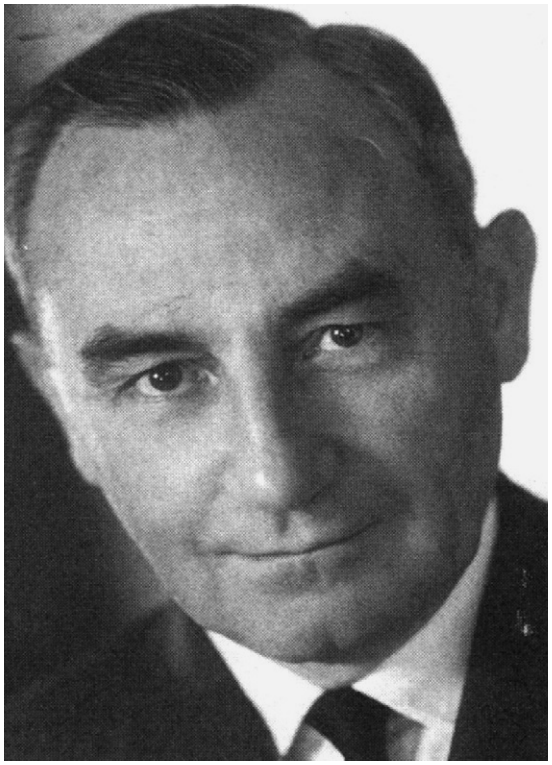

**FIGURE 1-11** Fritz Rehbein, Bremen, Germany.

In Italy, early evidence of a hospital devoted to children dates back to the 15th century with the Hospital of the Innocents in Florence, which was more of a foundling home than a hospital. Other facilities for sick children were documented in the 1800s in many Italian cities. The first hospital dedicated to children's surgery was in Naples in 1880. In Milan in 1897, Formiggini was the surgeon-in-charge, and he eventually started the first Italian pediatric surgical journal, *Archivio di Chirurgia Infantile,* in 1934. It was a short-lived effort, however. Once again WW II delayed progress. Carlo Montagnani spent 18 months in Boston in 1949 and returned to Florence, where he translated Gross' textbook into Italian. He had a productive career as a pioneer pediatric surgeon. He organized the Italian Society of Pediatric Surgery in 1964, with Pasquale Romualdi of Rome serving as the first president. That was the same year Franco Soave of Genoa described the endorectal pull-through for Hirschsprung disease (Fig. 1-12). In 1992, the Italian journal ceased to publish, and the *European Journal of Pediatric Surgery* became the official journal of the Italian Society. Major advances in the management of neonatal conditions, childhood tumors, Hirschsprung disease, esophageal disorders, and pediatric urology have emanated from Italy in the past 2 decades from centers in Rome, Milan, Genoa, Naples, Pavia, Florence, Bologna, Turin, and others.

In the Netherlands, the first children's hospital was opened in Rotterdam in 1863, with eight beds located in a first-floor apartment. The children's hospital in Amsterdam followed in 1865 in an old orphanage. In 1899, the name of the facility was changed to Emma Children's Hospital, after the Queen. Volunteer adult surgeons did whatever children's surgical work that presented. Throughout the rest of the 19th century, additional children's facilities sprung up in other cities. R.J. Harrenstein was the first full-time surgeon appointed at the Emma Children's Hospital. In the 1970s, Born at The Hague and David Vervat in Rotterdam dedicated themselves to children's care. Vervat was also an early editorial consultant for the *Journal of Pediatric Surgery.* Jan Molenaar trained with Vervat and eventually replaced him at Erasmus University in Rotterdam in 1972. Molenaar served as the editor-for-Europe for the *Journal of Pediatric Surgery.* Franz Hazebroeck replaced Molenaar as chief in 1998, and Klaas Bax subsequently succeeded Hazebroeck. The Rotterdam school focused on basic

**FIGURE 1-12** Franco Soave, Genoa, Italy.

science research and a high level of clinical care. Anton Vos spent time in Boston with Gross and Folkman and later returned to Amsterdam as an associate of Professor Mak Schoorl. In 1991, he was appointed professor of pediatric surgery at the University of Amsterdam with a strong focus on pediatric oncology. Hugo Heij succeeded Vos as chief in 1999. Currently there are five pediatric surgery training programs in the Netherlands located in Rotterdam, Amsterdam, Utrecht, Nijmegen, and Groningen. Trainees are certified by the European Board of Pediatric Surgery (EBPS), sponsored by the Union of European Medical Specialties (EUMS).

In Spain, the modern day pioneers included Julio Monoreo, who was appointed the first head of pediatric surgery at the Hospital of the University of La Paz, Madrid in 1965. Pepe Boix-Ochoa filled the same role at Hospital Valle de Hebron in Barcelona. Juan Tovar succeeded Monoreo after his passing. In the 1970s and 1980s, major regional pediatric surgical centers were located in numerous cities around the country. The Spanish Pediatric Surgical Association was formed as an independent group for pediatrics in 1984. Tovar is the current editor-for-Europe for the *Journal of Pediatric Surgery* and served as president of EUPSA.

Other leaders in Europe included Aurel Koos, Imre Pilaszanovich, and Andras Pinter in Hungary; Petropoulos, Voyatzis, Moutsouris Pappis, and Keramidis in Greece; Kafka, Tosovsky, and Skaba in the Czech Republic; Kossakowski, Kalicinski, Lodzinski, and Czernik in Poland; and Ivan Fattorini in Croatia. In Austria, the leaders in the field included Sauer and Hoellwarth in Graz, Rokitansky and Horcher in Vienna, Menardi in Innsbruck, Oesch in Salzburg, and Brandesky in Klangenfurt. In Turkey, Ihsan Numanoglu developed the first pediatric surgery service in Izmir in 1961. Akgun Hiksonmez started the program at Hacettepe University in Ankara in 1963. Acun Gokdemir was an early pediatric urologist in Istanbul. Daver Yeker, Cenk Buyukunal, Nebil Buyukpamukcu, and Tolga Dagli are major contributors to contemporary Turkish pediatric surgery and urology. The Turkish Association of Pediatric Surgeons (TAPS) formed in 1977, with Hicsonmez elected the first president.

## AUSTRALIA AND NEW ZEALAND

The first children's hospital opened in Melbourne, Australia in 1870.[69] In 1897, Clubbe performed a successful bowel resection for intussusception in Sydney. In 1899, Russell published the method of high ligation of an inguinal hernia sac. Hipsley described successful saline enema reduction of intussusception in 1927. As was the case elsewhere, pediatric surgery did not experience significant growth until after WW II. Howard performed the first successful repair of esophageal atresia in Melbourne in 1949. He was joined there by F. Douglas Stephens, who had spent time with Denis Browne in London, and he directed the research program at the Royal Melbourne Children's Hospital for many years. Bob Fowler and Durham Smith later joined the Melbourne group. They set a standard for investigation of malformations of the urinary tract and anorectum. Stephens developed the sacroperineal pull-through operation for high anorectal malformations. The pediatric surgery staff in Melbourne was exemplary and added Nate Myers, Peter Jones, Alex Auldist, Justin Kelley, Helen Noblett, and Max Kent to the group. Archie Middleton, Douglas Cohen, and Toby Bowring led the way in Sydney, Geoff Wylie in Adelaide, Alastair MacKellar in Perth, and Fred Leditschke in Brisbane.

Pediatric surgical contributions from Australia were considerable. Myers was an expert in esophageal atresia and provided the first long-term outcome studies.[70] Noblett promoted nonoperative gastrografin enema for simple meconium ileus and devised the first forceps for submucosal rectal biopsy for Hirschsprung disease.[71,72] Jones spearheaded the nonoperative management of torticollis and management of surgical infections. Fowler devised the long-loop vas operation for high undescended testis[73]; MacKellar instituted the first trauma prevention program; Kelly developed a scoring system for fecal incontinence and total repair of bladder exstrophy; and Smith and Stephens developed the Wingspread classification for anorectal malformations. Hutson's studies on the influence of hormones and the genitofemoral nerve on testicular descent and colonic motility, Cass' insights into the genetics of Hirschsprung disease, and Borzi and Tan's leadership in pediatric MIS are more recent examples of Australian contributions to the field. Pediatric surgery in New Zealand took longer to develop. There are now four major training centers in Auckland, Hamilton, and Wellington on the North Island and Christchurch on the South Island. Leaders include Morreau in Auckland, supported by Stuart Ferguson and others; Brown in Hamilton; Pringle in Wellington; and Beasley in Christchurch. A significant outreach program for the islands of the South Pacific is in place.

## ASIA

There have been significant contributions to pediatric surgery from Japan, China, Taiwan, and other Asian countries following WW II. In China, Jin-Zhe Zhang in Beijing survived war,

national turmoil, and the Cultural Revolution to emerge as that nation's father figure in children's surgery. Other early leaders included She Yan-Xiong and Ma in Shanghai and Tong in Wuhan. The latter was the first editor of the *Chinese Journal of Pediatric Surgery*. The first pediatric surgery congress in China was held in 1980, and the China Society of Pediatric Surgeons was formed in 1987. There is a new generation of pediatric surgeons, including Long Li, G-D Wang, and others. Major children's hospitals are now located in Beijing, Shanghai, Fudan, Shenyang, Wuhan, and many other mainland cities. The use of saline enemas under ultrasound guidance, as well as the introduction of the air-enema for reduction of intussusception, are examples of significant Chinese contributions. Paul Yue started the first pediatric surgery unit in Hong Kong in 1967. H. Thut Saing was appointed the first chair of pediatric surgery at the University of Hong Kong in 1979.[74] Paul Tam and CK Yeung trained with Saing and went on to have very productive careers. Tam spent time at Oxford in the United Kingdom and returned to become chair of pediatric surgery at the University of Hong Kong in 1996. Yeung succeeded Kelvin Liu as chief of pediatric surgery at the Chinese University Prince of Wales Hospital. Both Tam and Yeung provided pediatric surgery leadership in Hong Kong and have been productive in the study of the genetic implications of many surgical disorders, including Hirschsprung disease and neuroblastoma (Tam) and application of MIS, particularly in pediatric urology (Yeung).

V.T. Joseph was the first director of pediatric surgery in Singapore in 1981. Following his departure, Anette Jacobsen has been influential in further developing the specialty and providing strong leadership in children's surgery in Singapore.[74] Sootiporn Chittmittrapap, Sriwongse Havananda, and Niramis have been strong advocates in establishing a high level of pediatric surgical care in Thailand. In Vietnam, years of political strife and conflict delayed progress in children's surgery. Nguyen Thanh Liem has emerged as a leading contributor from Hanoi, with extensive experience in the use of MIS for managing a myriad of pediatric surgical conditions. There are now 13 pediatric surgical centers in Vietnam.[74]

In Japan, the first generation of pediatric surgeons appeared in the early 1950s: Ueda in Osaka, Suruga at Juntendo University in Tokyo, Kasai at Tohoku University in Sendai, and Ikeda at Kyushu University in Fukuoka. Suruga performed the first operation for intestinal atresia in 1952. Kasai performed the first hepatoportoenterostomy for uncorrectable biliary atresia in 1955 (Fig. 1-13), and Ueda performed the first successful repair of esophageal atresia in 1959.[14] The first children's hospital in the country was the National Children's Hospital in Tokyo, opened in 1965. The first department of pediatric surgery was established at Juntendo University in Tokyo in 1968 by Suruga (Fig. 1-14); today, training programs exist in nearly all the major university centers. The Japanese Society of Pediatric Surgeons and its journal were established in 1964, paralleling developments in other parts of the world. The second generation of pediatric surgeons include Okamoto and Okada in Osaka; Nakajo, Akiyama, Tsuchida, and Miyano in Tokyo; Ohi and Nio in Sendai; Suita in Fukuoka and Ken Kimura in Kobe and later in Iowa and Honolulu. These individuals made seminal contributions in the fields of nutrition, biliary and pancreatic disease, management of choledochal cyst, oncology, and intestinal disorders, including Hirschsprung disease, esophageal atresia, duodenal atresia, and tracheal reconstruction. In recent decades, laboratories and clinical centers in Asia, particularly in Japan and Hong Kong, have generated exciting new information in the clinical and basic biological sciences that continues to enrich the field of children's surgery.

## DEVELOPING COUNTRIES

Nowhere in the world is the global burden of surgical disease more evident than in Africa. Pediatric surgery in underdeveloped areas of the world suffers from a lack of infrastructure, financial resources, and governmental support. In Africa, hepatitis B, malaria, malnutrition, human immunodeficiency virus–acquired immune deficiency virus (HIV-AIDS), and the ravages of political unrest and conflict play a major role in the higher childhood mortality noted on the continent. There are some exceptions, such as South Africa, where pediatric surgery is an established specialty with major children's centers in Cape Town, Johannesburg, Durban, Pretoria, and Bloemfontein; in Egypt with centers in Cairo and Alexandria; and in Nairobi, Kenya. The pioneer pediatric surgeon in South Africa was Jan Louw of Cape Town (Fig. 1-15). Collaborating with Christian Barnard in 1955, they demonstrated, in a fetal dog model, that most jejunoileal atresias were related to late intrauterine vascular accidents to the bowel and/or mesentery. Sidney Cywes succeeded Louw at the Red Cross Memorial Children's Hospital in 1975. He was the first surgeon in the country to limit his practice to children.

Cywes was joined in Cape Town by Michael Davies, Heinz Rode, Alastair Millar, Rob Brown, and Sam Moore. Millar is the current surgeon-in-chief. Michael Dinner was the first professor of pediatric surgery at Witwatersrand University in Johannesburg. Derksen and Jacobs started the pediatric surgery service in Pretoria and were succeeded by Jan Becker in 1980. R. Mikel was the first professor of pediatric surgery at the University of Natal in Durban; he was succeeded by Larry Hadley. The South African Association of Pediatric Surgeons was formed in 1975, with Louw serving as its first president.[75] Major contributions to pediatric surgical care from South Africa include management of intersex, separation of conjoined twins, childhood burn care, pediatric surgical oncology, treatment of jejunoileal atresia, caustic esophageal injury, Hirschsprung disease, and liver transplantation. In 1994 in Nairobi, where pediatric surgery was pioneered by Julius Kyambi, the Pan African Pediatric Surgical Association (PAPSA) was established with pediatric surgeons from all the nations on the continent joining as members.

**FIGURE 1-15** Professor Jan Louw, Cape Town, South Africa.

In India, the Association of Indian Surgeons first recognized pediatric surgery as a separate section in 1964. This organization subsequently became independent as the Indian Association of Pediatric Surgeons (IAPS) and met for the first time in New Delhi in 1966. Facilities for pediatric surgical care were limited to a few centers in metropolitan areas. Early leaders in the field included S. Chatterjee, R.K. Ghandi, P. Upadhaya, R.M. Ramakrishnan, V. Talwalker, and S. Dalal. Ms. Mridula Rohatgi was the first female professor of pediatric surgery. Professor Ghandi served as president of the WOFAPS, and presently, Professor Devendra Gupta of New Delhi is the president-elect of that organization. There are currently 24 pediatric surgery teaching centers in the country, all located in major cities. Rural care is still less than desirable, and there are only 710 pediatric surgeons to care for a population of 1.2 billion people.

Space limitations prevent individual mention of some other countries and deserving physicians who have made contributions to the field of pediatric surgery.

The discipline of pediatric surgery around the world is mature at this point and as sophisticated as any medical field. It has become a science-based enterprise in a high-technology environment. In the developed world, children with surgical problems have never been as fortunate as now. Pediatric surgery has truly become internationalized, with various countries developing national societies and striving to improve the surgical care of infants and children. The availability of the Internet to rapidly disseminate information has provided a method to share knowledge and information regarding patient care. The World Federation of Associations of Pediatric Surgeons (WOFAPS), which originated in 1974 and under the leadership of Professor Boix-Ochoa, the organization's secretary general, has grown and matured as an organization that now comprises more than 100 national associations.[76] It is an international voice for the specialty and sponsors a world congress of pediatric surgery every 3 years in a host country and provides education, support, and assistance to underdeveloped countries to improve the surgical care of infants and children. With children representing a higher percentage of the population in the developing world, this becomes an increasingly important factor in enhancing the global effort to provide better surgical care for children.

CHAPTER 2

# Molecular Clinical Genetics and Gene Therapy

Alan W. Flake

The topics of this chapter are broad in scope and outside the realm of a classic core education in pediatric surgery. However both molecular genetics and gene therapy will be of increasing clinical importance in all medical specialties, including pediatric surgery, in the near future. A few conservative predictions include improvements in the diagnostic accuracy and prediction of phenotype, the development of new therapeutic options for many disorders, and the optimization of pharmacotherapy based on patient genotype, but there are many other possible uses. The goal here is to provide an overview of recent developments that are relevant or potentially relevant to pediatric surgery.

## Molecular Clinical Genetics

Although hereditary disease has been recognized for centuries, only relatively recently has heredity become the prevailing explanation for numerous human diseases. Before the 1970s, physicians considered genetic diseases to be relatively rare and irrelevant to clinical care. With the advent of rapid advances in molecular genetics, we currently recognize that genes are critical factors in virtually all human diseases. Although an incomplete indicator, McKusick's *Mendelian Inheritance in Man* has grown from about 1500 entries in 1965[1] to 12,000 in 2010, documenting the acceleration of knowledge of human genetics. Even disorders that were once considered to be purely acquired, such as infectious diseases, are now recognized to be influenced by genetic mechanisms of inherent vulnerability and genetically driven immune system responses.

Despite this phenomenal increase in genetic information and the associated insight into human disease, until recently there was a wide gap between the identification of genotypic abnormalities that are linked to phenotypic manifestations in humans and any practical application to patient treatment. With the notable exceptions of genetic counseling and prenatal diagnosis, molecular genetics had little impact on the daily practice of medicine or more specifically on the practice of pediatric surgery. The promise of molecular genetics cannot be denied however. Identifying the fundamental basis of human disorders and of individual responses to environmental, pharmacologic, and disease-induced perturbations is the first step toward understanding the downstream pathways that may have a profound impact on clinical therapy. The ultimate application of genetics would be the correction of germline defects for affected individuals and their progeny. Although germline correction remains a future fantasy fraught with ethical controversy,[2] there is no question that molecular genetics will begin to impact clinical practice in myriad ways within the next decade. A comprehensive discussion of the field of molecular genetics is beyond the scope of this chapter, and there are many sources of information on the clinical genetics of pediatric surgical disorders.

### HUMAN MOLECULAR GENETICS AND PEDIATRIC SURGICAL DISEASE

The rapid identification of genes associated with human disease has revolutionized the field of medical genetics, providing more accurate diagnostic, prognostic, and potentially therapeutic tools. However, increased knowledge is always associated with increased complexity. The classic model assumed that the spread of certain traits in families is associated with the transmission of a single molecular defect, with individual alleles segregating into families according to Mendel's laws, whereas today's model recognizes that very few phenotypes can be satisfactorily explained by a mutation at a single gene locus. The phenotypic diversity recognized in disorders that were once considered monogenic has led to a reconceptualization of genetic disease. Although mendelian models are useful for identifying the primary cause of familial disorders, they appear to be incomplete as models of the true physiologic and cellular nature of defects.[3–5] Numerous disorders that were initially characterized as monogenic are proving to be either caused or modulated by the action of a small number of loci. These disorders are described as oligogenic disorders, an evolving concept that encompasses a large spectrum of phenotypes that are neither monogenic nor polygenic. In contrast to polygenic or complex traits, which are thought to result from poorly understood interactions between many genes and the environment, oligogenic disorders are primarily genetic in cause but require the synergistic action of mutant alleles at

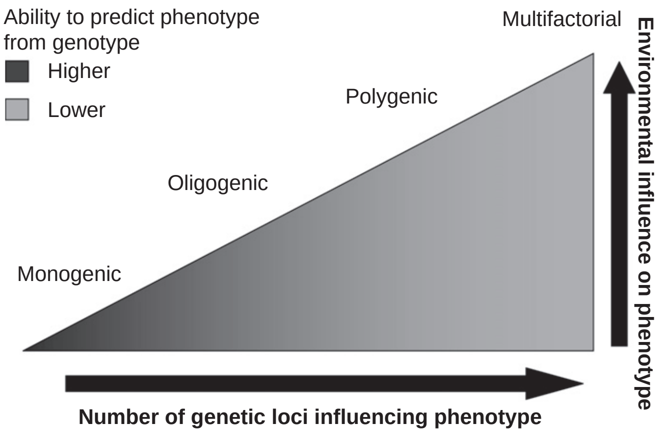

FIGURE 2-1 Conceptual continuum of modern molecular genetics. The genetic characterization of a disorder depends on (1) whether a major locus makes a dominant contribution to the phenotype, (2) the number of loci that influence the phenotype, and (3) the presence and extent of environmental influence on phenotype. The farther toward the right a disorder lies, the greater the complexity of the genetic analysis and the less predictive genotype is of phenotype.

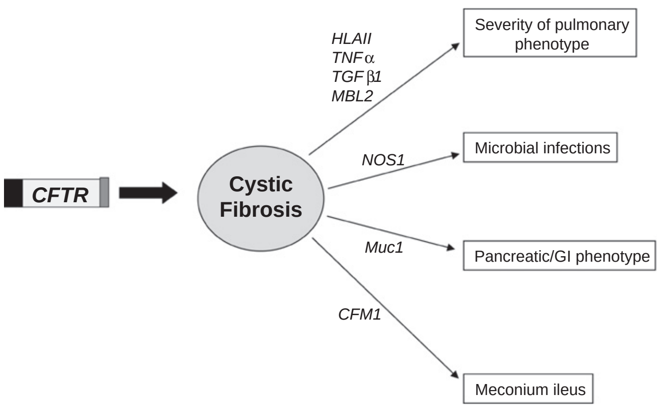

FIGURE 2-2 Complexity in monogenic diseases. Mutations in the *cystic fibrosis transmembrane conductance regulator* (*CFTR*) almost always cause the cystic fibrosis (CF) phenotype. Owing to modification effects by other genetic factors, the presence and nature of mutations at the *CFTR* locus cannot predict the phenotypic manifestation of the disease. Therefore, although CF is considered a mendelian recessive disease, the phenotype in each patient depends on a discrete number of alleles at different loci. *CFM1*, cystic fibrosis modifier 1; GI, gastrointestinal; HLAII, major histocompatibility complex class II antigen; *MBL2*, mannose-binding lectin (protein C) 2; *Muc1*, mucin 1; *NOS1*, nitric oxide synthase 1; *TGFB1*, transforming growth factor-β1; *TNF*, tumor necrosis factor encoding gene.

a small number of loci. One can look at modern molecular genetics as a conceptual continuum between classic mendelian and complex traits (Fig. 2-1). The position of any given disorder along this continuum depends on three main variables: (1) whether a major locus makes a dominant contribution to the phenotype, (2) the number of loci that influence the phenotype, and (3) the presence and extent of environmental influence on the phenotype.

## DISEASE-SPECIFIC EXAMPLES OF CHANGING CONCEPTS IN MOLECULAR GENETICS

### Monogenic Disorders

Cystic fibrosis (CF) is an example of a disorder close to the monogenic end of the continuum, but it also illustrates the complexity of the genetics of some disorders, even when a mutation of a major locus is the primary determinant of phenotype. On the basis of the observed autosomal recessive inheritance in families, the gene *CFTR* (cystic fibrosis transmembrane conductance regulator) was first mapped in humans to chromosome 7q31.2.[6] Once the *CFTR* gene was cloned,[7] it was widely anticipated that mutation analyses might be sufficient to predict the clinical outcome of patients. However analyses of *CFTR* mutations in large and ethnically diverse cohorts indicated that this assumption was an oversimplification of the true genetic nature of this phenotype, particularly with respect to the substantial phenotypic variability observed in some patients with CF. For instance, although *CFTR* mutations show a degree of correlation with the severity of pancreatic disease, the severity of the pulmonary phenotype, which is the main cause of mortality, is difficult to predict.[8–10] Realization of the limitations of a pure monogenic model prompted an evaluation of more complex inheritance schemes. This led to the mapping of a modifier locus for the intestinal component of CF in both human and mouse.[11,12] Further phenotypic analysis led to the discovery of several other loci linked to phenotype, including (1) the association of low-expressing mannose-binding lectin (*MBL2*; previously known as *MBL*) alleles, human leukocyte antigen (HLA) class II polymorphisms, and variants in tumor necrosis factor-α (*TNFA*) and transforming growth factor-β1 (*TGFB1*) with pulmonary aspects of the disease;[13–16] (2) the correlation of intronic nitric oxide synthase 1 (*NOS1*) polymorphisms with variability in the frequency and severity of microbial infections[17]; and (3) the contribution of mucin 1 (*Muc1*) to the gastrointestinal aspects of the CF phenotype in mice (Fig. 2-2).[18] Further layers of complexity have been discovered for both *CFTR* and its associated phenotype. First, heterozygous CF mutations have been associated with susceptibility to rhinosinusitis, an established polygenic trait.[19] Second, and perhaps more surprising, a study group reported that some patients with a milder CF phenotype do not have any mutations in *CFTR*. This indicates that the hypothesis that *CFTR* gene dysfunction is a requisite for the development of CF might not be true.[20] Identification of these and many other gene modifiers and appreciation of their importance in this and other diseases is a major step forward. Although at the present time, the effects of these polymorphisms are incompletely understood, such findings could lead to potential therapeutic targets for CF or identification of risk factors early in life.

### Oligogenic Disorders

Recent developments in defining the molecular genetics of Hirschsprung disease (HD) exemplify a relatively new concept in genetics—the oligogenic disorder. Although mathematic analyses of oligogenicity are beyond the scope of this discussion,[21,22] it is important to recognize that modifications of traditional linkage approaches are useful tools for the study of oligogenic diseases, especially if a major locus that contributes greatly to the phenotype is known. In the case of HD, two main phenotypic groups can be distinguished on the basis of the extent of aganglionosis: short-segment HD (S-HD) and the more severe long-segment HD (L-HD). Autosomal dominant inheritance with incomplete penetrance has been proposed for L-HD, whereas complex inheritance that involves

an autosomal recessive trait has been observed in S-HD. Oligogenicity has been established in both HD variants by virtue of several factors: a recurrence risk that varies from 3% to 25%, depending on the length of aganglionosis and the sex of the patient; heritability values close to 100%, which indicates an exclusively genetic basis; significant clinical variability and reduced penetrance; and nonrandom association of hypomorphic changes in the endothelin receptor type B (*EDNRB*) with rearranged during transfection (*RET*) polymorphisms and HD.[23,24] So far a combination of linkage, positional cloning studies, and functional candidate gene analyses has identified eight HD genes (Table 2-1),[25] of which the proto-oncogene *RET* is thought to be the main predisposing locus,[26,27] particularly in families with a high incidence of L-HD.[28]

The non-mendelian transmission of HD has hindered the identification of predisposing modifier loci by conventional linkage approaches. When these approaches (parametric and nonparametric linkage studies) were carried out on a group of 12 L-HD families, very weak linkage was observed on chromosome 9q31. However based on the hypothesis that only milder *RET* mutations could be associated with another locus, families were categorized according to the *RET* mutational data. Significant linkage on chromosome 9q31 was detected when families with potentially weak *RET* mutations were analyzed independently,[27] indicating that mild *RET* alleles, in conjunction with alleles at an unknown gene on chromosome 9, might be required for pathogenesis. The mode of inheritance in S-HD has proved to be more complex than that in L-HD, requiring further adjustments to the linkage strategies. Recently the application of model-free linkage, without assumptions about the number and inheritance mode of segregating factors, showed that a three-locus segregation was both necessary and sufficient to manifest S-HD, with *RET* being the main locus, and that the transmission of susceptibility alleles was additive.[28]

The inheritance patterns observed in disorders such as HD illustrate the power of both expanded models of disease inheritance that account for reduced penetrance and phenotypic variability and the ability of these models to genetically map loci involved in oligogenic diseases, which is a first step toward identifying their underlying genes. More important, the establishment of non-mendelian models caused a change of perception in human genetics, which in turn accelerated the discovery of oligogenic traits.

## Polygenic or Complex Disorders

Polygenic or complex disorders are thought to result from poorly understood interactions between many genes and the environment. An example of a polygenic disorder relevant to pediatric surgery is hypertrophic pyloric stenosis (HPS). The genetic cause of HPS has long been recognized, with frequent familial aggregation, a concordance rate of 25% to 40% in monogenetic twins, a recurrence rate of 10% for males and 2% for females born after an affected child, and a ratio of risk of 18 for first-degree relatives compared with the general population.[29] However this risk is considerably less than would be predicted based on mendelian patterns of inheritance.[30] In addition, HPS has been reported as an associated feature in multiple defined genetic syndromes[31–35] and chromosomal abnormalities[36–40] and anecdotally with many other defects,[41–45] suggesting a polygenic basis. Although the molecular genetic basis of HPS remains poorly defined, a likely common final pathway causing the disorder is altered expression of neural nitric oxide synthase (*NOS1*) within the pyloric muscle.[46] A detailed analysis of the molecular mechanisms of this alteration has been published, describing a reduction of messenger RNA (mRNA) expression of *NOS1* exon 1c, with a compensatory up-regulation of *NOS1* exon 1f variant mRNA in HPS.[46] DNA samples of 16 HPS patients and 81 controls were analyzed for *NOS1* exon 1c promoter mutations and single nucleotide polymorphism (SNP). Sequencing of the 5′-flanking region of exon 1c revealed mutations in 3 of 16 HPS tissues, whereas 81 controls showed the wild-type sequence exclusively. Carriers of the A allele of a previously

AD, autosomal dominant; AR, autosomal recessive; CCHS, congenital central hypoventilation syndrome (Ondine's curse); *ECE1*, endothelin-converting enzyme-1; *EDNRB*, endothelin receptor type B; *EDN3*, endothelin 3; *GDNF*, glial cell line–derived neurotrophic factor; *GFRA1*, GDNF family receptor α-1; HD, Hirschsprung disease; L-HD, long-segment HD; MEN, multiple endocrine neoplasia; *NRTN*, neurturin; RET, rearranged during transfection; S-HD, short-segment HD; SOX, SRY (sex determining region Y)-box 10.

uncharacterized *NOS1* exon 1c promoter SNP (-84G/A SNP) had an increased risk of HPS developing (odds ratio, 8.0; 95% confidence interval, 2.5 to 25.6), which could indicate that the -84G/A promoter SNP alters expression of *NOS1* exon 1c or is in linkage dysequilibrium with a functionally important sequence variant elsewhere in the *NOS1* transcription unit and therefore may serve as an informative marker for a functionally important genetic alteration. The observed correlation of the -84G/A SNP with an increased risk for the development of HPS is consistent with a report showing a strong correlation of a microsatellite polymorphism in the *NOS1* gene with a familial form of HPS.[47] However the -84G/A SNP does not account for all HPS cases; therefore other components of the nitric oxide–dependent signal transduction pathway or additional mechanisms and genes may be involved in the pathogenesis of HPS. This is in accordance with other observations suggesting a multifactorial cause of HPS.[29] In summary, genetic alterations in the *NOS1* exon 1c regulatory region influence expression of the *NOS1* gene and may contribute to the pathogenesis of HPS, but there are likely numerous other genes that contribute to the development of HPS as well as predispose to environmental influences in this disorder.

These examples provide insight into the complexity of current models of molecular genetics and illustrate the inadequacy of current methods of analysis to fully define genetic causes of disease, particularly polygenic disorders. The majority of pediatric surgical disorders currently fall into the category of undefined multifactorial inheritance, which is even less well understood than the genetic categories described. In these disorders, no causative, predisposing, or influencing gene loci have been identified. Isolated regional malformations are presumed to result from interactions between the environment and the actions of multiple genes. Multifactorial inheritance is characterized by the presence of a greater number of risk genes within a family. The presumption of a genetic basis for the anomalies is based on recurrence risk. The recurrence risks in multifactorial inheritance disorders, although generally low, are higher than in the general population; they are increased further if more than one family member is affected, if there are more severe malformations in the proband, or if the parents are closely related. Beyond these generalizations, genetics can provide little specific information about this category of disorder.

## UTILITY OF MOLECULAR GENETICS IN CLINICAL PEDIATRIC SURGERY

### Genetic Counseling and Prenatal Diagnosis

As mentioned earlier there is still a gap between genotypic understanding of a disorder and direct application to clinical treatment. The exceptions are in the areas of genetic counseling and prenatal diagnosis. Pediatric surgeons are likely to require some knowledge of molecular genetics as their role in prenatal counseling of parents continues to increase. Molecular genetics can supply specific information about an affected fetus by providing genotypic confirmation of a phenotypic abnormality, a phenotypic correlate for a confirmed genotype, and in many instances the recurrence risk for subsequent pregnancies and the need for concern (or lack thereof) about other family members. Once again HD is an example of how molecular genetics can be valuable in genetic counseling.[48,49] The generalized risk to siblings is 4% and increases as the length of involved segment increases. In HD associated with known syndromes, genetic counseling may focus more on prognosis related to the syndrome than on recurrence risk. In isolated HD a more precise risk table can be created. Risk of recurrence of the disease is greater in relatives of an affected female than of an affected male. Risk of recurrence is also greater in relatives of an individual with long-segment compared with short-segment disease. For example the recurrence risk in a sibling of a female with aganglionosis beginning proximal to the splenic flexure is approximately 23% for a male and 18% for a female, whereas the recurrence risk in a sibling of a male with aganglionosis beginning proximal to the splenic flexure is approximately 11% for a male and 8% for a female. These risks fall to 6% and lower for siblings of an individual with short-segment disease. Prenatal diagnosis is possible if the mutation within the family is known. However because the penetrance of single gene mutations is low (except for *SOX10* mutations in Waardenburg syndrome), the clinical usefulness of prenatal diagnosis is limited.

More commonly, a general knowledge of genetics can allow accurate counseling of recurrence risk and reassurance for parents of an affected fetus diagnosed with a multifactorial inheritance defect, the most common circumstance involving prenatal consultation with a pediatric surgeon. Pediatric surgeons should also be aware of the value of genetic evaluation of abortus tissue in cases of multiple anomalies when after counseling the parents choose to terminate the pregnancy. It is a disservice to the family not to send the fetus to an appropriate center for a detailed gross examination and a state-of-the-art molecular genetic assessment when appropriate.

As molecular genetics increasingly characterizes the genes responsible for specific disorders, their predisposing and modifier loci, and other genetic interactions, a better ability to predict the presence and severity of specific phenotypes will inevitably follow. This will allow prenatal counseling to be tailored to the specific fetus and lead to improved prognostic accuracy, giving parents the opportunity to make more informed prenatal choices.

### Postnatal Treatment

In the future molecular genetics will allow specific therapies to be optimized for individual patients. This may range from specific pharmacologic treatments for individual patients based on genotype and predicted pharmacologic response to anticipation of propensities for specific postoperative complications, such as infection or postoperative stress response. Of course the ultimate treatment for an affected individual and his or her progeny would be to correct the germline genetic alteration responsible for a specific phenotype. Although there are many scientific and ethical obstacles to overcome before considering such therapy, it is conceivable that a combination of molecular genetics and gene transfer technologies could correct a germline mutation, replacing an abnormal gene by the integration of a normal gene and providing the ultimate preventive therapy. Although the state of gene transfer technology is far from this level of sophistication, progress in the past 3 decades can only be described as astounding. The next section provides an overview of the current state of gene transfer and its potential application for therapy.

# Gene Therapy

Gene therapy remains controversial; however its tremendous potential cannot be denied, and significant strides in safety have been made in the past few years. The year 2000 brought the first clinical gene therapy success—treatment of X-linked severe combined immune deficiency (XSCID)[50]—only to have this dramatic achievement undermined by the induction of leukemia by a mechanism of insertional oncogenesis in four of the nine successfully treated patients.[51] This and other adverse events[52,53] threatened to overshadow the substantial progress made in gene transfer technology in recent years. The adversity has accelerated progress in our understanding of the mechanisms of insertional oncogenesis and in the design of vectors with much lower propensity to induce malignancies.[54] Methods for gene transfer are being developed that have greater safety, specificity, and efficacy than ever before. With improved understanding of the risks and better vector design, several recent trials of gene therapy for immunodeficiency disorders[55] and for ocular disease[56] have demonstrated early success. The technology of gene transfer can be divided into viral vector–based gene transfer and nonviral gene transfer. Because of the limited scope of this chapter and the limited efficiency of nonviral-based gene transfer thus far, only the current state of viral-based gene transfer is reviewed.

## VIRAL VECTORS FOR GENE TRANSFER

Viruses are highly evolved biologic machines that efficiently penetrate hostile host cells and exploit the host's cellular machinery to facilitate their replication. Ideally viral vectors harness the viral infection pathway but avoid the subsequent replicative expression of viral genes that causes toxicity. This is traditionally achieved by deleting some or all of the coding regions from the viral genome but leaving intact those sequences that are needed for the vector function, such as elements required for the packaging of viral DNA into virus capsid or the integration of vector DNA into host chromatin. The chosen expression cassette is then cloned into the viral backbone in place of those sequences that were deleted. The deleted genes encoding proteins involved in replication or capsid or envelope proteins are included in a separate packaging construct. The vector genome and packaging construct are then cotransfected into packaging cells to produce recombinant vector particles (Fig. 2-3).

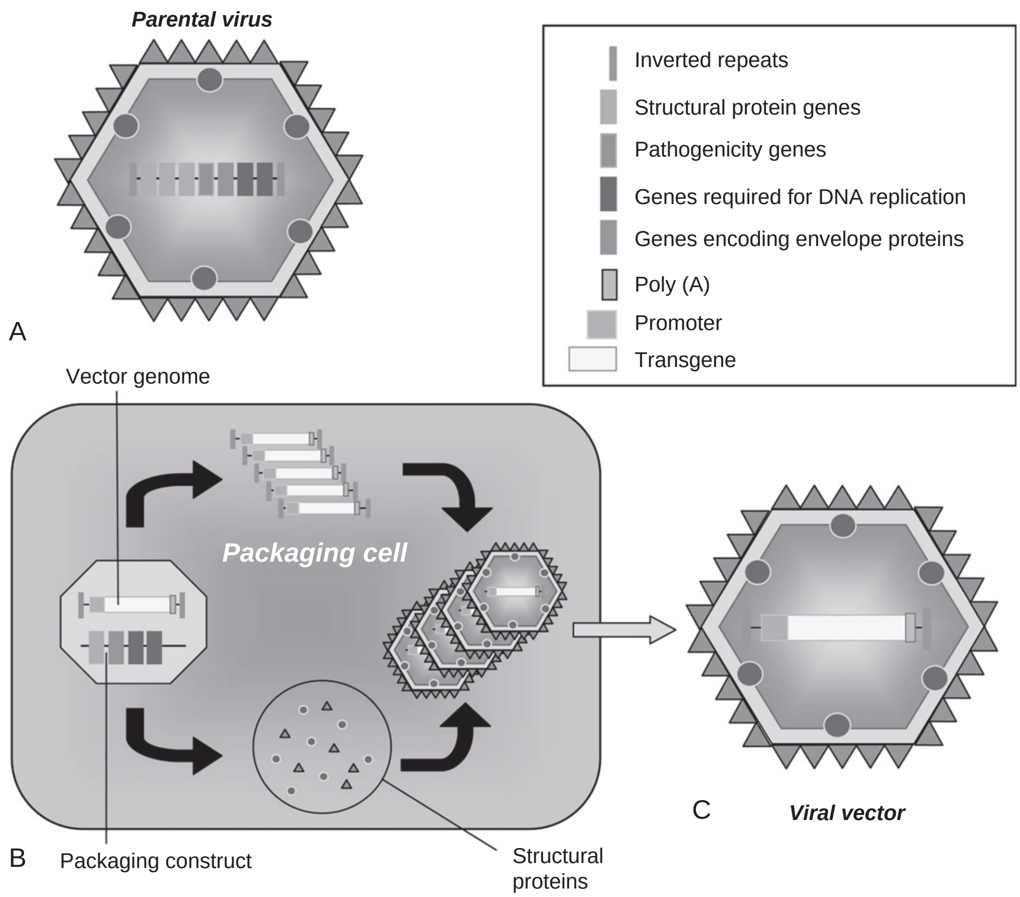

**FIGURE 2-3** Requirements for the creation of a generic viral vector. **A,** The basic machinery of a chosen parental virus is used, including genes encoding specific structural protein genes, envelope proteins, and proteins required for DNA replication, but not genes encoding proteins conferring pathogenicity. **B,** The vector is assembled in a packaging cell. A packaging (helper) construct, containing genes derived from the parent virus, can be delivered as a plasmid or helper virus or stably integrated into the chromatin of the packaging cell. Pathogenicity functions and sequences required for encapsidation are eliminated from the helper construct so that it cannot be packaged into a viral particle. In contrast, the vector genome contains the transgenic expression cassette flanked by inverted terminal repeats and *cis*-acting sequences that are required for genome encapsidation. Viral structural proteins and proteins required for replication of the vector DNA are expressed from the packaging construct, and the replicated vector genomes are packaged into the virus particles. **C,** The viral vector particles are released from the packaging cell and contain only the vector genome.

**TABLE 2-2**
**Five Main Viral Vector Groups**

| *Vector* | *Coding* | *Packaging Capacity (kb)* | *Tissue Tropism* | *Vector Genome* | *Type Advantages* | *Material Disadvantages* |
|---|---|---|---|---|---|---|
| Retrovirus | RNA | 8 | Dividing cells only | Integrated | Persistent gene transfer in dividing cells | Requires cell division; may induce oncogenesis |
| Lentivirus | RNA | 8 | Broad, including stem cells | Integrated | Integrates into nondividing cells; persistent gene transfer | Potential for oncogenesis |
| HSV-1 | dsDNA | 40 | Neural | Episomal | Inflammatory response; limited tropism | Large packaging capacity; strong tropism for neurons |
| AAV | ssDNA | <5 | Broad | Episomal (90%) Integrated (<10%) | Noninflammatory; nonpathogenic | Small packaging capacity |
| Adenovirus | dsDNA | 8 30* | Broad | Episomal | Extremely efficient gene transfer in most tissues | Capsid-mediated potent immune response; transient expression in dividing cells |

*Helper dependent.
AAV, adeno-associated vector; ds, double-strand; HSV-1; herpes simplex virus-1; ss, single-strand.

Given the diversity of therapeutic strategies and disease targets involving gene transfer, it is not surprising that a large number of vector systems have been devised. Although there is no single vector suitable for all applications, certain characteristics are desirable for all vectors if they are to be clinically useful: (1) the ability to be reproducibly and stably propagated, (2) the ability to be purified to high titers, (3) the ability to mediate targeted delivery (i.e., to avoid widespread vector dissemination), and (4) the ability to achieve gene delivery and expression without harmful side effects. There are currently five main classes of vectors that, at least under specific circumstances, satisfy these requirements: oncoretroviruses, lentiviruses, adeno-associated viruses (AAVs), adenoviruses, and herpesviruses. Table 2-2 compares the general characteristics of these vectors.

Oncoretroviruses and lentiviruses are "integrating," that is, they insert their genomes into the host cellular chromatin. Thus they share the advantage of persistent gene expression. Nonintegrating viruses can achieve persistent gene expression in nondividing cells, but integrating vectors are the tools of choice if stable genetic alteration must be maintained in dividing cells. It is important to note, however, that stable transcription is not guaranteed by integration and that transgene expression from integrated viral genomes can be silenced over time.[57] Oncoretroviruses and lentiviruses differ in their ability to penetrate an intact nuclear membrane. Retroviruses can transduce only dividing cells, whereas lentiviruses can naturally penetrate nuclear membranes and can transduce nondividing cells, making them particularly useful for stem cell targeting applications.[58,59] Because of this difference, lentivirus vectors are superseding retrovirus vectors for most applications. Because of their ability to integrate, both types of vector share the potential hazard of alteration of the host cell genome. This could lead to the undesirable complications of human germline alteration or insertional mutagenesis, particularly important considerations for pediatric or fetal gene therapy.[2] Nevertheless these vectors have proved most efficient for long-term gene transfer into cells in rapidly proliferative tissues and for stem cell directed gene transfer.

Nonintegrating vectors include adenovirus, AAV, and herpesvirus vectors. Adenovirus vectors have the advantages of broad tropism, moderate packaging capacity, and high efficiency, but they carry the usually undesirable properties of high immunogenicity and consequent short duration of gene expression. Modifications of adenovirus vectors to reduce immunogenicity and further increase the transgene capacity have consisted primarily of deletion of "early" (E1-E4) viral genes that encode immunogenic viral proteins responsible for the cytotoxic immune response.[60,61] The most important advance, however, has been the development of helper-dependent adenoviruses (HD-Ads) from which all viral genes are deleted, thus eliminating the immune response to adenoviral-associated proteins.[62] These vectors may ultimately be most valuable for long-term gene transfer in tissues with very low rates of cell division, such as muscle or brain. AAV is a helper-dependent parvovirus that in the presence of adenovirus or herpesvirus infection undergoes a productive replication cycle. AAV vectors are single-strand DNA vectors and represent one of the most promising vector systems for safe long-term gene transfer and expression in nonproliferating tissues. AAV is the only vector system for which the wild-type virus has no known human pathogenicity, adding to its safety profile. In addition the small size and simplicity of the vector particle make systemic administration of high doses of vector possible without eliciting an acute inflammatory response or other toxicity. Although the majority of the AAV vector genome after transduction remains episomal, an approximately 10% rate of integration has been observed.[63] There are two primary limitations of AAV vectors. The first is the need to convert a single-strand DNA genome into a double strand, limiting the efficiency of transduction. This obstacle has been overcome by the development of double-strand vectors that exploit a hairpin intermediate of the AAV replication cycle.[64] Although these vectors can mediate a 10- to 100-fold increase in transgene expression in vitro and in vivo, they can package only 2.4 kb of double-strand DNA, limiting their therapeutic usefulness. This relates to the second primary limitation of AAV vectors, which is limited packaging capacity (4.8 kb of single-strand DNA). One approach to address this limitation is to split the expression cassette across two vectors, exploiting the in vivo concatemerization of rAAV genomes. This results in reconstitution of a functional cassette after concatemerization in the cell nucleus.[65,66] Finally, an approach that has become common for enhancing or redirecting the

tissue tropism of AAV vectors is to pseudotype the vectors with capsid proteins from alternative serotypes of AAV.[67] Although most rAAV vectors have been derived from AAV2, nine distinct AAV serotypes have been identified thus far, all of which differ in efficiency for transduction of specific cell types. AAV vectors have proved particularly useful for muscle, liver, and central nervous system directed gene transfer.

Herpes simplex virus (HSV-1) vectors are the largest and most complex of all currently used vector systems. Their primary advantages are a very large packaging capacity (up to 40 kb) and their strong neurotropism, allowing lifelong expression in sensory neurons. This has made neuropathologic disorders a primary target for HSV-1–mediated gene transfer.

## CLINICALLY RELEVANT CHALLENGES IN GENE TRANSFER

The adverse events described previously demonstrate the potential for disaster when using vector-based gene transfer. Major initiatives must be undertaken to delineate the potential complications of gene transfer with specific vectors to convince physicians and the public of their safety for future clinical trials. Nevertheless because of the potential benefit, continued efforts to develop safe and efficacious strategies for clinical gene transfer are warranted.

One of the primary obstacles to successful gene therapy continues to be the host immune response. The intact immune system is highly capable of activation against viral vectors using the same defense systems that combat wild-type infections. Viral products or new transgene encoded proteins are recognized as foreign and are capable of activating an immune response of variable intensity. Adenovirus vectors are the most immunogenic of all the viral vector types and induce multiple components of the immune response, including cytotoxic T-lymphocyte responses, humoral virus-neutralizing responses, and potent cytokine-mediated inflammatory responses.[68] Great progress has been made in reducing T-cell responses against adenoviral antigens by the development of HD-Ad vectors from which all adenoviral genes are deleted. These vectors have demonstrated reduced immunogenicity with long-term phenotypic correction of mouse models and negligible toxicity.[69,70] However even HD-Ad vectors or less immunogenic vector systems such as AAV or lentivirus vectors can induce an immunologic response to capsid proteins[71] or to novel transgene encoded proteins,[72] a potentially limiting problem in a large number of human protein deficiency disorders caused by a null mutation. Thus the application of gene transfer technology to many human disorders may require the development of effective and nontoxic strategies for tolerance induction.[73]

Another major area of interest that may improve the safety profile of future viral vector–based gene transfer is specific targeting to affected tissues or organs. Wild-type virus infections are generally restricted to those tissues that are accessible through the route of transmission, whereas recombinant vectors are not subject to the same physical limitations. The promiscuity of viral vectors is a significant liability, because systemic or even local administration of a vector may lead to unwanted vector uptake by many different cell types in multiple organs. For instance, lack of adenovirus vector specificity was directly linked to the induction of a massive systemic immune response that resulted in a gene therapy–related death in 1999.[68] Because many of the toxic effects of viral vector–based gene transfer are directly related to dose, increasing the efficiency with which viral vectors infect specific cell populations should reduce viral load and improve safety.

There are a variety of promising methods to achieve the targeting of viral vectors for specific organs or cell types. Perhaps the simplest approach is vector pseudotyping, which has been performed for retrovirus, lentivirus, and AAV vectors. By changing the capsid envelope proteins to alternative viral types or serotypes, a portfolio of vectors with different tropisms can be generated.[74] Another approach is the conjugation of capsid proteins to molecular adapters such as bispecific antibodies with specific receptor binding properties.[75,76] A third approach is to genetically engineer the capsid proteins themselves to alter their receptor binding (i.e., to abolish their normal receptor binding) or to encode a small peptide ligand for an alternative receptor.[77] These and other approaches, when combined with the appropriate use of tissue-specific promoters, may significantly reduce the likelihood of toxicity from viral-based gene therapy.

Another important obstacle to human gene therapy—particularly fetal gene therapy—is the potential for insertional mutagenesis when using integrating vectors. Until recently this risk was considered extremely low to negligible, based on the assumption that oncogenesis requires multiple genetic lesions and the fact that induced cancer had not been observed in any of the hundreds of patients treated with retrovirus vectors in the many gene therapy trials. However in two trials of retroviral gene therapy for XSCID[50,78] leukemia developed in 5 of 20 patients treated.[51,79] Evidence suggests that this was caused by retroviral genome insertion in or near the oncogene *LM02*. These concerns have been further heightened by evidence that retroviral genes are not randomly inserted, as previously believed; rather, they preferentially integrate into transcriptionally active genes.[80] Although such events may be more likely to occur under the unique selective influences of XSCID, it is clear that the risk of insertional mutagenesis can no longer be ignored. Approaches designed to neutralize cells expressing transgene if and when an adverse event occurs, such as engineering suicide genes into the vector, are one option, but this would also neutralize any therapeutic effect. More exciting approaches are based on site-specific integration—for instance, taking advantage of site-integration machinery of bacteriophage $\phi$X31.[81] This is undoubtedly only one of many approaches that will use site-specific integration in the future and should, if successful, negate the risk of insertional mutagenesis. Even without site-specific integration, vector design, such as inclusion of a self-inactivating long terminal repeat in lentiviral vector design, can markedly reduce the likelihood of insertional mutagenesis.[54]

Finally, a critical issue for in vivo gene transfer with integrating vectors in individuals of reproductive age is the potential for germline transmission, with alteration of the human genome. The risk of this event is poorly defined at present and is most likely extremely low, although in some circumstances (e.g., fetal gene transfer), it could be increased.[2] Although still not technically possible, the intentional site-specific correction of defects in the germline would be the ultimate in gene therapy. However even if the technology becomes available, the intentional alteration of the human genome raises profound ethical and societal questions that

will need to be thoroughly addressed before its application. The considerations are similar to those for insertional mutagenesis, so many of the approaches mentioned earlier for gene targeting and reduction of the potential for insertional mutagenesis are applicable here as well.

## OVERVIEW OF THE CURRENT STATUS OF GENE TRANSFER

At present it is clear that viral vectors are the best available vehicle for efficient gene transfer into most tissues. Several gene therapy applications have shown promise in early-phase clinical trials. Although the adverse events noted in the XSCID trial have dampened enthusiasm, this still represents the first successful treatment of a disease by gene therapy. The treatment of hemophilia B using rAAV is promising,[82] as are the successful trials for ocular disease[56] and adenosine deaminase SCID[55] mentioned previously. The next few years are likely to bring advances in the treatment of certain types of cancer using conditionally replicating oncolytic viruses and in the treatment of vascular and coronary artery disease using viral vectors that express angiogenic factors. In the future new disease targets are likely to become approachable through the fusion of viral vector–mediated gene transfer with other technologies such as RNA interference, a powerful tool to achieve gene silencing. Such vectors could be useful in developing therapy for a range of diseases, such as dominantly inherited genetic disorders, infectious diseases, and cancer. Advances in the understanding of viral vector technology and DNA entry into cells and nuclei will likely lead to the development of more efficient nonviral vector systems that may rival viral vectors in efficiency and have superior safety. Gene vector systems of the future may be very different from those in use today and will ultimately provide efficient delivery of target-specific regulated transgene expression for an appropriate length of time.

CHAPTER 3

# Impact of Tissue Engineering in Pediatric Surgery

Howard I. Pryor II, David M. Hoganson, and Joseph P. Vacanti

Tissue engineering is a rapidly developing interdisciplinary field at the intersection of clinical medicine, cellular biology, and engineering. The goal of tissue engineering is to create living replacement organs and tissues to provide, restore, maintain, or improve lost or congenitally absent function.[1] Early attempts by surgeons to restore function include various wooden and metal prostheses mentioned in the Talmud and a description of a rhinoplasty using a forehead flap detailed in the *Sushruta Samhita* from around 6 BC. Modern medicine has embraced both the use of manufactured substitutes (such as Dacron aortic grafts) to repair abdominal aortic aneurysms and the approach of redirecting autologous tissue for a new function, as in the transfer of a toe to replace a finger. In the past half-century, the development of immunosuppressive medication has allowed for allogeneic substitution of tissues, as in organ transplantation, demonstrating that functional replacement can be lifesaving.

Unfortunately, all these approaches have significant limitations. In pediatric surgery, prosthetic material poses several problems, including material failure, increased rates of infection, and immunodestruction of foreign material. In addition, nonliving material does not grow with the patient nor does it adapt to changing circumstances, so pediatric patients may need to undergo multiple operations with increasing levels of complexity. Native substitutions of tissue are limited by the dilemma of prioritizing the value of various tissues and accepting the functional tradeoff that must be made when redirecting tissue to new functions. The effectiveness of organ transplantation is limited by a short supply of donor organs and a long list of associated morbidities related to lifelong immunosuppression. None of these approaches has permanently solved the need to replace composite tissues.

The field of tissue engineering evolved from the collaboration of Dr. Joseph Vacanti, a pediatric surgeon, and Robert Langer, Ph.D., a chemical engineer, in the laboratory of Dr. Judah Folkman at Children's Hospital Boston as a response to the need for replacement composite tissues. In a white paper published by the National Science Foundation, it was observed that "most lead authors in Tissue Engineering have worked at least once with Langer and Vacanti."[2] Tissue engineering is considered specifically applicable to pediatric surgery because the durability of surgical therapy must be greatest in children. The outcome may be measured over decades, and the surgical reconstruction is subjected to higher levels of growth and physiologic change. This can be especially challenging for congenital defects in which the amount of available donor tissue may be insufficient and prosthetic material may not approximate the functional, cosmetic, and growth requirements of the missing tissue. Satisfying this ongoing medical need is the focus of tissue engineering.

## Interdisciplinary Approach

Engineering is fundamentally different from science. The goal of science is to understand and define natural relationships. In contrast, the goal of engineering is to take advantage of relationships defined by science to address problems with solutions that do not exist in nature.[3] Engineering has been defined as the creative application of "scientific principles to design or develop structures, machines, apparatus, or processes" to solve a specific problem.[4] An engineer's invention must be communicated in concrete terms, and it must have defined geometry, dimensions, and characteristics. Engineers usually do not have all the information needed for their designs, and they are typically limited by insufficient scientific knowledge.[3] Traditionally, engineering has been based on physics, chemistry, and mathematics and their extensions into *materials science*, solid and *fluid mechanics*, thermodynamics, transfer phenomena, and systems analysis.[5] Tissue engineering is an approach that attempts to combine these traditional engineering principles with the biologic sciences to produce viable structures that replace diseased or deficient native structures.[6] As of 2004, aggregate development costs in tissue engineering exceeded $4.5 billion, and the field has encountered the kinds of challenges converting bench-top science into clinically marketable tools that were experienced during the development of other breakthrough medical technologies.[7]

Unlike biologic scientists, tissue engineers are not free to select the problems that interest them. Instead, tissue engineers must tackle the problems that present clinical

dilemmas. Frequently, the solutions must satisfy conflicting requirements; for instance, safety improvements increase complexity, but increased efficiency increases costs.[5] Problem solving is common to all engineering work. Although the problems may vary in scope and complexity, a common engineering design approach is applicable (Fig. 3-1). First, the problem is thoroughly analyzed, and a preliminary solution is selected. The preliminary solution is further subdefined by the identification of design variables that must be addressed. The preliminary solution is then refined by accounting for as many variables as possible and creatively synthesizing a new preliminary design. The preliminary design is checked for accuracy and adequacy. Finally, the results are interpreted in terms of the original problem. If the results are satisfactory, the engineering design process is complete. If the results do not adequately resolve the original problem, the design is analyzed for failure points, and the process is repeated until the original problem is solved.[5]

The short history of tissue engineering is replete with examples of this approach. For instance, monolayer cell culture has been used in the biologic sciences for decades, but this culture system typically supports only small numbers of cells in poorly organized sheets. Early attempts to organize these sheets into more clinically relevant constructs focused on the addition of an underlying support or scaffold for the cells as a substitute for the extracellular matrix (ECM).[8–11] Although these innovative approaches improved the handling characteristics and achievable cell mass of these constructs, new problems were identified in terms of poor clinical function, and the iterative process was begun anew, leading to the development of bioreactors. Early bioreactors were dynamic tissue culture devices with simple mechanical designs meant to provide oxygen exchange, defined nutrient flow rates, and electrical and mechanical stimulation that more closely approximated physiologic conditions. The results of these studies revealed further improvements in cell morphologic features, growth characteristics, and metabolic activity.[12–14] As the field of tissue engineering matures, the design variables that must be addressed for each construct will be expanded and refined accordingly.

Several fundamental biology-limited design variables of tissue engineering have been identified, including cell source, ECM, co-culture cell populations, and culture environment (Fig. 3-2). Many initial studies focused on the use of

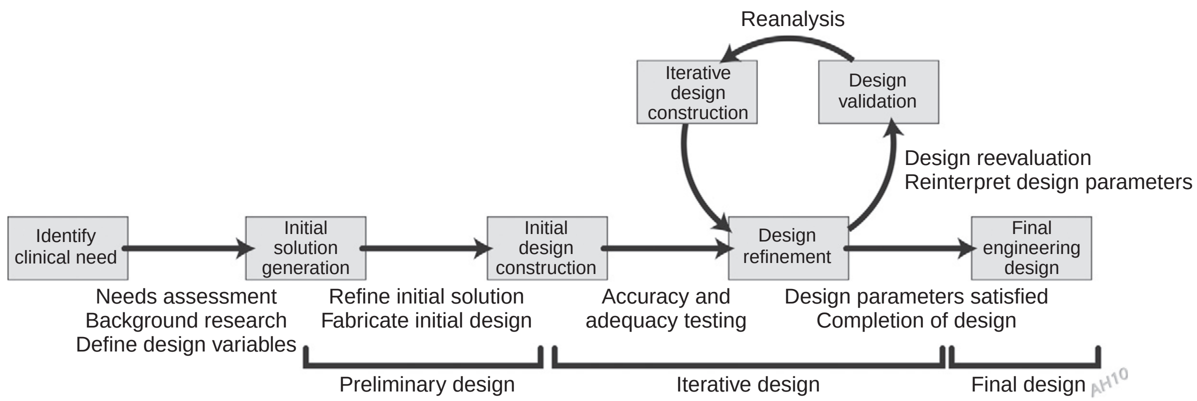

**FIGURE 3-1** The iterative engineering design process. The engineering design process begins with the identification of a problem. The problem is analyzed to assess the minimum solution requirements, research the background of previous work, and define the variables that must be addressed. The preliminary design phase begins with an initial solution design and ends when the preliminary design is constructed. The iterative design phase begins with testing of the preliminary design and proceeds through design refinement, validation, and creation of subsequent designs. If a secondary design fails to satisfy initial requirements, the iterative process is undertaken repeatedly until the criteria are met. The final design phase is characterized by the formal definition of the satisfactory design through mathematic equations, drawings, and operating parameters.

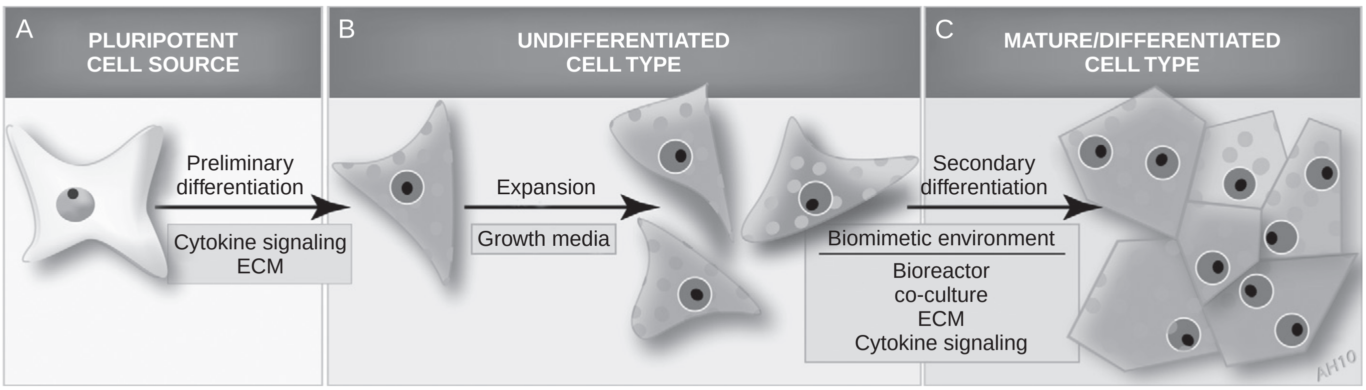

**FIGURE 3-2** Multipotent cell differentiation. Pluripotent cell populations have the ability to expand in culture and differentiate into a variety of mature cell types. **A,** The process begins with expansion of the pluripotent cell type in the presence of ECM and cytokines that preserve their expandability while focusing their differentiation down the desired lineage. **B,** The partially differentiated cells are then expanded in growth media to clinically significant quantities. **C,** Using biomimetic culture techniques—including ECM, cytokine signaling, co-culture, and bioreactors—the cells are differentiated into the desired mature cell type.

autologous organ-derived, fully differentiated parenchymal, or primary, cells. Because primary cells are typically in short supply and do not naturally replicate in large quantities, several other cell sources have been investigated, including autologous bone marrow and adipose-derived mesenchymal stem cells, umbilical cord blood cells, Wharton jelly–derived cells, amniotic fluid cells, and allogeneic embryonic stem cells.[15–21] These cell populations have the ability to expand in culture and have demonstrated adequate plasticity to differentiate into a variety of cells, including the epithelium of liver, lung, and gut, as well as the cells of both hematopoietic and endothelial systems.[16,17,22–25] As the differentiation scheme for each of these cellular populations becomes clarified, it has been suggested that cell banks for tissue-engineering applications be developed to respond more rapidly to the clinical need for tissue-engineered constructs.[26]

As more immature cell populations have been investigated, the essential role of ECM in differentiation and maintenance of organ structure has become apparent. For structural tissue constructs such as bone, merely providing the cell population with a polymer scaffold with properties similar to type I collagen has proved less satisfactory than adding elements commonly found in forming bone, such as hydroxyapatite or calcium phosphate.[26–29] Similarly, in liver tissue constructs that use collagen, Matrigel and PuraMatrix hydrogel sandwiches have resulted in greater hepatocyte longevity.[30,31] Work in liver tissue engineering also demonstrated the benefit of co-culturing primary cells with tissue-specific supporting cells.[32] The adult liver requires many complex cell-cell interactions for coordinated organ function, and in vitro investigations have shown that co-cultured hepatocytes and nonparenchymal cells were more tolerant of the culture environment.[33] Co-culture of embryonic stem cells with adipose-derived mesenchymal stem cells (ADSCs) or fibroblasts resulted in enhanced culture viability and formation of vascular tubelike structures.[12,22,34] Even with the correct combinations of cells and ECM, the culture environment must mimic the in vivo environment for the tissue construct to demonstrate clinical function. A fundamental limitation of the field to date has been the adequate mass transfer of nutrients and oxygen to meet the metabolic needs of tissue constructs. The driving force for mass transfer is a concentration gradient that must be kept in perfect balance with the supply of depleted resources precisely as they are used, perpetuating the net transfer of mass from an area of high concentration to an area of low concentration.[35] In addition to a precisely tuned nutrient supply, the mechanical and anatomic in vivo environment must also be mimicked. For cardiac tissue engineering, this has been shown to be important, because constructs cultured without electrical and mechanical stimulation fail to meet critical design criteria when compared with constructs in a biomimetic environment.[6] Highly complex flow bioreactors have been designed to systematically quantify the independent and coupled effects of cyclic flexure, stretch, and flow on engineered heart valve tissue formation in vitro.[36] Researchers have evaluated tissue-engineered heart valves using a bioreactor that automatically controls mean pressure, mean flow rate, beat frequency (heart rate), stroke volume, and the shape of the driving pressure waveform.[37] In addition, researchers studying the liver have developed a biomimetic flat-plate bioreactor system housing phenotypically stabilized hepatocyte-fibroblast co-cultures in an effort to recapture the zonal features of the liver.[38]

However, the nascent field of biomimetic bioreactors has only recently begun to bring the entire weight of the field of engineering to bear. Three critical advancements that the broad field of engineering will lend to the field of tissue engineering are computational fluid dynamics, advanced modeling, and real-time culture monitoring. Computational fluid dynamics is a technique of design analysis that allows for the accurate prediction of shear stress, culture medium dynamic velocity, and mass transfer of nutrients and oxygen.[36] This technique can be applied as a modeling method in which a virtual design is created and tested by simulation. The virtual design can then be refined and retested several times before the expense of building a real prototype.[6,36,37] This modeling strategy has been applied in a few instances to predict the production of collagenous ECM in engineered tissues, to accurately reproduce scaffold mechanical properties, and to mathematically model oxygen transport in a bioreactor.[6,36,38,39] This type of modeling in the field of tissue engineering will allow for the development of theoretical frameworks to model complex biologic phenomena that can be used to guide sound, hypothesis-driven examinations of new problems and analyze engineered implant performance in vitro and after implantation.[6] The broad field of engineering will also provide the monitoring strategies required to define success in the development of tissue-engineered constructs. One example is the use of nondestructive, high-resolution, nonlinear optical microscopic imaging to observe the development of collagen in tissue-engineered constructs over time.[40] Another example of advanced monitoring is the use of a computer-controlled closed-loop feedback bioreactor to study the effects of highly controlled pulsatile pressure and flow waveforms on biologically active heart valves.[37] As the field of tissue engineering evolves, the need for thoughtfully designed, well-monitored biomimetic culture systems that emulate physiologic conditions will be required to understand the complex culture protocols necessary to yield functional tissue grafts.[14,41]

## Cartilage and Bone Tissue Engineering

Pediatric surgeons encounter many congenital and acquired problems that are characterized by structural bone and cartilage defects. These defects may range from cleft palates and craniofacial abnormalities to significant long bone defects after cancer surgery. The current standard of care for most of these lesions includes bone grafting, but donor site morbidity after bone graft harvest remains a recognized limitation to this technique.[42] Grafting in children is also complicated by the fact that the pediatric skeletal system is still developing and the thickness of the nascent bone is thinner compared with adult bone.[43] To supplement the grafting approach, tissue engineers have sought to generate greater quantities of bone and cartilage. One of the earliest successes in bone and cartilage tissue engineering stemmed from the observation that chondrocytes harvested from articular surfaces differentiated in culture to cartilage, whereas chondrocytes from periosteum initially resembled cartilage but progressed in culture to

form new bone.[44] In the ensuing 15 years, the tissue engineering of bone and cartilage has evolved into a complex interaction of osteoinductive factors, osteoprogenitor cells, advanced scaffold technology, and an adequate blood supply.[25]

Cartilage is a relatively simple tissue with limited spontaneous regenerative capacity and a low metabolic rate.[45,46] However, early studies with polymer constructs of polyglycolic acid and polylactic acid molded into predetermined shapes led to the formation of cartilage in the shape of a human ear, a temporomandibular joint disk, and articular cartilage for meniscus replacement (Fig. 3-3).[47–50] Since these early studies, an entire research and industrial complex has evolved to develop adequate cartilage replacements for clinical use; a summary of the entire body of work would be beyond the scope of this book. The two principal limitations to the use of most of the resulting constructs are (1) the low replication rate of primary chondrocytes and (2) the relatively low construct strength compared with native tissue.[51] Several groups have addressed the cell source issue through the evaluation of stem cells focusing primarily on bone marrow–derived and adipose-derived mesenchymal stem cells. Both cell types are easily isolated and can be induced to secrete myriad cartilaginous ECM components after differentiation in chondrogenic culture conditions.[52,53] However, increasing construct cell density through the use of a stem cell source is not enough to address the issue of low construct strength. Several groups have shown that cartilaginous ECM secretion and subsequent construct strength are increased when

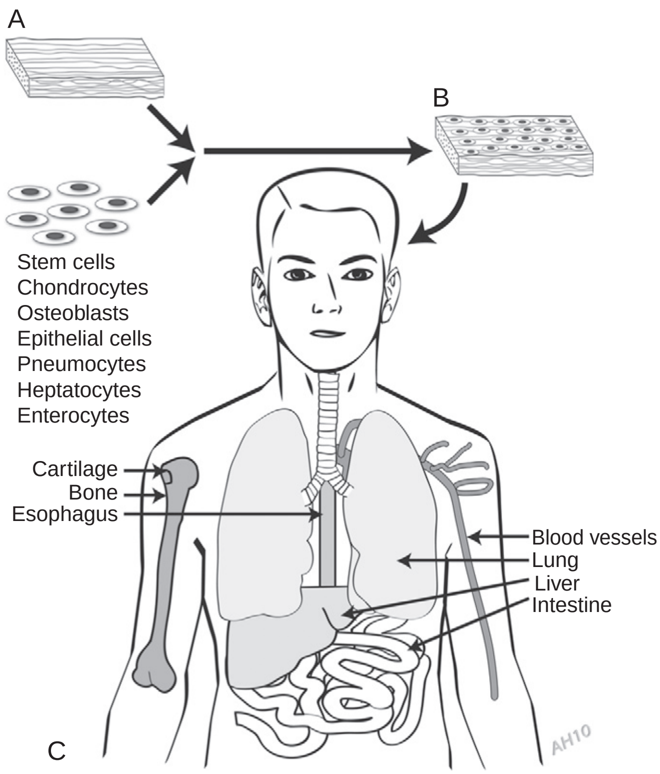

**FIGURE 3-3** The classic tissue-engineering paradigm. **A,** The classic tissue-engineering paradigm is based on the expansion of pluripotent or primary parenchymal cells in static culture and the creation of a biocompatible polymer scaffold. **B,** The expanded cellular population is seeded onto the scaffold and allowed to expand further in culture. **C** The tissue-engineered construct can then be implanted in a variety of positions to replace absent or lost tissue.

constructs are cultured under dynamic conditions. Such conditions include constant media perfusion, biaxial loading, and rolling media bottle bioreactors.[41,52,54] In each case, the histologic presence of cartilage ECM was markedly increased, and the compressive force sustained by each construct was significantly increased compared with controls. However the optimum culture conditions remain undefined and will likely be unique for each cartilage type applied in the clinical setting.

The tissue engineering of bone evolved from early studies in cartilage tissue engineering in which bovine periosteal cells were seeded onto polyglycolic acid scaffolds to repair cranial bone defects in nude rats.[55] Since these first steps, bone tissue engineering has been approached in many ways. Several methods have been tried, including the implantation of collagen scaffolds containing stem cells transfected with a virus for BMP-2 (a bone forming protein), which demonstrated accelerated osteogenesis.[25,56] Cellular implantation studies have demonstrated that biomimetic scaffolds with porosity greater than 90% and a pore size ranging from 300 to 500 μm improve bone tissue regeneration.[57,58] Ultrastructural evaluation has shown that when bone scaffolds contain nanometer surface features, bone regeneration can be further optimized.[59] As a tissue, bone is significantly more vascular than cartilage, and a principal limitation to bone construct size has been the diffusion distance from surface to center of the construct. One recent approach to this problem is the technique of co-culturing mesenchymal stem cells with endothelial cells in a fibronectin-collagen gel to induce spontaneous angiogenesis within the construct.[60] The use of vascular endothelial growth factor–releasing ADSCs and endothelial cells to more closely mimic the environment of developing bone and direct the growth of blood vessels into 3D PLAGA scaffolds has also been reported.[61] Applying typical engineering analytic tools, a mathematic framework for predicting the development of engineered collagenous matrix has been developed.[40] Some groups have taken advantage of the bone's natural regenerative capacity to use the periosteal space as a bioreactor to develop autologous bone grafts between the surface of a long bone and its periosteum.[13] Given the pace at which this field of tissue engineering is advancing, bone and cartilage tissue engineering will likely provide the most short-term clinically useful products, including constructs to address joint reconstruction and complex congenital anomalies with which pediatric orthopedic surgeons must contend.

## CARDIAC TISSUE ENGINEERING

Approximately 1% of all newborns are diagnosed with cardiac defects, including valvular disorders, making heart malformations the most common pathologic congenital condition in humans.[26] Limited options exist for the successful treatment of these patients and include mechanical valve replacement, biologic valve replacement, and ultimately, heart transplantation. Mechanical valves are an imperfect solution because they require lifelong anticoagulation and can spawn systemic thromboembolism.[62] Biologic valves do not require systemic anticoagulation but often calcify, and they must be replaced after several years.[59] Although heart transplantation is the ultimate therapeutic option, this modality is limited by the scarcity of suitable donor organs, requires lifelong immunosuppression, and is associated with serious complications,

such as kidney failure and malignancies.[26] The perfect solution to this clinical dilemma would be the development of a nonthrombotic, self-repairing tissue valve replacement that grows with the patient and remodels in response to in vivo stimuli.[59,63]

Over the past decade, an enormous amount of research has been focused on developing a tissue-engineered heart valve meeting these criteria. Although a thorough review would be outside the scope of this book, highlights from such research illustrating tissue engineering's interdisciplinary approach follow.

Initial studies evaluated single-cell populations grown on biocompatible scaffolds in static culture conditions and clearly demonstrated short-term hemodynamic functionality with minimal calcification when implanted in sheep.[64,65] Valves co-cultured with autologous medial and endothelial cells before implantation were shown to function in vivo for up to 5 months and resemble native valves in terms of matrix formation, histologic characteristics, and biomechanics.[66] It was hypothesized that further improvement in valve performance could be obtained by culturing valves under pulsatile flow to generate a biomimetic environment resembling in vivo conditions.[6] Valves cultured under these conditions have demonstrated increased mechanical strength and improved cellular function within the construct.

Although a great deal of progress has been made in the pursuit of a tissue-engineered heart valve, these valves still need to be tested and succeed in the aortic position, where they are needed most.[63] Furthermore, the critical ability of these tissue-engineered constructs to grow with the patient must be clearly demonstrated and will be the focus of the next decade of research.

## Vascular Tissue Engineering

In addition to valvular repair, children with complex *congenital heart defects* often require a new vascular conduit to reroute blood flow due to an anomaly. One such example is the Fontan procedure, in which *venous blood* is directed to the *pulmonary arteries* without passing through the *right ventricle*.[67] A host of synthetic and biologic conduits have been deployed in this location, but none of them has provided perfect results. Synthetic conduits incite a foreign body reaction and are a significant cause of thromboembolic complications.[68] Biologic grafts have significantly lower thromboembolic complication rates compared with synthetic grafts but become stenotic and calcify over time because of an immune-mediated process found to be more aggressive in younger patients.[69,70] Moreover, both graft types lack significant growth potential, and it is assumed that all such conduits will eventually need to be replaced.[69,71] Given the morbidity of repeated open-heart procedures on a child, investigators have looked to tissue engineering as an alternative to the use of synthetic and biologic conduits.[72]

As the most successful example of applied tissue engineering to date, Shin'oka and colleagues reported the first human use of a tissue-engineered blood vessel in a 4-year-old girl to replace an occluded pulmonary artery after a Fontan procedure (Fig. 3-4).[72] The conduit used was a 1:1 polycaprolactone, polylactic acid copolymer scaffold seeded with autologous peripheral venous endothelial cells. After 7 months of follow-up, no complications were noted. This successful experience has launched a clinical trial of 42 patients receiving similar scaffolds seeded with autologous bone marrow–derived cells.[73] At 16 months of follow-up, the group reported no significant complications, although one patient died from unrelated causes. The harvest of bone marrow–derived cells is associated with several morbidities, including pain and infection, so several alternative cells sources have been sought. Two such cell sources include adipose-derived endothelial progenitor cells and umbilical cord–derived cells.[23,74]

As the interdisciplinary approach of tissue engineering has been applied to the development of the tissue-engineered vascular graft (TEVG), several areas for improvement have been identified. Using a bioreactor that provided physiologic stimulation similar to the pulmonary artery, physiologically

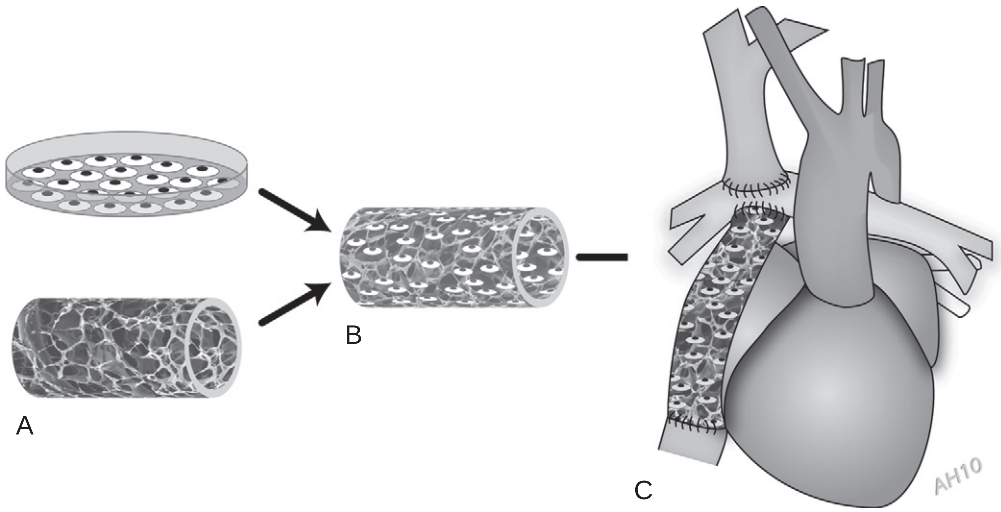

**FIGURE 3-4** Tissue-engineered vascular graft. **A,** Tissue-engineered vascular grafts are constructed from a host of cells expanded in culture (autologous peripheral venous endothelial cells, bone marrow–derived cells, adipose-derived endothelial progenitor cells, and umbilical cord–derived cells) and a conduit composed of 1:1 polycaprolactone and polylactic acid copolymer scaffold. **B,** The expanded cellular population is seeded onto the construct and allowed to attach in culture before implantation. **C,** The tissue-engineered vascular graft has been used as an extracardiac conduit in the Fontan procedure.

dynamic conditions up-regulated collagen production by fourfold over the static controls in an in vitro TEVG.[37] Sophisticated monitoring techniques have been developed to evaluate TEVG for the development of normal vascular architecture. Qualitative immunohistochemical and quantitative biochemical analyses demonstrate that the ECM of the TEVG resembled the ECM of the native inferior vena cava after explantation in animal studies.[75]

This type of successful translation of cardiovascular tissue-engineering principles from the bench to the clinic could lead to improved vascular grafts for other cardiovascular surgical applications.[68] Two obvious applications of this developing field are small-diameter vascular grafts and new vascular stent materials.[59] The development of a small-diameter tissue-engineered graft could fill a significant void in the field of vascular surgery, because grafts smaller than 6 mm cannot be satisfactorily constructed from textile or polytetrafluoroethylene (PTFE) and must be bypassed with autologous arteries and veins, with a limited supply for multiple operations.[76] Further, the development of an inexhaustible supply of vascular constructs for in vitro use could lead to the rapid advancement of stenting technologies by eliminating the expense and time expended in animal trials. The pursuit of these near-term goals would result in a dramatic expansion of the field of tissue engineering over the next 10 years.

## Gastrointestinal Tissue Engineering

Gastrointestinal tissue engineering has the potential to improve outcomes in two clinical settings for pediatric surgeons: esophageal atresia and short-bowel syndrome. Long-gap esophageal atresia is a daunting clinical problem requiring delayed repair and transposition of a remote portion of bowel.[77–79] Complications from these procedures abound, including stricture, leakage, and malnutrition secondary to shortening of the gastrointestinal tract.[80,81] Moreover, synthetic conduits are unavailable and would lack the critical ability to grow with the patient throughout childhood. As a result, many groups have sought to develop a tissue-engineered esophageal construct that could be used to treat long-gap atresia. Initially, it was demonstrated that organoid units transplanted from adult autologous esophagus onto a biodegradable scaffold form complex tissue indistinguishable from native esophagus.[82] Tissue-engineered esophagus has been used both as a patch and as an interposition graft in rats in preliminary studies.[82] However, these organoid units required resection of significant esophageal length. Recent studies have revealed that isolated esophageal cells could be seeded under low density on collagen polymers and could be expanded in vitro, leading to a potential autologous tissue–engineered esophageal construct.[83]

Of the morbid conditions associated with bowel resection, short-bowel syndrome is the most devastating. It is characterized by progressive weight loss, malnutrition, vitamin deficiency, and infections associated with the vascular access commonly used to support patients with this syndrome.[84,85] This clinical condition develops when less than one third of normal jejunal-ileal length remains, a distance of 25 to 100 cm in neonates.[86] Pediatric surgeons influence the morbidity and mortality of patients with pediatric gastrointestinal disorders such as inflammatory bowel disease and necrotizing enterocolitis because these disorders can require resection of large portions of small bowel.[20,87] Despite efforts to maximize bowel preservation at the time of surgery and the use of gut lengthening procedures to extend the remaining small bowel's functional surface area, many patients become dependent on total parenteral nutrition.[88] These patients are at risk for liver dysfunction as a result of impaired enterohepatic bile salt circulation and abnormal bile acid metabolism, resulting in overt liver failure. This liver dysfunction is recognized as an indication for small intestine transplantation, a procedure fraught with poor survival and lifelong morbidities.[89]

The generation of a composite tissue resembling small intestine from intestinal cells heterotopically transplanted as organoid units was first reported in 1998.[86] Organoid units were derived from full-thickness harvests of intestine and loaded on 2-mm cylindric bioresorbable polymers before implantation in the omentum. The resulting engineered bowel demonstrated polarization of the epithelial cells, which faced the lumen of the cyst. The other layers of the intestinal wall were histologically present with substantial vascularization.[86] Subsequent studies have evaluated a variety of scaffold and cellular combinations that further improve the clinical potential of this therapy.

These evaluations revealed that the ability of intestinal organoid units to recapitulate full-thickness bowel was based on the presence of a mesenchymal core surrounded by a polarized intestinal epithelium, representing all the cells within a full-thickness section of bowel.[90,91] The neomucosa generated by this method in rats demonstrated epithelial barrier function and active transepithelial electrolyte movement equal to that of native adult tissue.[86] Additional studies have supported the finding that the neointestine is not merely anatomically intact but is able to absorb energy-dense nutrients, suggesting a future human application for tissue-engineered intestine.[20] Unfortunately, the use of organoid units requires invasive procedures for harvest, and a more ideal cell source is needed. Such a source would possess the ability to differentiate into all aspects of the intestine, including absorptive and secretory cells as well as vasculature and physical support structures.[20]

The ideal scaffold material has similarly not yet been identified. Initial work on the topic evaluated several options, including AlloDerm and small intestinal submucosa (SIS).[92,93] The latter has been used to support mucosal regeneration across a gap in resected bowel in experimental models.[94] It has also been shown to degrade within 3 months after operative implantation replaced by host-derived tissue.[95] In one large animal study, a commonly used human biomaterial, polyglycolic acid, was used as the scaffold for the first engineered intestine implanted during a single anesthetic administration. It was seeded with autologous tissue arising from organ-specific stem cells.[96] Although all these results point to a future tissue-engineered construct that increases absorptive surface area, a future challenge will focus on the recovery of peristaltic activity of the regenerated bowel. This will require advances in both smooth muscle incorporation and reinnervation of the regenerated bowel.[95] Tissue-engineered gastrointestinal replacement with peristalsis would provide a critical advancement in the treatment of many pediatric surgical diseases and may significantly affect patient care, with improved surface area, transporter function, immune characteristics, and architecture.

## Liver Replacement and Tissue Engineering

The liver is a complex vital organ that supports homeostasis through metabolism, excretion, detoxification, storage, and phagocytosis of nutrients and toxins. Acute or chronic liver dysfunction accounts for the death of 29,000 Americans each year, with acute failure mortality rates exceeding 80%.[97,98] In children, liver dysfunction can be caused by biliary atresia–related liver cirrhosis and metabolic diseases such as alpha-1 antitrypsin deficiency, Wilson disease, tyrosinemia, and others.[99] Despite investigation into a wide array of liver support protocols, orthotopic liver transplantation remains the only definitive treatment for severe hepatic failure. Three thousand of these procedures are performed annually, leaving thousands of patients on waiting lists in need of an alternative option. The field of hepatic tissue engineering developed as an attempt to solve this problem.

Initial studies in the field of hepatic tissue engineering were based on the injection of isolated hepatocytes into the portal vein, peritoneal cavity, spleen, and pancreas.[100–102] These cells engrafted and corrected both isolated and global metabolic deficiencies, but these successes were time-limited because the mass of the injected cells was small, and the functional capacity of the cells decreased over time. Methods to increase the tissue-engineered liver mass included concurrent hepatotropic stimulation through partial hepatectomy, portacaval shunting, and injection of liver toxins.[103–106] Even with maximal hepatotropic stimulation, these methods failed to yield adequate hepatocellular function to detoxify a patient in fulminant hepatic failure. A more advanced tissue-engineered liver construct was sought to provide temporary liver function replacement based on the concept of kidney dialysis therapy and was referred to as an extracorporeal bioartificial liver device (BAL).[107] The goal of such a device is to support patients in acute liver failure while liver regeneration occurs and, if that fails, to serve as a bridge to transplantation.[108] Unfortunately, despite a wide array of devices tested, none has delivered the desired results.[107] Most BALs tested to date contain a singular hepatocyte cell population without associated nonparenchymal cells. Such a device's lifetime is limited because hepatocytes degenerate within hours to days in such an environment.

The cellular physiology of the liver is complex. Hepatocytes are anchorage-dependent cells and require an insoluble ECM for survival and proliferation.[85] The adult liver also requires a complex cell-cell interplay between hepatocytes and the nonparenchymal cell populations, including biliary epithelium, Kupffer cells, stellate cells, and sinusoidal endothelial cells. These interactions are essential for proper organ function, and hepatocytes dedifferentiate within 2 weeks when these communications are severed.[109] To preserve and encourage these necessary interactions in future BALs, several groups have proposed to organize the underlying scaffold to serve as a template to guide cell organization and growth.[85] Given the high metabolic requirements of liver tissue, this organized structure would allow more efficient diffusion of oxygen and nutrients and removal of waste. A further advance of this concept, being refined at the Massachusetts General Hospital Tissue Engineering and Organ Fabrication Laboratory, is the development of a polymer device with an integrated vascular network to provide immediate access to the blood supply after implantation (see the discussion on future directions in the next section).[18] This de novo vascular system could be used as a template for any complex tissue such as liver or lung. Future designs are based on a modular concept that allows for the fabrication of implantable devices containing a large mass of cells within a structured environment, complete with de novo blood supply.

One significant challenge that remains entirely unaddressed in the field of hepatic tissue engineering is the development of an artificial biliary system. One solution may lie in the use of multipotent cells that can differentiate down both the hepatocytic and biliary lineages during postimplantation remodeling.[99]

## Future Directions: Vascular Networks

The advances of tissue engineering have occurred primarily through interdisciplinary efforts of electrical, chemical, and mechanical engineers; scientists, in fields such as developmental biology, biomaterials science, and stem cell biology; and clinicians from surgical and medical fields.[110] This approach has been successful in the initial development of avascular or thin tissues with low metabolic activity and functions limited to mechanical activity, such as skin, bone, cartilage, and heart valves (Table 3-1).[12,18,59] Engineering more complex tissues with a significant homeostatic contribution and high metabolic activity necessitates the development of a vasculature within the construct that promotes cell survival, tissue organization, and rapid nutrient supply immediately after implantation.[12,18]

Native tissues are supplied by capillaries that are spaced a maximum of 200 μm from one another, permitting a natural diffusion limit for nutrients and gases.[111,112] Two approaches have been investigated to address this goal of providing nutrients to every cell in a tissue construct within the tissue's natural diffusion limit (Fig. 3-5).[12,113] One strategy relies on the tissue construct's natural ability to sprout new or bridging vessels or to invite ingrowth of existing vessels.[12] Despite numerous attempts, it has been difficult to develop a de novo angiogenesis-based vasculature within a tissue construct because of the challenges involved in the differentiation and sustenance of multiple (i.e., vascular progenitor and parenchymal) cell types in a concomitant fashion.[13] To date, only one group has had success in a tissue-engineered bone construct.[60] Several previous attempts to invite ingrowth after implantation have revealed that blood vessel invasion from the host tissue is limited to a depth of several hundred micrometers from the surface of the implant.[61] This results in a central zone of necrosis because only the periphery of the graft is efficiently vascularized.[60,114] The difficulties with in vitro vascularization have led to the development of an alternative solution: preformed vascular networks.[26]

The design of preformed vascular networks is only beginning to be defined as a natural extension of previously identified axioms of vascular biology. Such networks will have to be designed individually for the intended tissue based on the tissue's inherent resistance to flow, nutrient transfer requirements, and waste removal needs.[113] Such control of the microenvironmental niche within each tissue will be

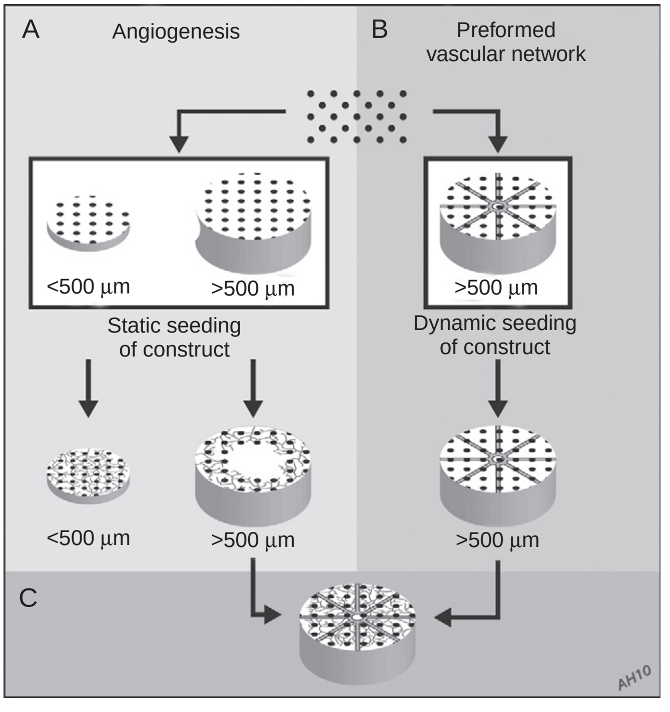

**FIGURE 3-5** Angiogenesis versus preformed vascular networks. **A,** The angiogenesis approach to vascularized tissue constructs relies on the natural ability of a construct to form new vessels or invite ingrowth of existing vessels. For constructs less than 500 µm in every dimension, cells can survive on diffusion alone as new vessel ingrowth reaches the entire cellular population. For constructs larger than 500 µm, a necrotic core develops because cells greater than 500 µm from nutrients cannot survive on diffusion long enough to allow vessel ingrowth. **B,** Using tissue-specific design criteria, preformed vascular networks can provide nutrients to within 150 µm of each cell in a construct with dimensions greater than 500 µm, thereby preventing a necrotic core. **C,** Using a resorbable scaffold to manufacture the preformed vascular network will allow the network to serve as a starting point for angiogenesis in the construct while providing the required nutrients during the ingrowth process.

key to successful tissue regeneration and has only been possible because of recent manufacturing advancements in the field of mechanical engineering, such as electrical discharge machining and micromilling.[113] Such networks can serve as the "vascular scaffold" for subsequent post-implantation remodeling.[12] As solutions to these near-term limitations evolve, more problems will be identified that will require an interdisciplinary approach to tissue engineering.

The future of tissue engineering is dependent on a robust blend of fundamental iterative engineering design, developmental and cellular biology, and surgical expertise to optimize the clinical use of new engineered constructs. The initial efforts to develop clinically useful tissues have succeeded in thin tissues supplied by diffusion. Future successful efforts in the design of vascularized structures and the evolution of autologous cell sources for tissues will eventually result in the development of clinically useful tissue-engineered organs.

# CHAPTER 4

# Advanced and Emerging Surgical Technologies and the Process of Innovation

Sanjeev Dutta, Russell K. Woo, and Thomas M. Krummel

*"Change is inevitable. Change is constant."*

**—Benjamin Disraeli**

From the eons of evolutionary change that gifted *Homo sapiens* with an opposable thumb, to the minute-to-minute changes of the neonatal surgical patient, change and the adaptive response to change defines either success or failure.

The development and use of tools and technologies remains a distinguishing characteristic of mankind. The first hunter-gatherers created, built, and modified tools to the demands of a specific task. In much the same fashion, the relentless development and use of surgical tools and technologies has defined both our craft and our care since the first bone needles were used in prehistoric times.

This chapter attempts to highlight those advanced and emerging surgical technologies that shape the present and direct future changes. A framework to facilitate both thought and action about those innovations to come is presented. Finally, the surgeon's role in the ethical process of innovation is discussed. The authors remain acutely attuned to Yogi Berra's admonition, "Predictions are difficult, especially about the future."

As advances in surgical technologies have occurred, our field has moved forward, often in quantum leaps. A thoughtful look around our operating rooms, interventional suites, critical care units, and even teaching facilities is cause to reflect on our use of and even dependence on tools and technologies. Clamps, catheters, retractors, energy sources, and monitors fill these spaces; they facilitate and enhance surgeons' capabilities in the process of diagnosis, imaging, physiologic care, molecular triage, and in the performance of surgical procedures. Surgeons constantly function as users of technology; thus a fundamental understanding underpins their thoughtful use. The use of a drug without understanding the mechanism and side effects would be regarded as malpractice. A similar case must be made for surgical tools and technologies.

New technologies result from an endless cycle through which innovation occurs. Such a cycle may begin with a fundamental research discovery or begin at the bedside with an unsolved patient problem. Frequently, innovation requires a complex interplay of both. Surgeons are uniquely positioned and privileged to contribute to and even define this cycle. The face of a patient with the unsolvable problem is a constant reminder of our responsibility to advance our field. Theodore Kocher's success in thyroid surgery was enabled by his toothed modification of existing clamps to facilitate thyroid operations. Tom Fogarty's development of the balloon catheter began as a surgical assistant witnessing both the failures and disastrous consequences of extensive arteriotomies for extraction of emboli. His simple, brilliant concept has arguably created the entire field of catheter-based manipulation. John Gibbon's successful construction of a heart-lung machine was initially motivated by the patient with the unsolved problem of pulmonary emboli and the need for surgical extraction. Although his original intention has been eclipsed by Lazar Greenfield's suction embolectomy catheter and vena-caval filter, and dwarfed by the utility of the heart-lung machine in cardiac surgery, the story remains the same. Unresolved problems and a surgeon determined to find a solution have led to countless innovations that have changed our field forever. The surgeon's role must extend outside the operating room. Surgeons must remain aware and connected to the tools and techniques of diagnosis, monitoring, and education. Mark M. Ravitch, an extraordinary pediatric surgeon, innovator, and one of the most literate surgeons of the twentieth century, described surgery as an intellectual discipline characterized not only by operative procedures but also by the attitude or responsibility toward care of the sick. Dr. Ravitch's contribution to the development of stapling devices deserves enormous credit.[1]

A surgical operation can be defined as "an act performed with instruments or by the hands of a surgeon." This implies an image and a manipulation; the manipulation implies an energy source. Historically, we have regarded the "image" to be that of a direct visual image and "manipulation" performed with the direct contact of two hands or surgical tools.

**TABLE 4-1**
**Surgical Operation: Image and Manipulation**

| *Image* | *Manipulation* |
|---|---|
| Direct visual | Two hands direct |
| Video image | Two hands, long tools robots |
| Ultrasonography (US) | Cold, thermal |
| Computed tomography | Radiofrequency |
| Magnetic resonance imaging | Photodynamic energy |
| | Focused US energy |

The laparoscopic revolution has taught us that the image can be a video image and the manipulation performed by two hands using long tools. Now those long tools are occasionally attached to surgical robots. Our notion about the image has come to include ultrasonography/ultrasound (US), computed tomography (CT), or magnetic resonance imaging (MRI), and the manipulation can include such energy sources as cold, heat, radiofrequency, photodynamic, or chemical energy. Extracorporeal shock wave lithotripsy is an important example of this principle, when applied to renal calculi. How will the "image" and "manipulation" exist in the future (Table 4-1)?

## Current and Future Diagnostic Technologies

Accurate evaluation of surgical disease has always been a vital aspect of surgical practice, always preceding operation. Whether in the clinic, the emergency room, or a hospital bed, precise assessment to correctly guide operative or nonoperative therapy defines surgical judgment and care. A thorough history and detailed physical examination will forever remain the foundation of assessment; however, the thoughtful addition of adjunctive imaging studies has added considerably to the evaluation of surgical patients. Driven by advancements in medicine, engineering, and biology, these studies use increasingly sophisticated technologies. These technologies promise to arm surgeons with more detailed anatomic, functional, and even molecular information in the coming years.

During the last 3 decades, the introduction and improvement of US, CT, and MRI techniques have revolutionized the clinical evaluation of surgical disease. The fine anatomic data that these imaging modalities provide has facilitated the accurate diagnosis of a wide variety of conditions. Functional imaging techniques, such as positron emission tomography (PET) and functional MRI, have been developed to provide accurate and often real-time biologic or physiologic information. In the field of pediatric surgery, these imaging modalities may be used in the diagnosis and characterization of disease, for preoperative surgical planning, and for postoperative follow-up and evaluation. This section will provide an overview of the imaging modalities used in pediatric surgery, focusing on emerging techniques and systems.

### ULTRASONOGRAPHY

Ultrasound imaging has become a truly invaluable tool in the evaluation of the pediatric surgical patient. Providing anatomic as well as real-time functional information, US imaging has several unique advantages that have made it particularly useful in the care of children. These include their relatively low cost, their portability and flexibility (seamless movement from the operating room, intensive care unit, or emergency room), and their safety in children and fetuses because they do not rely on ionizing radiation. For these reasons, this section will pay particular attention to US imaging, highlighting emerging advances in its technology and practice including three-dimensional (3D) US imaging, US contrast imaging, and US harmonic imaging.

Ultrasonography uses the emission and reflection of sound waves to construct images of body structures. In essence, medical US operates on the same principle as active sound navigation and ranging (SONAR): a sound beam is projected by the US probe into the body, and based on the time to "hear" the echo, the distance to a target structure can be calculated.[2] In the body, the sound waves are primarily reflected at tissue interfaces, with the strength of the returning echoes mainly correlating with the properties of the tissues being examined. The advantages of US imaging include lack of ionizing radiation, real-time imaging with motion, and relatively fast procedure times.[3]

In modern US imagers, numerous transducer elements are placed side by side in the transducer probe. The majority of US imaging devices currently use linear or sector scan transducers. These consist of 64 to 256 piezoelectric elements arranged in a single row. With this arrangement, the transducer can interrogate a single slice of tissue whose thickness is correlated to the thickness of the transducer elements.[2] This information is then used to construct real-time, dynamic, two-dimensional images. Color, power, and pulsed wave Doppler imaging are variations of this technology that allow color or graphical visualization of motion.[3] Specifically, conventional Doppler imaging provides information of flow velocity and direction of flow by tracking scattering objects in a region of interest.[4] In contrast, power Doppler displays the power of the Doppler signal and has proven to be a more sensitive method in terms of signal-to-noise ratio and low flow detectability.[5]

In pediatric surgery, US imaging is widely used in the evaluation of multiple pathologies, including appendicitis, testicular torsion, intussusception, and hypertrophic pyloric stenosis.[6,7] In addition, US is a powerful and relatively safe tool for the prenatal diagnosis of congenital diseases. Prenatal US evaluation is useful in facilitating the prenatal diagnosis of abdominal wall defects, congenital diaphragmatic hernias, sacrococcygeal teratomas, cystic adenomatoid malformation, pulmonary sequestration, neural tube defects, obstructive uropathy, facial clefting, and twin-twin syndromes.[8] Furthermore, sonographic guidance is vital to accomplishing more invasive prenatal diagnostic techniques such as amniocentesis and fetal blood sampling.[8]

#### Three-Dimensional Ultrasonography

Although two-dimensional (2D) US systems have improved dramatically over the last 30 years, the two-dimensional images produced by these systems continue to require a relatively large amount of experience to effectively interpret. This stems from the fact that the images represent one cross section, or slice, of the target anatomy, requiring users to reconstruct the three-dimensional picture in their mind. Given these limitations, 3D US systems, which provide volumetric

instead of cross-sectional images, have recently been developed and have seen increased use for many applications.

The first reported clinical use of a 3D US system occurred in 1986 when Kazunori Baba at the Institute of Medical Electronics, University of Tokyo, Japan, succeeded in obtaining 3D fetal images by processing 2D images on a mini-computer.[9] Since then, multiple 3D US systems have been developed with the purpose of providing more detailed and user-friendly anatomic information. These multislice, or volumetric, images are generally acquired by one of the following techniques:

1. Use of a two-dimensional array where a transducer with multiple element rows is used to capture multiple slices at once and render a volume from real 3D data.
2. Use of a one-dimensional phased array to acquire several 2D slices over time. The resultant images are then fused by the US computer's reconstruction algorithm.

The three-dimensional information acquired by these techniques is then used to reconstruct and display a 3D image by either maximum signal intensity processing, volume rendering, or surface rendering. Currently, 3D US systems are available from several manufacturers, including General Electric, Phillips, and Siemens. When these three-dimensional images are displayed in a real-time fashion; they have the ability to provide functional information on the physiology of a patient. An example of this is the evaluation of cardiac function using real-time US. Real-time, 3D US is sometimes referred to as 4D US, though it is still essentially providing a three-dimensional image. Figure 4-1 represents a 3D US view of a fetus in utero.

In the field of pediatric surgery, 3D US systems have not yet seen routine clinical application. However, their utility in perinatal medicine has been increasingly investigated. Specifically, 3D US systems have been used for detailed prenatal evaluation of congenital anomalies. In a study published in 2000, Dyson and colleagues[10] prospectively scanned 63 patients with 103 anomalies with both 2D and 3D US techniques. Each anomaly was reviewed to determine whether 3D US data were either advantageous, equivalent, or disadvantageous compared with 2D US images. They found that the 3D US images provided additional information in 51% of the anomalies, provided equivalent information in 45% of the anomalies, and were disadvantageous in 4% of the anomalies. Specifically, they found that 3D US techniques were most helpful in evaluating fetuses with facial anomalies, hand and foot abnormalities, and axial spine and neural tube defects. 3D ultrasonography offered diagnostic advantages in about one half of the selected cases studied and affected patient management in 5% of cases. They concluded that 3D US was therefore a powerful adjunctive tool to 2D US in the prenatal evaluation of congenital anomalies.[10]

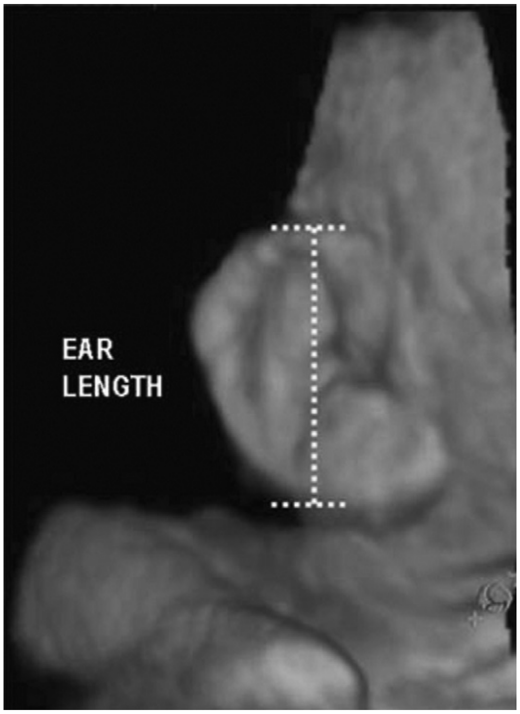

**FIGURE 4-1** Three-dimensional ultrasound image of a fetal ear. (From Kurjak A, Miskovic B, Andonotopo W, et al: How useful is 3D and 4D US in perinatal medicine? J Perinat Med, 2007;35:10-27.)

Similarly, Chang and colleagues reported several series where 3D US techniques were used to effectively evaluate fetal organ volumes, estimating fetal lung volume for the evaluation of pulmonary hypoplasia,[11] cerebellar volume,[13,14] heart volume,[15] adrenal gland volume,[16] and liver volume.[17] In all of these studies, 3D US images provided more accurate data than 2D images.[11]

In 2007, Kurjak and colleagues reviewed, in *Perinatology*, the published experience with 3D and 4D US.[18] Their analysis highlighted reports detailing the use of 3D US to more accurately evaluate fetal craniofacial anomalies. In one study, 4D US was used to measure external ear length, a parameter that is classically difficult to accurately determine using 2D US. Short external ear length is one of the most consistent anthropomorphic characteristics found in neonates with Down syndrome (see Fig. 4-1). In another report, 3D US evaluation of the fetal central nervous system was found to improve the diagnosis of malformations with a sensitivity of up to 80%. More relevant to pediatric surgery, 3D US systems combined with the use of high-frequency transvaginal US probes enhanced the detection rate of cystic hygromas, with earlier and more frequent detection of these lesions. The use of 3D US to evaluate the fetal heart has also shown promise. A recently introduced US technique, tomographic US imaging (TUI), allows the examiner to review multiple parallel images of the beating heart. Using the known advantages of multislice imaging commonly used in computed tomography and magnetic resonance imaging, TUI can provide a more precise determination of the relationships between adjacent cardiac structures.

In addition to prenatal evaluation, 3D US systems have been used to image the ventricular system in neonates and infants to aid in the preoperative planning of neuroendoscopic interventions.[19,20] Similarly, these systems have seen relatively extensive use in the area of transthoracic echocardiographic imaging for the evaluation of congenital cardiac anomalies.[21,22] From an experimental standpoint, Cannon and colleagues studied the ability of 3D US to guide basic surgical tasks in a simulated endoscopic environment.[23] They found that 3D US imaging guided these tasks more efficiently and more accurately than 2D US imaging.[23] Overall, 3D US systems appear to allow the visualization of complex structures in a more intuitive manner compared with 2D systems. In addition, they appear to enable more precise measurements of volume and the relative orientation of structures.[24] As technology improves, the use of such systems in the field of pediatric surgery is likely to increase.

### Ultrasound Contrast Imaging and Ultrasound Harmonic Imaging

In addition to 3D US, significant advances have recently been made with respect to US contrast imaging and harmonic imaging, which may serve to improve the quality of information obtained by US techniques and may expand the clinical use of US as an imaging modality.

Ultrasound contrast imaging techniques are currently used for the visualization of intracardiac blood flow to evaluate structural anomalies of the heart.[25] In general, US contrast agents are classified as free gas bubbles or encapsulated gas bubbles. Simply stated, these gas bubbles exhibit a unique resonance phenomenon when isonified by an US wave, resulting in a frequency-dependent volume pulsation that makes the resonating bubble behave as a source of sound, not just a reflector of it.[4] Currently, new methods are being developed to enhance the contrast effect, including harmonic imaging, harmonic power Doppler imaging, pulse inversion imaging, release-burst imaging, and subharmonic imaging.[4] As these methods improve, US contrast imaging may serve to provide clinicians with more detailed perfusion imaging of the heart as well as tumors and other anatomic structures. Figure 4-2 depicts an US image of the left ventricle using microbubble contrast.

Interest in US harmonic imaging occurred in 1996 after Burns observed harmonics generated by US contrast agents.[26] Since then, significant developments have occurred in the use of the harmonic properties of sound waves to improve the quality of US images. In brief, sound waves are the sum of different component frequencies, the fundamental frequency (first harmonic) and harmonics, which are integral multiples of the fundamental frequency. The combination of the fundamental frequency and its specific harmonics gives a signal its unique characteristics. When US contrast agents are used, harmonics are generated by reflections from the injected agent and not by reflections from tissue. When no contrast is used, harmonics are generated by the tissue itself.[27]

Although the fundamental frequency consists of echoes produced by tissue interfaces and differences in tissue properties, the harmonics are generated by the tissue itself. In this manner, harmonic intensity increases with depth until natural tissue attenuation overcomes this effect. In contrast, the intensity of the fundamental frequency is attenuated linearly with depth.[27] Tissue harmonic imaging takes advantage of these properties by using the harmonic signals that are generated by tissue and by filtering out the fundamental echo signals that are generated by the transmitted acoustic energy.[28] This theoretically leads to an improved signal-to-noise ratio and contrast-to-noise ratio. Additional benefits of US harmonic imaging include improved spatial resolution, better visualization of deep structures, and a reduction in artifacts produced by US contrast agents.[27] Figure 4-3 compares an image obtained by US harmonic imaging and one obtained by standard 2D US.

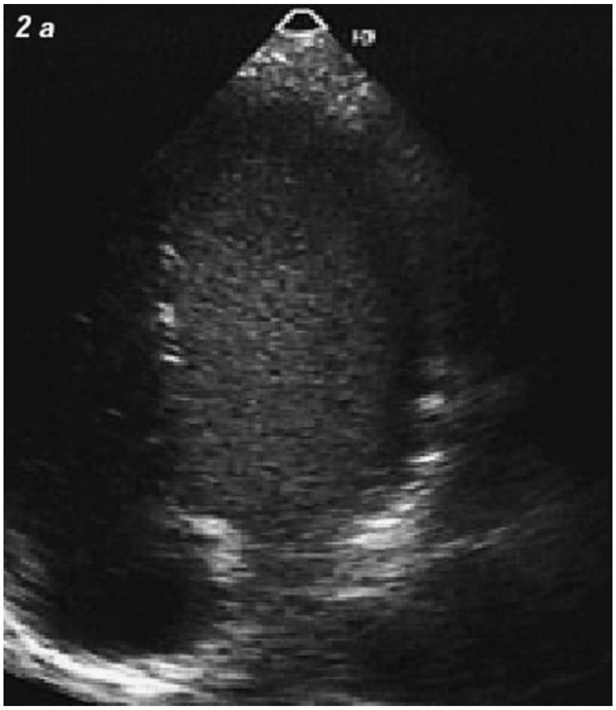

FIGURE 4-2 Ultrasound contrast image of the left ventricle. (From Frinking PJ, Bouakaz A, Kirkhorn J, et al: US contrast imaging: Current and new potential methods. US Med Biol 2000;26:965-975.)

### Ultrasonography and Fetal Surgery

With the advent of fetal surgery in 1980, US evaluation became an increasingly important noninvasive modality for diagnosing and characterizing diseases that are amenable to fetal surgical intervention.[29] Today, fetal surgical techniques are used in selected centers to perform a variety of procedures, including surgical repair of myelomeningocele, resection of sacrococcygeal teratoma in fetuses with nonimmune hydrops, resection of an enlarging congenital cystic adenomatoid malformation that is not amenable to thoracoamniotic shunting, and tracheal balloon occlusion for severe left congenital diaphragmatic hernia.[30,31] In all of these procedures, sonography currently remains the modality of choice for fetal diagnosis and treatment because of its safety and real-time capabilities. Specifically, fetal US can be used to characterize the severity of the congenital anomaly and to determine its appropriateness for intervention. During open hysterotomy, US is used to determine an appropriate location for the uterine incision away from the placenta and to monitor fetal heart rate and contractility. During procedures that do not use open hysterotomy, such as radiofrequency ablation for twin-reversed arterial perfusion sequence, laser ablation for twin-twin transfusion syndrome, and shunt placements for large pleural effusions, and bladder outlet obstruction, fetal US is used to directly guide the intervention. In addition, US imaging is vital to the postoperative care and follow-up of fetal surgical patients, because they remain in utero after their surgical procedure.

## COMPUTED TOMOGRAPHY

Computed tomography was invented in 1972 by British engineer Godfrey Hounsfield of EMI Laboratories, England, and independently by South African–born physicist Allan Cormack of Tufts University, Massachusetts. Since then, the use of CT imaging has become widespread in multiple fields of medicine and surgery. Currently, advances in technology have improved the speed, comfort, and image quality of modern CT scanners. In addition, recent advances, such as multidetector CT computed tomography (MDCT) and volumetric reconstruction, or 3D CT, may be particularly valuable in

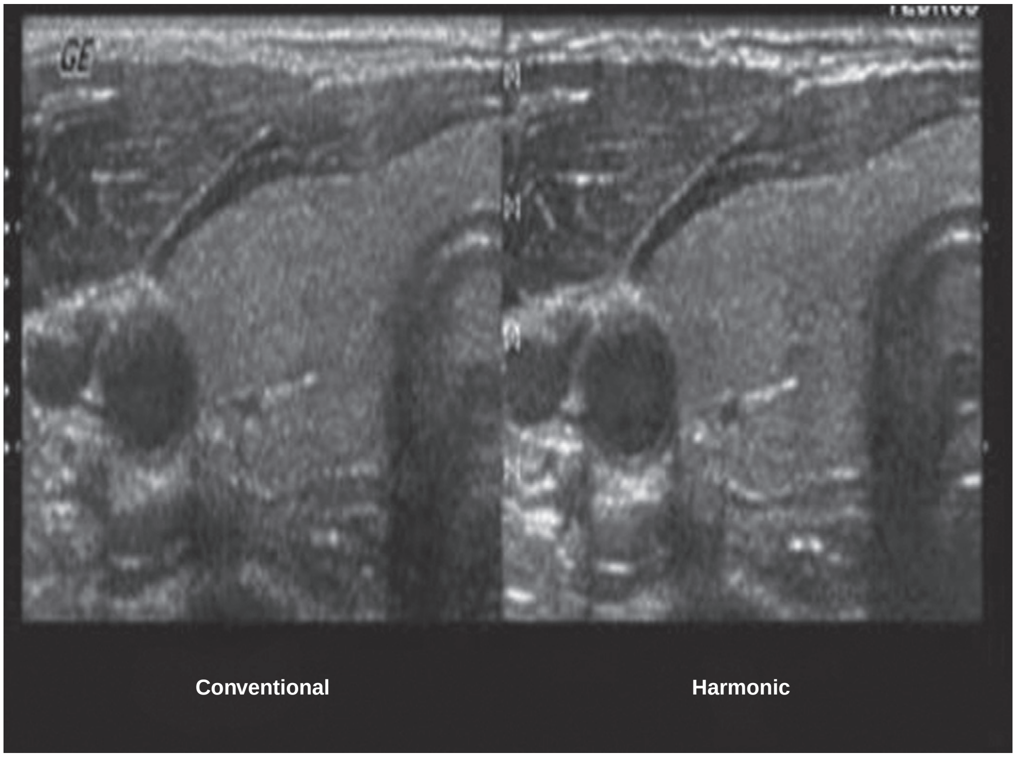

**FIGURE 4-3** Conventional versus ultrasound harmonic imaging. (From Tranquart F, Grener N, Eder V, Pourcelot L, et al: Clinical use of US tissue harmonic imaging. US Med Biol 1999;25:889-894.)

the care of pediatric surgical patients. This section will provide a brief overview of CT imaging, focusing on MDCT and volumetric imaging and their implications in pediatric surgery.

### Multidetector Computed Tomography

Computed tomography uses a tightly arranged strip of radiation emitters and detectors that circles around a patient to obtain a two-dimensional map of x-ray attenuation values. Numerical regression techniques are then used to turn this list of attenuation values into a two-dimensional slice image. CT has undergone several major developments since its introduction.

Introduced in the early 1990s, single-detector helical or spiral CT scanning revolutionized diagnostic CT imaging by using slip rings to allow for continuous image acquisition.[32] Before this development, the table and patient were moved in a stepwise fashion after the acquisition of each image slice, resulting in relatively long scanning times. Helical CT scanners use slip ring technology that allows the tube and detector to continually rotate around the patient. Combined with continuous table motion through the rotating gantry, this significantly improves the speed of CT studies. The improved speed of helical CT scanners enables the acquisition of large volumes of data in a single breath hold.

Helical CT has improved during the past 15 years, with faster gantry rotation, more powerful x-ray tubes, and improved interpolation algorithms.[33] However, the greatest advance has been the recent introduction of multidetector-row CT (MDCT) scanners.[32] In contrast to single-detector–row CT, MDCT uses multiple parallel rows of detectors that spiral around the patient simultaneously. Currently capable of acquiring four channels of helical data at the same time, MDCT scanners are significantly faster than single-detector helical CT scanners. This has profound implications for the clinical application of CT imaging, especially in the pediatric patient where the issues of radiation exposure and patient cooperation are magnified. Fundamental advantages of MDCT compared with earlier modalities include substantially shorter acquisition times, retrospective creation of thinner or thicker sections from the same raw data, and improved 3D rendering with diminished helical artifacts.[33]

In the pediatric population, MDCT provides a number of advantages compared with standard helical CT. Because of the increased speed of MDCT, there may be a decreased need for sedation in some pediatric studies. There is also a reduction in patient movement artifact as well as a potential for more optimal contrast enhancement over a greater portion of the anatomy of interest. The volumetric data acquired also provides for the ability of multiplanar reconstruction, which can be an important problem-solving tool. MDCT has been increasingly used for pediatric trauma, pediatric tumors, evaluation of solid abdominal parenchymal organ masses, suspected abscess, or inflammatory disorders.[34] Specifically, MDCT is increasingly used in the evaluation of children with abdominal pain, particularly in patients with suspected appendicitis.[35] Callahan and colleagues used MDCT in the evaluation of children with appendicitis and reduced the total number of hospital days, negative laparotomy rate, and cost per patient.[36] In addition, MDCT may be useful in identifying alternative diagnoses, including other bowel pathologies, ovarian pathologies, and urinary tract pathologies (Fig. 4-4).[35]

Similarly, MDCT may be valuable in the evaluation of urolithiasis and inflammatory bowel disease (IBD). MDCT has gained acceptance as a primary modality for the evaluation of children with abdominal pain and hematuria in which urolithiasis is suspected.[35] CT findings of urolithiasis include visualization of the radiopaque stone, dilatation of the ureter

**FIGURE 4-4** Multidetector computed tomography of an 8-year-old boy with appendicitis. The *arrows* point to an inflammatory mass in the right lower quadrant with a possible appendicolith *(arrowhead)*. (From Donnelly LF, Frush DP: Pediatric multidetector body CT. Radiol Clin North Am 2003;41:637–655.)

or collecting system, asymmetric enlargement of the kidney, and perinephric stranding.[35] Of note, MDCT evaluation of these patients usually requires a noncontrast study. Another area in which CT is showing increased use is for the evaluation of children with IBD.[35] In these patients, CT may be superior to fluoroscopy for demonstrating inflammatory changes within the bowel as well as extraluminal manifestations of IBD, such as peribowel inflammatory change or abscess.[35]

In the chest, MDCT is used for the evaluation of infection and complication of infections, as well as cancer detection and surveillance. Evaluation of congenital abnormalities of the lung, mediastinum, and heart are also indications. In particular, MDCT may be useful in the assessment of bronchopulmonary foregut malformations in which sequestration is a consideration.[34] Similarly, the use of MDCT in the evaluation of the pediatric cardiovascular system has been particularly valuable.[37] Assessment of cardiovascular conditions, such as aortic aneurysms, dissections, and vascular rings, may be significantly better than with echocardiography. Finally, MDCT is advantageous in the evaluation of patients with pectus malformations, because it allows for lower doses of radiation.[35]

### Three-Dimensional Computed Tomography

The advent of helical CT and MDCT has enabled the postacquisition processing of individual studies for the creation of three-dimensional CT image reconstructions. These 3D reconstructions are valuable in the preoperative planning of complex surgical procedures. Although 3D CT imaging has been possible for almost 25 years, the quality, speed, and affordability of these techniques have only recently improved enough to result in their incorporation into routine clinical practice.[38] Currently, four main visualization techniques are used in CT reconstruction labs to create 3D CT images. These include multiplanar reformation, maximum intensity projections, shaded surface displays, and volume rendering. Multiplanar reformation and maximum intensity projections are limited to external visualization, while shaded surface displays and volume rendering allow immersive or internal visualization, such as virtual endoscopy.[33]

**FIGURE 4-5** 3D computed tomography reconstruction of an infant skull showing premature closure of the right coronal suture. (From Rubin GD: 3-D imaging with MDCT. Eur J Radiol 2003;45(Suppl 1):S37–S41.)

Three-dimensional CT has been beneficial in the preoperative planning of pediatric craniofacial, vascular, and spinal operations. Specifically, 3D CT has been used to evaluate maxillofacial fractures[39] and craniofacial abnormalities, as well as vascular malformations. Figure 4-5 illustrates a 3D CT reconstruction of an infant with craniosynostosis. Similarly, 3D CT has been reported useful in the planning of hemivertebra excision procedures for thoracic and thoracolumbar congenital deformities.[40] A particularly interesting application of 3D CT is the creation of "virtual endoscopy" images for the interior surface of luminal structures, such as the bowel, airways, blood vessels, and urinary tract.[33] In particular, virtual endoscopy using 3D CT may be useful in the diagnosis of small bowel tumors, lesions that are often difficult to detect using standard modalities (Fig. 4-6).[38]

### Electron Beam Computed Tomography

Introduced clinically in the 1980s, electron beam computed tomography (EBCT) scanners are primarily used in adult cardiology to image the beating heart. As opposed to traditional CT scanners, EBCT systems do not use a rotating assembly consisting of an x-ray source directly opposite an x-ray detector. Instead, EBCT scanners use a large, stationary x-ray tube that partially surrounds the imaging field. The x-ray source is moved by electromagnetically sweeping the electron beam focal point along an array of tungsten anodes positioned around the patient. The anodes that are hit emit x-rays that are collimated in a similar fashion to standard CT scanners. Because this is not mechanically driven, the movement can be very fast. In fact, EBCT scanners can acquire images up to 10 times faster than helical CT scanners. Current EBCT systems are capable of performing an image sweep in 0.025 seconds compared with the 0.33

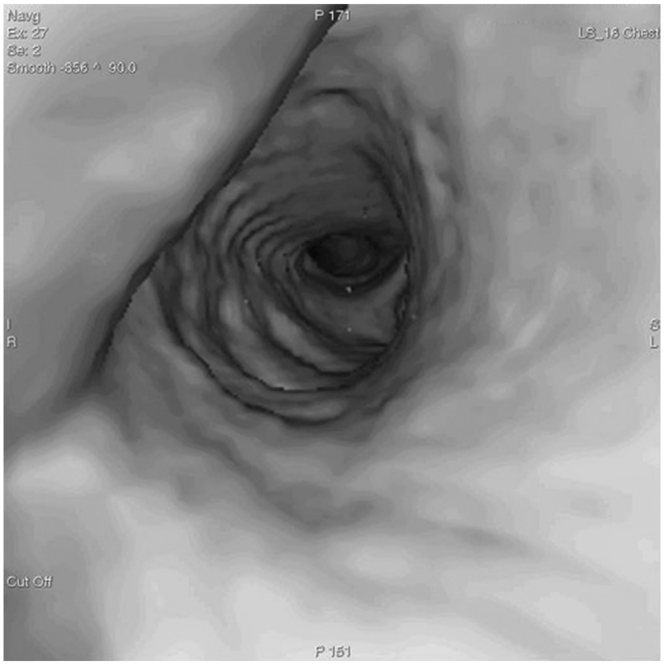

**FIGURE 4-6** Virtual colonoscopy.

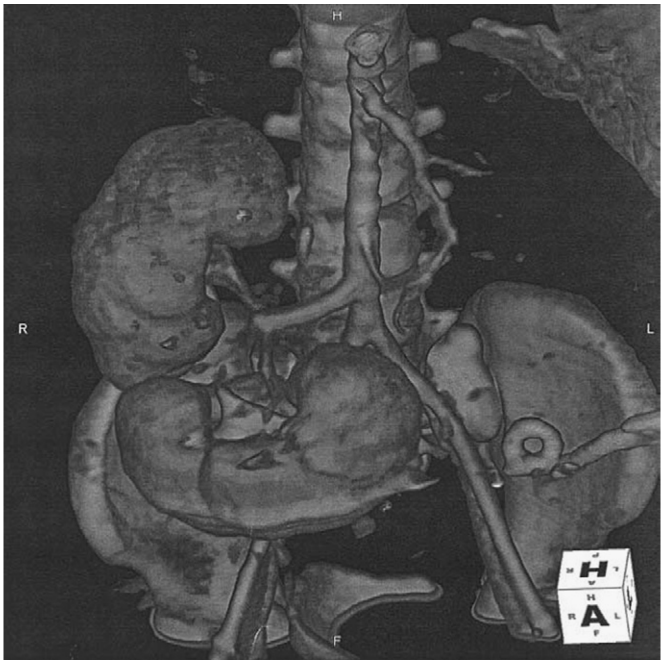

**FIGURE 4-7** Electron beam computed tomography of transplanted kidney. (From Talisetti A, Jelnin V, Ruiz C, et al: Electron beam CT scan is a valuable and safe imaging tool for the pediatric surgical patient. J Pediatr Surg 2004;39:1859–1862.)

seconds for the fastest mechanically swept CT systems. This rapid acquisition speed minimizes motion artifacts, enabling the use of EBCT scanners for imaging the beating heart. In addition to faster image acquisition times resulting in decreased motion artifacts, EBCT scanners generally result in a 6- to 10-fold decrease in radiation exposure compared with traditional CT scanners.

To date, EBCT scanners have not yet seen widespread adoption. The systems are necessarily larger and more expensive than helical CT scanners. Advances in multidetector helical CT scan designs have enabled cardiac imaging using standard, mechanically driven systems.

The use of EBCT in the pediatric population has primarily been reported for the imaging of cardiac anomalies.[41,42] However, as we increasingly understand the risks associated with ionizing radiation exposure in children, the decreased exposure associated with EBCT systems appears attractive. In addition, the faster acquisition times and minimization of motion artifact could theoretically result in decreased sedation requirements in young patients. Talisetti and colleagues reported the use of EBCT to evaluate several pediatric surgical patients—one patient with thoracic dystrophy and an abdominal wall hernia, one patient with ascites status postrenal transplant (Fig. 4-7), and several patients with renal and pelvic tumors.[43] In their report, they highlighted the potential advantages of decreased radiation exposure and sedation requirements associated with EBCT systems.

## MAGNETIC RESONANCE IMAGING

The first MRI examination on a human was performed in 1977 by Dr. Raymond Damadian, with colleagues Dr. Larry Minkoff and Dr. Michael Goldsmith. This initial exam took 5 hours to produce one, relatively poor quality image. Since then, technological improvements have increased the resolution and speed of MRI. Today, MRI is able to provide unparalleled noninvasive images of the human body. In addition, newer MRI systems now allow images to be obtained at subsecond intervals, facilitating fast, near real-time MRI. Similarly, new MRI techniques are now being developed to provide functional information on the physiologic state of the body. This section will provide a brief overview of MRI, focusing on recent technologic advances, such as *ultrafast MRI, higher field strength MRI systems, motion artifact reduction techniques,* and *functional MRI.*

MRI creates images by using a strong, uniform magnetic field to align the spinning hydrogen protons of the human body. A radiofrequency (RF) pulse is then applied, causing some of the protons to absorb the energy and spin in a different direction. When the RF pulse is turned off, these protons realign and release their stored energy. This release of energy gives off a signal that is detected, quantified, and sent to a computer. Because different tissues respond to the magnetic field and RF pulse in a different manner, they give off variable energy signals. These signals are then used to create an image using mathematical algorithms.

### Higher Field Strength MRI Systems

Over the last decade, MRI has advanced significantly with the transition from 1.5 Tesla (T) to 3.0 T field strength systems (Fig. 4-8). Using higher magnetic field strength, 3.0 T systems demonstrate improved image resolution, faster image acquisition speeds, and improved fat suppression.[44] In addition, 3.0 T systems theoretically enable a twofold increase in signal-to-noise ratio (SNR) compared with 1.5 T systems as SNR increases linearly with field strength. This is particularly important for imaging smaller patients with anatomical structures. Although 3.0 T systems are rapidly becoming the standard in pediatric MRI imaging, ultrahigh field strength 7.0 T systems are currently being evaluated. These systems

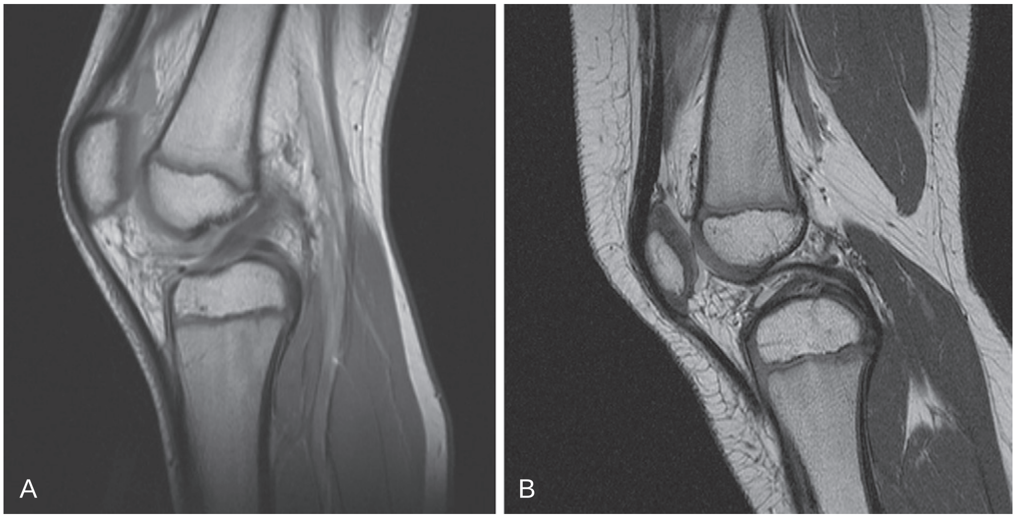

**FIGURE 4-8** Comparison of image quality between 1.5 T (**A**) and 3.0 T (**B**). (From MacKenzie JD, Vasanawala SS: Advances in pediatric MR imaging. Magn Reson Imaging Clin N Am 2008;16:385–402.)

potentially provide the same advantages listed above but to a higher degree. Disadvantages include higher deposition of radiofrequency energy, magnification of artifacts, and more challenging hardware and software design. Although still under investigation, ultrahigh field strength MRI may enable unique studies such as sodium imaging, which can be used to monitor renal physiology and function, myocardial viability, and phosphorous imaging, which has been suggested as a method of evaluating organ pH and cancer metabolism.[44]

## Ultrafast MRI

The first major development in high speed MRI occurred in 1986 with the introduction of the gradient-echo pulse sequence technique (GRE). This technique decreased practical scan times to as little as 10 seconds. In addition to increasing the patient throughput of MRI scanners, the faster scan times significantly increased the application of MR imaging in body regions (e.g., the abdomen) where suspended respiration could eliminate most motion-related image distortions.[45,46] Since then, GRE techniques have undergone iterations and further developments, such as balanced steady-state imaging, achieving subsecond level scan times.

More recently, parallel imaging (or parallel MRI) has emerged as a method of increasing MRI imaging speed. Parallel imaging techniques are able to construct images using reduced data sets by combining the signals of several coil elements in a phased array. In this manner, higher imaging speeds are achievable, generally allowing speed increases of two- to threefold.[44] In addition, MRI parallel imaging results in improved signal-to-noise ratio, thereby decreasing artifact and improving image quality.

The high speed of ultrafast MRI represents a significant advantage in the care of children. Most traditional MR protocols require 30 to 40 minutes of table occupancy. During this time the patient must remain still to avoid motion artifact.[47] For many children, this often requires sedation, general anesthesia, and even muscular blockade to enable them to remain motionless long enough for a quality study to be completed. This is obviously a significant impediment toward the widespread use of MRI in children. Ultrafast MRI significantly reduces this requirement, not only minimizing the potential side effects of sedation during routine MRI studies but also allowing the use of MRI to study high-risk infants who cannot be adequately sedated or paralyzed.[48]

Ultrafast MRI also significantly reduces the motion artifacts that occur in the abdomen and thorax resulting from normal respiratory and peristaltic movements. In particular, the smearing artifact associated with the use of oral contrast agents during MR imaging of the intestinal tract had previously decreased image quality.[49] Using GRE and parallel imaging techniques, modern MRI can achieve scan times that are fast enough to be completed during a breath hold and are fast relative to normal abdominal motion.[44] In addition, by decreasing motion artifact and enabling fast image acquisition, ultrafast MRI protocols enable the practical application of cardiac MRI and fetal MRI.[50] Similarly, volumetric or 3D MRI has become practically feasible in children with ultrafast MRI techniques that decrease the acquisition time required for these data intensive studies.[44]

### Motion Artifact Reduction Techniques

Motion artifacts may be secondary to physiologic movement (cardiac, respiratory, and peristaltic) as well as voluntary movement. This is particularly significant in pediatric patients. Recently, several techniques have been used to minimize motion artifacts. One broad method employs high-speed image acquisition as detailed above. Another method is navigation imaging where extra navigator echoes are used to detect image displacements. These displacements are used to reject or correct data reducing artifacts.[44] Currently, navigation imaging has been applied to cardiac imaging and hepatobiliary imaging to reduce motion artifacts caused by respiratory movement. Similarly, PROPELLER (periodically rotated overlapping parallel lines with enhanced reconstruction) imaging is a method for reducing motion artifacts by signal averaging successive rotating samples of data.

### Functional Magnetic Resonance Imaging

Functional magnetic resonance imaging (fMRI) is a rapidly evolving imaging technique that uses blood flow differences in the brain to provide in vivo images of neuronal activity. First described just more than 15 years ago, fMRI has seen widespread clinical and research application in the adult

population. Functional MRI is founded on two basic physiologic assumptions regarding neuronal activity and metabolism. Specifically, fMRI assumes that neuronal activation induces an increase in local glucose metabolism, and that this increased metabolic demand is answered by an increase in local cerebral blood flow.[51] By detecting small changes in local blood flow, fMRI techniques are able to provide a "functional" image of brain activity. Currently, the most commonly used technique is known as "blood oxygen level–dependent" (BOLD) contrast, which uses blood as an internal contrast medium.[52] BOLD imaging takes advantage of small differences in the magnetic properties of oxygenated and deoxygenated hemoglobin. Since neuronal activation is followed by increased and relatively excessive local cerebral blood flow, more oxygenated hemoglobin appears in the venous capillaries of activated regions of the brain. These differences are detected as minute distortions in the magnetic field by fMRI and can be used to create a functional image of brain activity.[51]

Functional magnetic resonance imaging requires significant subject preparation in order to prepare the child to lie still in the scanner for the duration of the study. Various preparation techniques have been described that decrease the anxiety and uncertainty that a child might experience regarding the study. These include presession educational videos, presession tours with members of the radiology staff, and presession practice runs. Optimally, fMRI studies require a nonsedated, cooperative patient to assess functional neuronal activity. However, it has been recently shown that passive range of motion may activate the sensorimotor complex in sedated patients. This may enable functional motor mapping in patients who are unable to cooperate with active tasks.[53]

At this time, the use of fMRI in the pediatric population is still at the earliest stages. However, fMRI holds tremendous promise in the evaluation of central nervous system (CNS) organization and development, characterization of brain plasticity, and the evaluation and understanding of neurobehavioral disorders.[51] In addition, current clinical applications of fMRI include the delineation of eloquent cortex near a space-occupying lesion and the determination of the dominant hemisphere for language. fMRI is also used to map the motor cortex. These clinical applications are designed to provide preoperative functional information for patients undergoing epilepsy or tumor surgery.[53] This information can be used to guide resection and to predict postoperative deficits.[53]

### Fetal Magnetic Resonance Imaging

Magnetic resonance imaging has become an increasingly used imaging modality for the evaluation of fetal abnormalities. Rapid image acquisition times and motion artifact reduction techniques allow for effective imaging studies despite fetal movement. Although US remains the primary modality for imaging the unborn fetus, fetal MRI has demonstrated several distinct advantages. In addition to providing fine anatomic detail, fetal MRI is not limited by maternal obesity, fetal position, or oligohydramnios—all factors that can limit the effectiveness of US evaluation.[54] The use of fetal MRI to characterize fetal CNS, thoracic, abdominal, genitourinary, and extremity anomalies has been well described. Particularly relevant to the field of pediatric surgery, fetal MRI has been used to assist in the prenatal differentiation between enteric cysts and meconium pseudocysts. Similarly, fetal MRI is used to characterize the nature and origin of abdominal masses and to evaluate fetal tumors.[54] Such information may be valuable for prenatal counseling and decision making as well as for preoperative planning. As the field of fetal surgery matures, fetal MRI may become increasingly useful in the evaluation of abnormalities amenable to fetal intervention.

## POSITRON EMISSION TOMOGRAPHY IMAGING

Positron emission tomography, or PET, is an increasingly used imaging technology that provides information on the functional status of the human body. First developed in 1973 by Edward Hoffman, Michael Ter-Pogossian, and Michael Phelps at Washington University, PET imaging is now one of the most commonly performed nuclear medicine studies in the United States.[55] Although CT, MRI, and US imaging techniques provide detailed information regarding the anatomic state of a patient, PET imaging provides information on the current metabolic state of the patient's tissues. In this manner, PET imaging is often able to detect metabolic changes indicative of a pathologic state before anatomic changes can be visualized.

PET imaging is based on the detection of photons released when positron emitting radionuclides undergo annihilation with electrons.[56] These radionuclides are created by bombarding target material with protons that have been accelerated in a cyclotron.[56] These positron-emitting radionuclides are then used to synthesize radiopharmaceuticals that are part of biochemical pathways in the human body.[56] The most commonly used example of this is the use of the fluorinated analog of glucose, 2-deoxy-2-(18)F-fluoro-D-deoxyglucose (FDG).[57] Like glucose, FDG is phosphorylated by the intracellular enzyme hexokinase. In its phosphorylated form, FDG does not cross cell membranes and therefore accumulates within metabolically active cells. In this manner, PET imaging using FDG provides information about the glucose use in different body tissues.[57]

In order to be detected, FDG is synthesized using $^{18}F$, a radioisotope with a half-life of 110 minutes.[57] The synthesis process begins by accelerating negatively charged hydrogen ions in a cyclotron until they gain approximately 8 MeV of energy. The orbital electrons from these hydrogen ions are then removed by passing through a carbon foil. The resultant high-energy protons are then directed toward a target chamber that contains stable $^{18}O$ enriched water.[56] The protons undergo a nuclear reaction with the $^{18}O$ enriched water to form hydrogen $^{18}F$ fluoride. The reaction is detailed in the equation that follows.[56]

$$H_2(^{18}O) + {}^1H + \text{ energy} \rightarrow H_2(^{18}F)$$

$^{18}F$ is an unstable radioisotope that decays by beta-plus emission or electron capture and emits a neutrino ($\nu$) and a positron ($\beta^+$).[56] The emitted positrons are then annihilated with electrons to release energy in the form of photons, which are detected by modern PET scanners and are the basis of PET imaging. The detectors in PET scanners are scintillation crystals coupled to photomultiplier tubes. Currently, most PET scanners use crystals composed of bismuth germinate, cerium-doped lutetium oxyorthosilicate, or cerium-doped gadolinium silicate.[56] Because PET scanning uses unstable radioisotopes, PET probes must be synthesized immediately prior to a PET study. This limits the immediate and widespread

availability of PET imaging, because the studies must therefore be scheduled in advance. FDG is a convenient probe because its half-life of 110 minutes allows it to be transported from a remote cyclotron to a PET scanner in enough time to perform a typical whole-body PET imaging study ($\geq$30 minutes).[57]

In a typical PET study, the radiopharmaceutical agent is systemically administered to the patient by intravenous injection. The patient is then imaged by the PET scanner, which measures the radioactivity (photon emission as above) throughout the body and creates 3D pictures or images of tissue function. Currently, PET imaging is used extensively for the accurate evaluation and monitoring of tumors of the lung, colon, breast, lymph nodes, and skin.[58] PET imaging is used to facilitate tumor diagnosis, localization, and staging; monitoring of antitumor therapy; tumor tissue characterization; radionuclide therapy; and screening for tumor recurrence.[59] Though nonspecific, FDG is often used because malignant cells generally display increased glucose use with up-regulation of hexokinase activity.[56]

PET imaging has also been used to assess the activity of noncancerous tissues to provide information on their viability or metabolic activity. In adults, PET scans are used to determine the viability of cardiac tissue in order to decide whether a patient would benefit from coronary bypass grafting.[60,61] Recently, this application was extended to the pediatric population in order to assess cardiac function after arterial switch operations with suspected myocardial infarction.[62] Similarly, PET scans can be used to visualize viability of brain tissue in order to make prognostic determinations after stroke.[63] Finally, PET imaging is used to identify regions of abnormal activity in brain tissue, helping to localize seizure foci or diagnose functional disorders, such as Parkinson disease and Alzheimer disease.[64,65]

Though PET imaging provides important functional information regarding the metabolic activity of human tissues, it often provides relatively imprecise images compared with traditional anatomic imaging modalities. This is in large part because of the physics of PET as an imaging modality. Specifically, the positrons emitted by radionuclides, such as FDG, generally have enough kinetic energy to travel a small distance before annihilating with an electron.[56] This distance is called the *mean positron range* and varies depending on tissue density. The difference in position between the initial location of the positron and its site of annihilation results in positron range blurring. This limits the spatial resolution of PET imaging, which is typically considered to be approximately 5 mm using current scanners.[56] *Noncollinearity* or variation in the path of emitted photons other than the expected 180 degrees, also contributes to decreased spatial resolution in PET imaging. Because of these limitations, PET imaging is often useful for highlighting areas suspicious for malignancy but may be difficult to use during preoperative planning, because it does not accurately correlate the area of suspicion with detailed anatomic information.[58]

Recently, combined PET/CT scanners have been developed that simultaneously perform PET scans and high resolution CT scans. Introduced 10 years ago, these scanners provide functional information obtained from the PET scan and accurately map it to the fine anatomic detail of the CT scan (Fig. 4-9).[57] Prior to the availability of PET/CT scanners, CT and PET scans of the same patient acquired on different scanners at different times were often aligned using complex, labor-intensive algorithms.[57] However, other than for brain imaging, these algorithms often failed to adequately fuse the studies. In contrast, combined PET/CT scanners rely on hardware fusion and not solely software manipulation and do not suffer these limitations.

In the field of pediatric surgery, PET/CT scanning represents a new imaging modality with tremendous potential in regard to preoperative planning and postoperative follow-up. However, several issues specific to the pediatric population make the implementation of PET imaging challenging, including the need for fasting, intravenous access, bladder catheterization, sedation, and clearance from the urinary tract.[66,67] Currently, the clinical application of combined PET/CT imaging in the pediatric population has not been extensively studied. However, the combination of functional information with fine anatomic data provides obvious advantages with regard to surgical planning and will therefore likely play a large role in surgical practice.

## MOLECULAR IMAGING

Ultrasonography, CT, MRI, and PET imaging represent established technologies that are commonly used in the care of pediatric patients around the world. Although these technologies provide detailed anatomic and even functional information, their clinical application has yet to provide information at the cellular/molecular level. In contrast to these classical imaging modalities, a new field termed "molecular imaging" sets forth to probe the molecular abnormalities that are the basis of disease rather than to image the end effects of these alterations.[68] Molecular imaging is a rapidly growing research discipline that combines the modern tools of molecular and cell biology with noninvasive imaging technologies. The goal of this new field is to develop techniques and assays for imaging physiologic events and pathways in living organisms at the cellular/molecular level, particularly those pathways that are key targets in specific disease processes. The development and application of molecular imaging will someday directly affect patient care by elucidating the molecular processes underlying disease and lead to the early detection of molecular changes that represent "predisease" states.[69]

Molecular imaging can be defined as "the in vivo characterization and measurement of biologic processes at the cellular and molecular level."[68] From a simplistic standpoint, molecular imaging consists of two basic elements:

1. Molecular probes whose concentration, activity and/or luminescent properties are changed by the specific biologic process under investigation[69]
2. A means by which to monitor these probes[69]

Currently, most molecular probes are either radioisotopes that emit detectable radioactive signals or light- or near-infrared (NIR)–emitting molecules.[69] These probes are considered either direct binding probes or indirect binding probes.[70] Radiolabeled antibodies designed to facilitate the imaging of cell-specific surface antigens or epitopes are commonly used examples of direct binding probes.[70] Similarly, radiolabeled oligonucleotide antisense probes developed to specifically hybridize with target messenger RNA (mRNA) or proteins for the purpose of direct, in vivo imaging are more recent examples.[70] Radiolabeled oligonucleotides represent complimentary sequences to a small segment of target mRNA or DNA, allowing for the direct imaging of endogenous gene

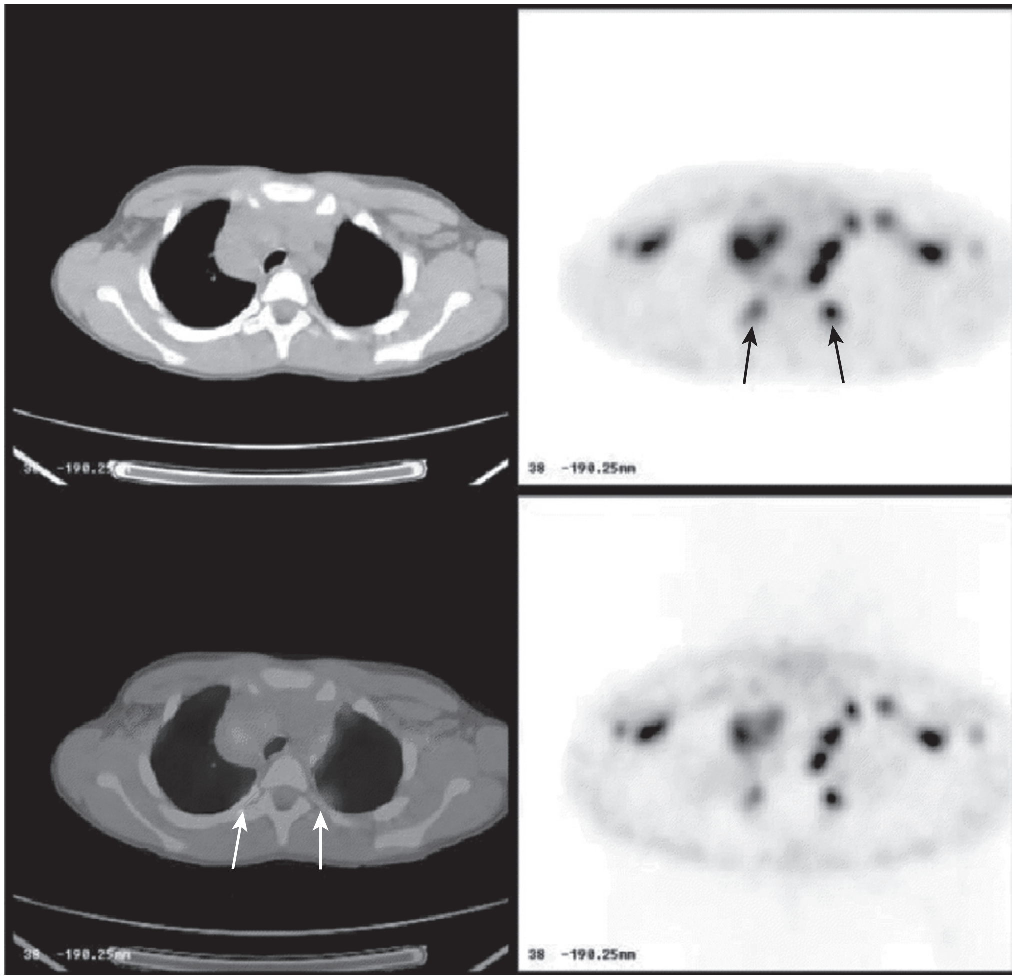

**FIGURE 4-9** Combined positron emission tomography (PET)-CT images (axial) through the upper chest of a 7-year-old girl with a mediastinal mass found to be a necrotizing granuloma. Multiple sites of 2-deoxy-2-(18)F-fluoro-D-deoxyglucose (FDG)–avid axillary lymph nodes and multiple foci within the mediastinal mass are visualized. Arrows highlight the symmetric avidity of the costovertebral junctions for FDG that can be seen in children. (From Kaste SC: Issues specific to implementing PET-CT for pediatric oncology: What we have learned along the way? Pediatr Radiol 2004;34:205-213.)

expression at the transcriptional level.[70] Finally, positron-emitting analogs of dopamine, used to image the dopamine receptors of the brain, are other examples of direct binding probes.[69]

Although direct binding probes assist in the imaging of the amount or concentration of their targets, indirect probes reflect the activities of their macromolecular targets. Perhaps the most widely used example of an indirect binding probe is the hexokinase substrate FDG. The most common probe used in clinical PET imaging, FDG is used for neurologic, cardiovascular, and oncology investigations.[69] Systemically administered FDG is accessible to essentially all tissues.[69]

The use of reporter transgene technology is another powerful example of molecular imaging with indirect binding probes. Reporter genes are nucleic acid sequences encoding easily assayed proteins. Such reporter genes have been long used in molecular biology and genetics studies to investigate intracellular properties and events, such as promoter function/strength, protein trafficking, and gene delivery. Using molecular imaging techniques, reporter genes have now been used to analyze gene delivery, immune cell therapies, and the in vivo efficacy of inhibitory mRNAs in animal models.[71] In vivo bioluminescent imaging using the firefly or *Rinella* luciferase or fluorescent optical imaging using green fluorescent protein (GFP) or DsRed are optical imaging examples of this technique (Fig. 4-10).[72,73] Recently, semiconductor quantum dots have been used in fluorescent optical imaging studies. Although fluorescent proteins are limited in their number of available colors, quantum dots can fluoresce at different colors over a broad region of the spectrum by altering their size and surface coating. To date, the quantum dots that have been tested with in vivo experimental models include amphiphilicpoly (acrylic acid), short-chain (750 D) methoxy-PEG and long-chain (3400 D) carboxy-PEG quantum dots, and long-chain (5000 D) methoxy-PEG quantum dots.[74]

In the field of immunology and immunotherapy research, Costa and colleagues transduced the autoantigen-reactive CD4+ T-cell population specific for myelin basic protein (MBP) with a retrovirus that encoded a dual reporter protein composed of GFP and luciferase, along with a 40 kD monomer of interleukin-12 as a therapeutic protein.[75] Bioluminescent imaging (BLI) techniques were then used to monitor the migratory patterns of the cells in an animal model of multiple sclerosis. BLI demonstrated that the immune cells that would typically cause destruction of myelin trafficked to the central nervous system in symptomatic animals. Furthermore, they

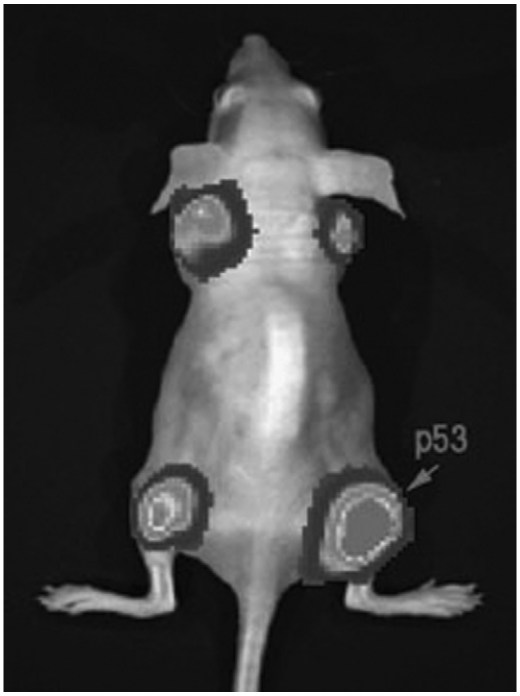

FIGURE 4-10 Nude mouse carrying a wild-type *TP53*-expressing human colon xenograft with a stably integrated *TP53*-responsive luciferase reporter gene. Injection of exogenous *TP53* expressed by an adenovirus vector led to detectable increase in luciferase activity within an established tumor *(arrow)*. (From Wang W, El-Deiry WS. Bioluminescent molecular imaging of endogenous and exogenous p53-mediated transcription in vitro and in vivo using an HCT116 human colon carcinoma xenograft model. Cancer Biol Ther. 2003 Mar-Apr;2(2):196-202.) *(See Expert Consult site for color version.)*

found that CD4 T-cell expression of the IL-12 immune modulator resulted in a clinical reduction in disease severity.[75]

Similarly, Vooijs and colleagues generated transgenic mice in which activation of luciferase expression was coupled to deletion of the retinoblastoma (*Rb*) tumor suppressor gene.[76] Loss of *Rb* triggered the development of pituitary tumors in their animal model, allowing them to monitor tumor onset, progression, and response to therapy in individual animals by repeated CCD (charged coupled device) imaging of luciferase activity.[76] Although optical imaging techniques are commonly used, reporter genes can also encode for extracellular or intracellular receptors or transporters that bind or transport a radiolabeled or paramagnetic probe, allowing for PET-, SPECT- (single-photon emission tomography), or MRI-based molecular imaging.[70]

The second major element of molecular imaging is the imaging modality/technology itself. Direct and indirect binding probes can be radiolabeled to allow nuclear-based in vivo imaging of a desired cellular/molecular event or process using PET or SPECT imaging. In fact, micro-PET and micro-SPECT systems have been developed specifically for molecular imaging studies in animal models.[68] Similarly, optical imaging techniques, such as bioluminescent imaging, near-infrared spectroscopy, and visible light imaging using sensitive CCDs can be used with optically active probes to visualize desired cellular events. Finally, anatomic imaging modalities, such as MRI, CT, and US, have all been adopted for use in animal-based molecular imaging studies.[68]

At this time, the field of molecular imaging is largely an experimental one, with significant activity in the laboratory and little current clinical application. Molecular imaging research is largely focused on investigating the molecular basis of clinical disease states and their potential treatments, including mechanisms surrounding apoptosis, angiogenesis, tumor growth and development, and gene therapy.[68]

### DNA MICROARRAYS

The descriptive term *genomics* acknowledges the shift from a desire to understand the actions of single genes and their individual functions to a more integrated understanding of the simultaneous actions of multiple genes and the subsequent effect exerted on cellular behavior. DNA microarrays, or gene chips, are a recent advancement that allows the simultaneous assay of thousands of genes.[77] Microarray technology has been applied to redefine biologic behavior of tumors, cross-species genomic comparisons, and large scale analyses of gene expression in a variety of conditions. In essence, it represents a new form of patient and disease triage, *molecular triage*.

## Innovative Therapeutics: Technologies and Techniques

A surgical operation requires two key elements: an "image," or more broadly, information regarding the anatomy of interest, and a "manipulation" of the patient's tissue with the goal of a therapeutic effect. Classically, the "image" is obtained through the eyes of the surgeon and the "manipulation" is performed using the surgeon's hands and simple, traditional surgical instruments. During the last several decades, this paradigm has been broadened by technologies that enhance these two fundamental elements.

As opposed to standard, line-of-sight vision, an "image" may now be obtained through an operating microscope or through a flexible endoscope or laparoscope. This endoscope may be monocular or binocular, providing 2D or 3D visualization. These technologies provide the surgeon with high-quality, magnified images of anatomical areas that may be inaccessible to the naked eye. Similarly, a surgical "manipulation" of tissue and organs may be accomplished using a catheter, flexible endoscope, or longer laparoscopic instruments. Furthermore, devices such as staplers, electrocautery, ultrasonic energy tools, and radiofrequency emitters are all used to manipulate and affect tissue with a therapeutic goal. These technologies have changed the way surgical procedures are performed, enabling and even creating fields such as laparoscopic surgery, interventional endoscopy, and catheter-based intervention. In addition to these advances, several emerging technology platforms promise to further broaden this definition of surgery. These include stereotactic radiosurgery and surgical robotics. This section presents a review of several of these technologies with a focus on the current status of hemostatic and tissue ablative instruments, stereotactic radiosurgery, and surgical robotics.

### HEMOSTATIC AND TISSUE ABLATIVE INSTRUMENTS

Handheld energy devices designed to provide hemostasis and ablate tissue are some of the most widely used surgical technologies throughout the world. Since the first reports of

electrosurgery in the 1920s,[78] multiple devices and forms of energy have been developed to minimize blood loss during tissue dissection. These instruments, including monopolar and bipolar electrocautery, ultrasonic dissectors, argon beam coagulators, cryotherapy, and infrared coagulators, are used in operating rooms on a daily basis. In addition, improvements to these tools and their techniques or use are continually being developed.

### Electrocautery

The application of high-frequency alternating current is now known variously as electrocautery, electrosurgery, or simply "the Bovie." Although the concept of applying an electrical current to living tissue was reported as far back as the late sixteenth century, the practical application of electrocautery in surgery did not begin to develop until the early 1900s. In 1908, Lee de Forest developed a high-frequency generator that was capable of delivering a controlled cutting current. However, this device used expensive vacuum tubes and therefore saw very limited clinical application. In the 1920s, W.T. Bovie developed a low-cost spark-gap generator. The potential for using this device in surgery was recognized by Harvey Cushing during a demonstration in 1926, and the first practical electrosurgery units were in use soon thereafter.[78]

Monopolar electrocautery devices deliver the current through an application electrode through the patient's body returning to a grounding pad. Without a grounding pad, the patient would suffer a thermal burn injury wherever the current sought reentry. The area of contact is critical, because heat is inversely related to the size of the application device. Accordingly, the tip of the device is typically small, in order to generate heat efficiently, and the returning electrode is large, to broadly disperse energy. There are three other settings that are pertinent: the frequency of the current (power setting), the activation time, and the characteristics of the waveform produced by the generator (intermittent or continuous).

In the "cut" mode, heat is generated quickly with minimal lateral spread. As a result, the device separates tissue without significant coagulation of underlying vessels. In the "coag" mode, the device generates less heat at a slower frequency with larger lateral thermal spread. Consequently, tissue is desiccated and vessels become thrombosed.

Bipolar cautery creates a short circuit between the grasping tips of the instruments; thus the circuit is completed through the grasped tissue between the tips. Because heat develops only within the short-circuited tissue, there is less lateral thermal spread and the mechanical advantage of tissue compression, as well as thermal coagulation.

Recently, advanced bipolar devices use a combination of pressure and bipolar electrocautery to seal tissues. These devices then use a feedback-controlled system that automatically stops the energy delivery when the seal cycle is complete. The tissues are then divided sharply within the sealed zone. Advanced bipolar devices are capable of sealing blood vessels up to 7 mm in diameter, with the seal reportedly capable of withstanding 3 times normal systolic blood pressure. Examples of this class of device include the LigaSure distributed by Covidien (Mansfield, Mass.) and the ENSEAL device distributed by Ethicon Endosurgery (Cincinnati, Ohio).

### Argon Beam Coagulator

The argon beam coagulator creates an electric circuit between the tip of the probe and the target tissue through a flowing stream of ionized argon gas. The electrical current is conducted to the tissue through the argon gas and produces thermal coagulation. The flow of the argon gas improves visibility and disperses any surface blood, enhancing coagulation. Its applications in hepatic surgery are unparalleled.

### Surgical Lasers

Lasers (*L*ight *A*mplification by *S*timulated *E*mission of *R*adiation) are devices that produce an extremely intense and nearly nondivergent beam of monochromic radiation, usually in the visible region. When focused at close range, laser light is capable of producing intense heat with resultant coagulation. Lateral spread tends to be minimal, and critically, the laser can be delivered through a fiber optic system.

Based on power setting and the photon chosen, depth can be controlled. Penetration depth within the tissue is most shallow with the argon laser, intermediate with the carbon dioxide laser, and of greatest depth with the neodymium-yttrium aluminum garnet (Nd-YAG) laser. Photosensitizing agents provide an additional targeting advantage. The degree of absorption, and thus destruction, depends upon the wavelength selected and the absorptive properties of the tissue based on density, fibrosis, and vascularity.

### Photodynamic Therapy

A novel use of light energy is used in photodynamic therapy. A photosensitizer that is target cell–specific is administered and subsequently concentrated in the tissue to be eradicated. The photosensitizing agent may then be activated with a light energy source, leading to tissue destruction. Applications have been widespread.[79] Metaplastic cells, in particular in Barrett esophagus, may also be susceptible.[80]

### Ultrasonography

In addition to the diagnostic use of US at low frequency, the delivery of high-frequency US can be used to separate and coagulate tissue. Focused acoustic waves are now used extensively in the treatment of renal calculi as extracorporeal shock wave lithotripsy (ESWL). The focused energy produces a shock wave resulting in fragmentation of the stones to a size that can be spontaneously passed.

When high-intensity focused US (HIFU) energy from multiple beams is focused at a point on a target tissue, heating and thermal necrosis results. None of the individual ultrasonic beams is of sufficient magnitude to cause injury, only at the focus point does thermal injury result. Thus subcutaneous nodules may be targeted without injury to the skin, or nodules within the parenchyma of a solid organ may be destroyed without penetrating the surface. Thus far, however, the focal point is extremely small, thus limiting utility.

### Harmonic Scalpel

When US energy at very-high frequency (55,000 Hz) is used, tissue can be separated with minimal peripheral damage. Such high-frequency energy creates vibration, friction, heat, and ultimately, tissue destruction.

### Cavitation Devices

The CUSA, a cavitation ultrasonic aspirator, uses lower-frequency US energy with concomitant aspiration. Fragmentation of high-water–content tissue allows for parenchymal destruction, while highlighting vascular structures and permitting their precise coagulation.

### Radiofrequency Energy

High-frequency alternating current (350 to 500 kHz) may be used for tissue division, vessel sealing, or tissue ablation. The application of this energy source heats the target tissue, causing protein denaturization and necrosis. A feedback loop sensor discontinues the current at a selected point, minimizing collateral damage. Its targeted use in modulating the lower esophageal sphincter for the treatment of reflux has been reported.[81]

### Microwave Energy

Microwave energy (2,450 MHz) can be delivered by a probe to a target tissue. This rapidly alternating electrical signal produces heat and thus coagulation necrosis.

### Cryotherapy

At the other end of the temperature spectrum, cold temperatures destroy tissue with a cycle of freezing and thawing with ice crystal formation in the freezing phase and disruption during the thawing phase. Thus far this modality has less utility because high vascular flow, especially in tumors, tends to siphon off the cold.

## IMAGE-GUIDED THERAPY

In recent years, ultrasonography, computerized tomography, and magnetic resonance imaging have expanded beyond their role as mere diagnostic modalities, and are now the foundation of sophisticated interactive computer applications that directly guide surgical procedures.[3,82,83] Recent developments in computation technology have fundamentally enhanced the role of medical imaging, from diagnostics described previously to computer-assisted surgery (CAS). During the last decade, medical imaging methods have grown from their initial use as physically based models of human anatomy to applied computer vision and graphical techniques for planning and analyzing surgical procedures. With rapid advances in high-speed computation, the task of assembling and visualizing clinical data has been greatly facilitated, creating new opportunities for real-time, interactive computer applications during surgical procedures.[77–80] This area of development, termed image-guided surgery, has slowly evolved into a field best called *information-guided therapy* (IGT), reflecting the use of a variety of data sources to implement the best therapeutic intervention. Such therapeutic interventions could conceivably range from biopsy to simulation of tissue to direct implantation of medication to radiotherapy. Common to all these highly technical interventions is the need to precisely intervene with the therapeutic modality at a specific point.

However, the effective use of biomedical engineering, computation, and imaging concepts for IGT has not reached its full potential. Significant challenges remain in the development of basic scientific and mathematical frameworks that form the foundation for improving therapeutic interventions through application of relevant information sources.

### Significance

As stated in the National Institutes of Health 1995 *Support for Bioengineering Research Report* (http://grants.nih.gov/grants/becon/externalreport.html), an appropriate use of technology would be to replace traditional invasive procedures with non-invasive techniques. The current interest in research in CAS, or IGT, can be attributed in part to the considerable clinical interest in the well-recognized benefits of minimal access surgery (MAS), remaining cognizant of its limitations.

Image-based surgical guidance, on the other hand, addresses these limitations. Image-guided surgical navigational systems have now become the standard of care for cranial neurosurgical procedures in which precise localization within and movement through the brain is of utmost importance.

Patient-specific image data sets such as CT or MRI, when correlated with fixed anatomic reference points (fiducials), can provide surgeons with detailed spatial information about the region of interest. Surgeons can then use these images to precisely target and localize pathologies. Intraoperative computer-assisted imaging improves the surgeon's ability to follow preoperative plans by showing location and optimal directionality. Thus the addition of CAS provides the advantages of MAS with the added benefits of greater precision and the increased likelihood of complete and accurate resections. The junction between CAS and MAS presents research opportunities and challenges for both imaging scientists and surgeons.

### General Requirements

***Patient-Specific Models*** Unlike simulation, IGT requires that modeling data be matched specifically to the patient being treated, since standard fabricated models based upon typical anatomy are inadequate during actual surgical procedures upon a specific patient. Patient-specific images can be generated preoperatively (e.g., by CT or MRI) or intraoperatively (e.g., by US or x-ray).

***High Image Quality*** IGT depends on spatially accurate models. Images require exceptional resolution in order to portray realistic and consistent information.

***Real-Time Feedback*** Current systems make the surgeon wait while new images are being segmented and updated. Thus fast dynamic feedback is needed, and the latencies associated with visualization segmentation and registration should be minimized.

***High Accuracy and Precision*** An American Association of Neurosurgeons survey of 250 neurosurgeons[57] disclosed that surgeons had little tolerance for error (102-mm accuracy in general, and 2 to 3 mm for spinal and orthopedic applications). All elements of visualization, registration, and tracking must be accurate and precise, with special attention given to errors associated with intraoperative tissue deformation.

***Repeatability and Robustness*** Image-guided therapy systems must be able to automatically incorporate a variety of data so that algorithms work consistently and reliably in any situation.

***Correlation of Intraoperative Information with Preoperative Images*** This requirement is a critical area of interest to biomedical engineers and is especially critical for compensation of tissue deformation. Whether produced by microscopes, endoscopes, fluoroscopes, electrical recordings, physiological simulation, or other imaging techniques, preoperative and intraoperative images and information need to be incorporated into and correlated by the surgical guidance system.

***Intuitive Machine and User Interfaces*** The most important part of any IGT system is its usability. The surgeon's attention must be focused on the patient and not the details of the computational model.

### Ultrasound Image-Guided Therapy

Compared with adults, children have excellent US image resolution because of minimal subcutaneous tissue. Furthermore, the lack of ionizing radiation, fast procedure times, relatively low cost, as well as its real-time and multiplanar imaging capabilities, make US especially attractive in the pediatric population. US is the most accessible advanced imaging tool that surgeons can currently use independently. Intraoperative applications include using it as an aid to vascular access, intraoperative tumor localization and resection, and drainage procedures.[84–87]

### Computed Tomography and Magnetic Resonance Image-Guided Therapy

Computed tomography and magnetic resonance imaging are not widely used by surgeons without the involvement of radiologists. Although CT-based IGT offers excellent visualization that is not limited by the presence of air or bone, its use in the pediatric population has been limited by concern for the downstream effects of ionizing radiation.[88,89] In addition, there are limited imaging planes, poor differentiation of some lesions related to less fat in babies and children, as well as longer procedure times and greater costs than for US intervention. Nonetheless, CT-guided therapeutic interventions, such as lung and bone biopsies or drainage of deep fluid collections, are routinely done, particularly now that radiation exposure can be reduced with pulsed or intermittent fluoroscopic techniques and dedicated pediatric CT parameters.[82]

The advantages of MRI as a guiding tool include exquisite soft tissue detail, multiplanar real-time imaging, and the ability to assess physiologic and functional parameters (temperature, flow, perfusion).[82,90] Traditional interventional MRI units include an opening that allows easy access to the patient. These units have relatively low field strength, however, which results in poorer image resolution. Higher field strength magnets are now preferred, albeit at the cost of decreased patient accessibility and the requirement of nonferromagnetic instruments. To date, the majority of pediatric applications of MRI-guided therapy have been in the field of neurosurgery. Common applications include tumor ablation/resection or biopsy.[90,91] Currently, there are no data on MRI-guided abdominal interventions in the pediatric population. In 2005, Schulz and colleagues[90] reviewed indications for MR-guided interventions in children. They determined that MR-guided imaging is not a reliable method for chest interventions. They also suggested that the primary use of intraoperative MRI will be for lesions in particularly difficult-to-access areas with nonpalpable findings, such as intracranial and skull base tumors. Future potential applications of MRI include endovascular procedures[91] and thermal ablation of tumors.

Navigational systems establish the relationship between the surgeon's movements and image-based information. They enable the use of preoperative imaging for precise intraoperative localization and resection of lesions using an exact navigation pathway. Neuronavigation systems provide this precise surgical guidance by referencing a coordinate system of the brain with a parallel coordinate system of the three-dimensional image data of the patient.[92,93] These data are displayed on the console of the computer workstation so that the medical images become point-to-point maps of the corresponding actual locations within the brain. The spatial accuracy of these systems is further enhanced by the use of intraoperative MRI that provides real-time images to document the residual lesion and to assess for brain shift during surgery.[94] The precision (error rates of 0.1 to 0.6 mm) provided by neuronavigation systems enables minimal access neurosurgical procedures, significantly reducing morbidity for both adult and pediatric patients.[95] Neuronavigation has not yet been successfully deployed for abdominal surgery. The inability to simply transfer the methodology from neurosurgery is mainly a result of intraoperative organ shifting and corresponding technical difficulties in the online applicability of presurgical cross-sectional imaging data. Furthermore, it remains unclear whether 3D planning and interactive planning tools will increase precision and safety of abdominal surgery.

### Radiotherapy and Fractionation

The field of radiation oncology represents perhaps the most mature example of IGT. Radiation therapy, or *radiotherapy*, refers to the use of ionizing radiation for the treatment of pathologic disorders. The use of radiation to cure cancer was first reported in 1899, very soon after Roentgen's discovery of x-rays in 1895.[96] In the 1930s, Coutard described the practice of "fractionation," [96] which refers to the division of a total dose of radiation into multiple smaller doses, typically given on a daily basis. Fractionation is a bedrock principle that underlies the entire field of radiotherapy.[97,98] By administering radiation in multiple daily fractions over the course of several weeks, it is possible to irradiate a tumor with a higher total dose while relatively sparing the surrounding normal tissue from the most injurious effects of treatment. By fractionating the therapy, normal tissue should be allowed to recover while pathologic tissue is destroyed. Though fractionation regimens differ depending on specific pathology, current regimens often involve up to 30 treatments.[96]

### Stereotactic Radiosurgery

*Stereotactic radiosurgery* refers to the method and corresponding technology for delivering a single high dose of ablative radiation to target tissue using precision targeting and large numbers of cross-fired highly collimated beams of high-energy ionizing radiation. Conceptualized in the 1950s by Swedish neurosurgeon Lars Leksell, this technology has been used to treat/ablate a variety of benign and malignant intracranial lesions without any incision.[99] Leksell showed that there was an exponential relation between dose and the time during which necrosis developed.[96]

Most recently, radiosurgical techniques are being applied toward the treatment of extracranial diseases, including spinal tumors and lesions of the thoracic and abdominal cavities.[100,101] Many of the newest applications of stereotactic radiosurgery fall under the traditional realm of general surgery, including lung, liver, and pancreatic cancers. The lesioning of normal brain tissue, such as the trigeminal nerve (trigeminal neuralgia), thalamus (tremor), and epileptic foci (intractable seizures) is also an important clinical application of this technology.[102] Numerous studies have demonstrated radiosurgery to be an important treatment option for many otolaryngologic conditions, such as skull base and neck tumors.[103–106] As the scientific understanding and clinical practice of radiosurgery develops, such technology may become an increasingly valuable, minimally invasive option for treating a range of pediatric general surgical diseases.

Stereotactic radiosurgery has the potential advantage of delivering a much larger radiation dose to a pathologic lesion without exceeding the radiation tolerance of the surrounding normal tissue. This single, or limited, dose treatment of a small volume of tissue is achieved by targeting the tissue with large numbers of intersecting beams of radiation. "Stereotactic" refers to the fact that radiosurgery uses computer algorithms to coordinate the patient's real-time anatomy in the treatment suite with a preoperative image to allow precise targeting of a desired tissue area. To achieve this, the patient's anatomy must usually be fixed using a stereotactic frame.[96] The preoperative images are then taken with the frame in place, and the patient's anatomy is mapped in relation to the frame. This stereotactic frame is rigidly fixed to the patient's skull, thereby limiting movement of the target anatomy. In addition, the frame serves as an external fiducial system that correlates the coordinates of the target tissues, determined during preoperative imaging and planning, to the treatment room. Radiosurgical treatment is then delivered to the appropriate tissue using this coordinate system.

### Stereotactic Radiosurgical Platforms

Currently, there are several classes of stereotactic radiosurgery systems in use. These include heavy-particle radiosurgery systems, Gamma Knife radiosurgery, and linear accelerator radiosurgery. Currently, heavy particle radiosurgery systems and Gamma Knife radiosurgery systems are only used to treat intracranial lesions. In contrast, linear accelerator systems have been adapted to treat both cranial and extracranial lesions.

### Linear Accelerator Radiosurgery

Linear accelerators, or linacs, have long been a mainstay of standard fractionated radiotherapy and were modified for radiosurgery in 1982.[96] Linac radiosurgery has become a cost effective and widely used alternative to Gamma Knife radiosurgery. When used for radiosurgery, linacs crossfire a photon beam by moving in multiple arc-shaped paths around the patient's head. The area of crossfire where the multiple fired beams intersect receives a high amount of radiation, with minimal exposure to the surrounding normal tissue.[96] Patients treated with linac radiosurgery must also wear a stereotactic frame fixed to the skull for preoperative imaging and therapy. Currently, linac radiosurgery is the predominant modality in the United States, with approximately 6 times more active centers than Gamma Knife facilities.[96]

### Frameless Image-Guided Radiosurgery

Recently, novel systems have been developed that use linear accelerators with innovative hardware and software systems capable of performing frameless image-guided radiosurgery. One such system, the CyberKnife (Accuray, Sunnyvale, Calif.), uses a lightweight linac unit, designed for radiosurgery, mounted on a highly maneuverable robotic arm.[107] The robotic arm can position and point the linear accelerator with 6 degrees of freedom and 0.3-mm precision. In addition, the CyberKnife system features image guidance, which eliminates the need to use skeletal fixation.[102,108] The CyberKnife acquires a series of stereoscopic radiographs that identify a preoperatively placed gold fiducial. This fiducial is placed under local anesthetic during the preoperative imaging and planning sessions to allow the system to correlate the patient's target anatomy with the preoperative image for treatment. By actively acquiring radiographs during the treatment session, the system is able to track and follow the patient's target anatomy in near real-time during treatment.[102,108] With this image guidance system, the CyberKnife is able to function without a fixed stereotactic frame, enabling fractionation (often termed hypofractionated radiosurgery or radiotherapy) of treatments as well as extracorporeal stereotactic radiosurgery. In pediatric surgery, this may represent a significant technical advantage, because it may enable the use of radiosurgery for the treatment of intrathoracic and intraabdominal pathologies (Fig. 4-11). Similarly, the Novalis Tx (Varian Medical Systems, Palo Alto, Calif.) uses an integrated cone beam CT scan system to provide volumetric imaging as well as fluoroscopic imaging to compensate for respiratory motion to enable frameless, image-guided radiosurgery. In contrast, the Trilogy system (Varian Medical Systems, Palo Alto, Calif.) uses real-time optical guidance to direct radiation delivery to the target lesion (Fig. 4-12). Both of these systems use a multileaf collimator that adapts radiation treatment to complex shapes. In addition, they use intensity modulation to help limit toxicity to surrounding tissue. Both systems deliver treatments in sessions of less than 30 minutes, which may decrease the need for sedation in pediatric patients.[109] Furthermore, the Trilogy system minimizes radiation exposure further by using an optically based guidance system.[109]

## CLINICAL APPLICATION OF STEREOTACTIC RADIOSURGERY IN CHILDREN

To date, pediatric radiosurgery has primarily been used to treat intracranial pathologies. Hadjipanavis and colleagues reported a series of 37 patients (mean age 14) with unresectable pylocytic astrocytomas treated with stereotactic radiosurgery.[110] They found radiosurgery to be a valuable adjunctive strategy in patients whose disease was not amenable to surgical therapy.[110] Somaza and colleagues reported their experience with the use of stereotactic radiosurgery for the treatment of growing and unresectable deep-seated pilocytic astrocytomas in 9 pediatric patients.[111] Two of the patients had already failed fractionated radiotherapy, and 7 patients were considered to be at high risk for adverse radiation effects given their young age. After 19 months follow-up, there was a marked decrease in tumor size in 5 patients, while the remaining 4 patients displayed no further tumor growth. Overall, the authors felt that stereotactic radiosurgery offered a safe and effective therapy in the management of children with deep, small-volume pilocytic astrocytomas.[111]

The use of stereotactic radiosurgery for the treatment of nonmalignant intracranial lesions in children has also been described. Specifically, the use of radiosurgery for the treatment of cerebral arteriovenous malformations (AVMs) has been reported. Although microsurgical resection remains the treatment of choice for most accessible AVMs, lesions located in critical cortical areas or in deep portions of the brain are increasingly treated with radiosurgery because of the risk of surgical resection.[112] Foy and colleagues reported a series of 60 pediatric patients with AVMs treated with radiosurgery. Nidus obliteration was reported at 52% after a single radiosurgery session, increasing to 63% with repeated sessions.[112] Similarly Nicolato and colleagues reported a cohort of 62 children with AVMs treated with radiosurgery. They reported an obliteration rate of 85.5%.[113] Overall, these authors conclude that stereotactic radiosurgery is a safe and effective option for properly selected children with AVMs. In particular, it may benefit children with AVMs located in critical portions of the brain where surgical resection may pose a large risk.[112]

Compared with the adult population, the experience with stereotactic radiosurgery in children is still limited. The early reports described above all highlight the safety and efficacy of radiosurgery as a treatment modality, but clinical follow-up is still early, with many of the reports limiting the use of radiosurgery to the treatment of surgically unresectable disease. Despite relatively limited experience, the use of stereotactic radiosurgery in children may offer several theoretical advantages specific to the pediatric population. Compared with standard, fractionated radiotherapy, stereotactic radiosurgical techniques deliver conformal radiation treatment with millimeter versus centimeter accuracy. All radiation treatments are a balance between providing enough radiation to effectively treat pathologic tissues while minimizing harmful exposure to adjacent normal tissues. In pediatric patients, the distances between normal and pathologic tissues may be very small. In addition, the developing brains of children may be more sensitive to the effects of ionizing radiation than adult brains. In particular, potential cognitive and endocrine disabilities have been described in children after radiotherapy to the brain.[111,114,115] These concerns have largely limited the use of radiation for the treatment of intracranial tumors in infants. Therefore the improved accuracy provided by stereotactic radiosurgery may be particularly important in the pediatric population.

In addition to accuracy, stereotactic radiosurgical techniques differ from radiotherapy in that they use only one or few treatment sessions. As detailed above, standard, fractionated radiotherapy often uses tens of treatment sessions to maximize the beneficial effects of the treatment while minimizing the harmful effects to normal tissues. In children, these multiple treatment sessions may represent a significant challenge. In smaller children, sedation, or even anesthesia, may be necessary to avoid movement. Such interventions are not without risk, and limiting the number of treatment sessions may serve to minimize the overall risk to the child.

Although the advantages of stereotactic radiosurgery in the pediatric population appear promising, it should be noted that there also exist specific disadvantages and limitations that must be overcome. Radiosurgical techniques generally use a stereotactic frame to coordinate preoperative imaging with actual radiation delivery. However, these frames must be secured to the skull using pins and screws. In adults, this can often be performed using only local anesthetic agents. In children, this likely requires significant sedation and possibly general anesthesia. Furthermore, the skulls of infants are soft and less rigid, because their cranial sutures have not yet fused. Because of this, standard stereotactic frames often cannot be applied. Similarly, radiosurgery treatment sessions require the patient to remain still in order for the systems to accurately deliver the radiation treatment. Adults are able to cooperate with the therapy and do not require sedation, whereas younger children and infants may require conscious sedation or general anesthesia. Although this drawback is limited by the relatively few sessions necessary with radiosurgery, it still diminishes the minimally invasive nature of the therapy compared with its application in the adults.

Recently, frameless, image-guided stereotactic radiosurgery has been reported in children. Giller and colleagues described the use of the CyberKnife system in 21 patients, ages ranging from 8 months to 16 years, with tumors considered unresectable. Diagnoses included pilocytic astrocytomas, anaplastic astrocytomas, ependymomas, medulloblastomas, atypical teratoid/rhabdoid tumors, and craniopharyngiomas. Local control was achieved in the patients with pilocytic and anaplastic astrocytoma, three of the patients with medulloblastoma, and the three with craniopharyngioma, but not for those with ependymoma. There were no procedure-related mortalities or complications, and local control was achieved in more than half of the patients. Seventy-one percent of patients received only one treatment session, and 38% of patients did not require general anesthesia. No patients required rigid skull fixation.[115] In an additional report, the same group highlighted the use of the CyberKnife system to perform radiosurgery in five infants.[114] Although standard stereotactic frames were not required, patient immobilization was aided by general anesthesia, form-fitting head supports, face masks, and body molds. No treatment-related toxicity was encountered, and the authors concluded that "radiosurgery with minimal toxicity can be delivered to infants by use of a robotically controlled system that does not require rigid fixation."[114]

Whereas the use of stereotactic radiosurgery for intracranial lesions is well established, its use for treatment of extracranial lesions, specifically intrathoracic and intraabdominal pathologies is still developing. Intracranial contents can be easily immobilized using stereotactic frames, while abdominal and thoracic organs show significant movement resulting from respiration, peristalsis, and so on. As a result, only a small body of literature exists regarding the application of stereotactic radiosurgery for extracranial lesions. Recently, several reports have described the efficacy of stereotactic radiosurgery in adults for the treatment of lesions in the liver,[117,118] pancreas,[119,120] lung,[118,121] and kidney[122,123]—anatomical areas that have traditionally been under the watch of general surgeons. Novel image guidance technologies as well as soft tissue immobilization devices are used to make these therapies possible.

At this time, the majority of the literature represents case reports and series detailing the safety and feasibility of extracranial radiosurgery. In addition, many of the reports focus on the technical and engineering aspects of applying radiosurgical techniques to extracranial targets, with little data on patient outcomes. All of these reports have focused on the adult patient population with no significant reports in children. Despite this inexperience, the technology surrounding stereotactic radiosurgery is rapidly developing and shows significant promise toward the minimally invasive treatment of potentially poorly accessible lesions. Newer, frameless, image-guided systems may some day enable the minimally invasive treatment of a variety of pediatric malignancies.

### Radioimmunoguided Surgery

Antibodies labeled with radionuclides, when injected systemically, may bind specifically to tumors, thus allowing gamma probe detection.[124–126] For the most part, nonspecific binding and systemic persistence has minimized the signal-to-noise ratio, thus limiting this approach. The Food and Drug Administration (FDA) approved several new radiolabeled antibodies for the identification of occult metastases in patients. Beyond imaging, the theoretical opportunity to use a gamma probe to identify "hot spots" adds a new source of information to the surgeon. Full exploitation of this methodology beyond specific functioning endocrine tumors and draining nodal basins in breast cancer and melanoma shows real promise.

## NEXT-GENERATION MINIMAL ACCESS SURGERY

Minimal access surgery (MAS) forms the cornerstone of clinical innovation in present day pediatric surgery. Most pediatric general surgical procedures are now performed using some minimal access approach, and in many cases, these approaches are now considered standard of care. The next evolution in pediatric MAS involves further implementation of laparoscopic, endoscopic, and imaging techniques, with the ultimate goal of achieving scarless and painless surgery. Termed *stealth surgery,* this is an emerging surgical paradigm that encompasses a variety of techniques, each with the goal of performing complex operations without leaving visible evidence that they occurred.[127] This is achieved by placing incisions in inconspicuous or camouflaged locations and using MAS technologies to perform the operation. Examples of stealth surgery include subcutaneous endoscopy, single-incision laparoscopy, and natural orifice translumenal surgery (NOTES).

Traditionally, surgical culture has discounted the importance of scarring caused by surgical procedures. Scarring has been seen as either an unfortunate necessity or a minor outcome issue. This is interesting considering that the surgical scar is often the only collateral outcome of an operation that lasts a lifetime. At best, incisions have been placed in skin creases in an effort to camouflage the scar. Despite this, scarring is unpredictable, particularly if the scar is hypertrophic, keloid, or stretched, or if it becomes infected. There is evidence to suggest that visible scarring in children can result in reduced self-esteem, impaired socialization skills, and lower self-ratings of problem-solving ability.[128,129] Furthermore, other children judge children with facial deformities more negatively than those without facial deformities. Scarring of the chest and abdominal wall has not been as extensively studied, but it is likely that, at least in some circumstances, it can also have psychological implications. Stealth surgery aims to address surgical scarring, and collectively reflects a greater responsibility of surgeons toward the collateral damage of surgical procedures.

### Subcutaneous Endoscopy

Subcutaneous endoscopy involves tunneling under the skin from inconspicuous locations to target removal of lesions at more conspicuous locations. Many surgical subspecialties, including plastic surgery,[130] otolaryngology,[131] and maxillofacial surgery,[132] have used subcutaneous endoscopic techniques, typically through hidden incisions on the scalp, for management of a variety of benign forehead lesions. Endoscopic removal of such lesions through scalp incisions using browlift equipment is also described in the pediatric general surgery literature,[133] as is removal of neck lesions through two or three small incisions placed in the axilla. This latter approach, called transaxillary subcutaneous endoscopy, has been used to address torticollis,[134] and also to remove lesions, such as

thyroglossal cysts, cervical lymph nodes, parathyroid adenomas,[135] and thyroid nodules.[136] Transaxillary access has also been used for subcutaneous lesions of the chest wall, such as dermoid cysts and lipomas.[137]

Subcutaneous endoscopy for forehead lesions is performed through a 1.5- to 2.0-cm scalp incision using standard browlift equipment (Fig. 4-13). Dissecting instruments of 2- to 3-mm diameter are passed inline through the same incision as the endoscope. The subperiosteal plane is most commonly used to approach the lesion, but the subgaleal plane can also be used. The approach is ideal for lateral brow dermoid cysts or those found between the eyebrows (nasoglabellar cyst). The approach is not used for lesions that have intracranial extension.

Transaxillary subcutaneous endoscopic excision of neck lesions is performed by placing two or three endoscopic ports in the ipsilateral axilla, posterior to the lateral border of the pectoralis major muscle (Fig. 4-14). A subcutaneous workspace is then created, extending to the neck. The platysma muscle is traversed superior to the clavicle, and the target lesion is then dissected free. Recognition of landmarks and accurate anatomical orientation is subject to a learning curve, but visualization of all structures, including recurrent laryngeal nerves, is excellent. It is important to avoid extensive use of thermal energy sources in the neck, especially monopolar cautery, because of the thermal spread of such instruments. It is preferable to use bipolar cautery when possible, or else a thermal sealing/cutting device such as the Ligasure (Valleylab, Boulder, Colo.). The cosmetic benefits of this approach are apparent, because the patient is left with no scar on the face or neck. Pain is controlled with non-narcotic analgesics, and patients can typically be discharged the same day.

### Single Incision Laparoscopy

Single incision laparoscopy is an evolution of minimal access surgery that promises virtually scarless abdominal operations. Various acronyms, including SILS (single-incision laparoscopic surgery; Covidien), LESS (laparoendoscopic single-site surgery), SPA (single-port access surgery),[138] OPUS (one-port umbilical surgery), and SAS (single-access site surgery) have been applied to this technique. The essential element is the use of a single small incision, usually placed at the umbilicus through which multiple laparoscopic instruments are passed either through a single-port device with multiple conduits or through multiple closely spaced ports (Fig. 4-15). Single incision approaches have been described in the adult literature for appendectomy, nephrectomy,[139] adrenalectomy,[140] cholecystectomy,[141] and colectomy,[142] and in the pediatric general surgical literature for appendectomy,[143] varicocelectomy,[144] cholecystectomy, and splenectomy.[145]

Cosmesis is the most apparent benefit of single-incision laparoscopy, because the single scar produced can be effectively hidden in the existing umbilical scar. The cosmetic benefit, including psychosocial factors, has not been objectively demonstrated, but the complete absence of a visible scar is achievable with this method. The procedures are feasible in equivalent operative times to standard laparoscopy,

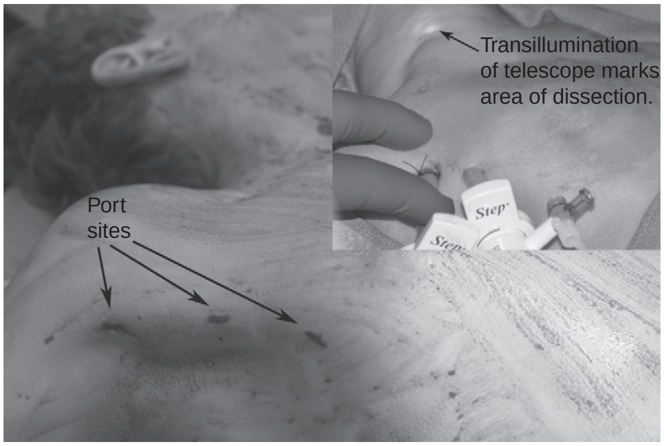

**FIGURE 4-14** Transaxillary subcutaneous access can be used to access lesions in the neck and chest wall. A cavernous subcutaneous workspace is created to facilitate dissection. In this image, the light at the tip of the telescope can be seen transilluminating the skin.

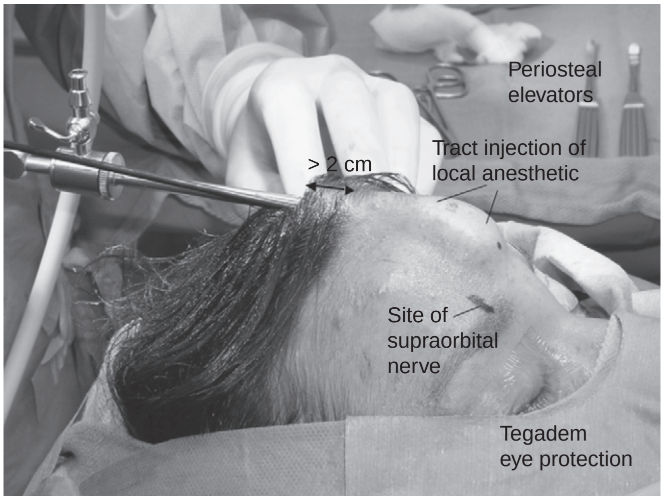

**FIGURE 4-13** For endoscopic excision of forehead lesions, hydrodissection with local anesthetic is used to create a path toward the lesion in the subperiosteal or subgaleal plane, starting about 2 centimeters posterior to the hairline. The telescope and dissecting instruments are placed through a 1 to 2 cm V-shaped incision on the scalp.

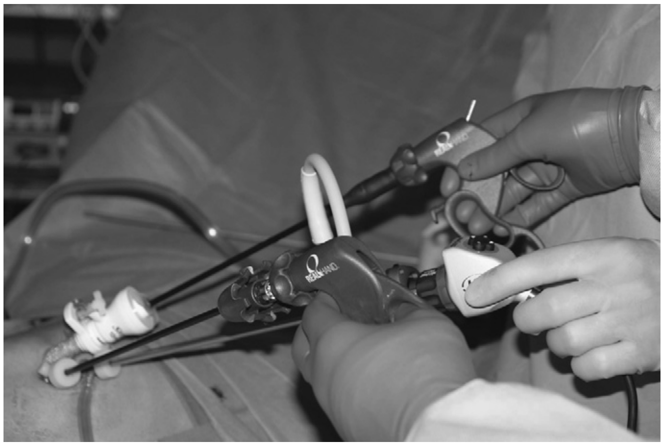

**FIGURE 4-15** Single-incision laparoscopic surgery involves placing multiple ports, or a commercially available single-port device, at the umbilicus. Instruments with dexterous end effectors can be exploited to achieve triangulation around the target tissue, which is otherwise difficult to achieve with standard rigid laparoscopic instruments in this setting.

without additional safety concerns. Although clinical trials are underway, outcomes in terms of pain, recovery, and hospital stay have not been assessed—anecdotally these outcomes mirror those of standard laparoscopy.

A number of critical challenges in performing single-incision laparoscopy have led to some innovative solutions. (1) Close co-location of the instruments can result in bothersome instrument backend, hand, and camera collisions that impair mobility. This is addressed with the use of ports and instruments of varying lengths to offset backends, angled light-cord adapters for rigid telescopes, or flexible tip telescopes with low-profile backends. (2) When using standard rigid laparoscopic instruments, it is difficult or impossible to achieve an equal degree of triangulation around the target tissues (ideally 60 degrees) as can be achieved in standard laparoscopy and that is necessary for safe, precise, and efficient dissection. Instruments with an additional joint near their tip that gives two additional degrees of freedom (Realhand, Novare Surgical, Cupertino, Calif.; Autonomy Laparo-Angle, Cambridge Endo, Framingham, Mass.; Roticulator, Covidien, Norwalk, Conn.) have been applied to single-incision laparoscopy for this reason. With these "dexterous" instruments, triangulation can be achieved by first crossing the instrument shafts at or just below the level of the fascia, then deflecting the tips inward to create triangulation. (3) The maneuvers necessary to work with instruments in this configuration can be confusing and counterintuitive, because the instrument tips are frequently opposite the hand configuration, or the surgeon's hands are sometimes crossed. Developers of surgical telemanipulation platforms have taken advantage of computer algorithms used in their existing telemanipulation platforms (e.g., da Vinci Si, Intuitive Surgical, Sunnyvale, Calif.) to provide a single-incision laparoscopy platform that can correct for paradoxical movements and give the surgeon the perception that their hand movements are being mirrored by the robotic instruments.[146]

Single-incision laparoscopy will likely play a role in pediatric surgical procedures for larger children and adolescents, primarily because of the avoidance of visible scarring. Its role in neonatal surgery is less clear. Existing instrumentation is too large for neonatal anatomy. Furthermore, proponents of umbilical laparotomy show that most abdominal procedures can be performed in neonates through umbilical incisions that can be camouflaged with an umbilicoplasty.[147] When possible, this approach offers a cheaper alternative to single-incision laparoscopy. Cost continues to be a consideration when adopting these novel minimal access procedures, because they generate the need for more complex technologies, but a cost assessment is difficult to perform in the early stages of adoption because of the dynamic nature of the technologies used and the costs they incur.

## NATURAL ORIFICE TRANSLUMENAL ENDOSURGERY

Perhaps a more extreme evolution of scarless surgery is natural orifice translumenal endosurgery (NOTES), which aims to perform abdominal or thoracic procedures by way of transoral, transgastric/transesophageal, transrectal or transvaginal access. Some surgeons consider single-incision laparoscopy a bridge to NOTES, while others see at as a more palatable alternative to NOTES. In adults, the potential advantages of NOTES include decreased or no postoperative pain, no requirement of general anesthetic, the performance of procedures in an outpatient setting, and possibility of reducing costs. In children, NOTES remains uncharted, and its application in this population seems not only conceptually unappealing (transvaginal access is unlikely to be considered in a young girl), but also currently fraught with undue risk (leakage and infection risk with transgastric or transrectal access). Adult subjects asked to rate their preference of technique in the absence of safety profile data preferred single-incision laparoscopy and standard laparoscopy versus NOTES and open surgery.[148] However, there are unique pediatric surgical conditions described below that are intriguing targets for this approach, and research in this area allows an opportunity to discover novel techniques and technologies that may be more generally applicable to pediatric minimal access surgery.

The development of NOTES is an interesting case study in surgical innovation because of the way it has progressed, in contrast to conventional laparoscopy. The rapid adoption of laparoscopy into mainstream surgical practice without oversight or appropriate training heralded increased complication rates, such as that of bile duct injury during laparoscopic cholecystectomy[149] and complications not previously seen, such as intestinal and vascular injury from port placement. To avoid a similar scenario with NOTES, delegates from the American Society of Gastrointestinal Endoscopy (ASGE) and the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) established the Natural Orifice Surgery Consortium for Assessment and Research (NOSCAR),[150] with the purpose of defining guidelines for the safe, ethical, and evidence-based development of NOTES. The technical challenges, and hence areas of research focus, they identified included (1) creation and secure closure of the defect created in the hollow viscus for peritoneal access, (2) prevention of peritoneal contamination and maintenance of sterility, (3) adequate visualization and orientation in the peritoneal cavity, and (4) effective instrument triangulation around target tissues and adequate retraction of adjacent tissues.

A second unique feature of NOTES is the early involvement of industry in device development, in close collaboration with both surgeons and gastroenterologists with an interest in therapeutic endoscopy. Both specialties have recognized the need to collaborate on NOTES development because of its hybrid use of endoscopic and laparoscopic techniques. The medical device industry, in turn, has engaged early in this effort to remain competitive and obtain market share in this potentially large market. Although widespread use of NOTES has not materialized, research and development in this area has resulted in the development of a host of novel technologies ranging from dexterous flexible endoscopic surgical tools to intraluminal suturing devices.

In pediatric surgery, the adoption of NOTES for common pediatric conditions in the near future seems improbable because of small markets, the persistent need for general anesthetic, and a lack of any clear significant benefit versus single-incision laparoscopy. There are, however, some interesting possibilities for the use of NOTES in neonatal surgery, such as for duodenal atresia, urologic anomalies, and esophageal atresia. The latter is perhaps the most compelling. Although a thoracoscopic approach to esophageal atresia is well described, there has been slow adoption of this approach because of its technical difficulty, particularly with respect to

thoracoscopic suturing of the anastomosis, which requires very precise movements in a limited workspace with highly fragile tissues that are under tension. The possibility of performing some or all of the operation transorally using flexible tools with purpose-specific attachments that allow fistula closure and/or esophageal anastomosis may allow a wider adoption of a minimal access approach to this condition by trivializing the technical difficulty of creating the anastomosis. Unfortunately, market sizes for diseases such as esophageal atresia do not support investment in purpose-specific technology, but development of dual-purpose tools that can also be applied to larger (adult) markets may provide the basis for their development.

### Endolumenal Therapies

Innovations in intraluminal endoscopic therapies have centered mainly on totally endoscopic antireflux procedures, some of which have been applied to children. Some of these procedures (Enteryx, Gatekeeper) have fallen out of favor because of safety concerns or lack of efficacy. Use of Enteryx came to a halt in 2005 when the FDA requested a recall by Boston Scientific of all Enteryx systems following reports of adverse effects (and cases of fatality) resulting from inadvertent Enteryx injection into the mediastinum, pleural space, and aorta (with consequent arterial embolism). The Enteryx system is mentioned here only to exemplify the potential for serious complications with novel technologies, and reinforce the need for proper efficacy and safety trials before their widespread application, particularly in the pediatric population.

Use of other devices, such as Endocinch (Bard, Warwick, RI), Stretta (Curon Medical, Sunnyvale, Calif.), NDO Plicator (NDO Surgical, Mansfield, Mass.), have shown short-term improvements in gastroesophageal reflux disease (GERD) symptoms but without objective evidence of reduced lower esophageal acid exposure or long-term durability.[151] The Stretta procedure was the first interventional endoscopic GERD therapy to gain FDA approval in 2000. Consisting of a catheter, soft guidewire tip, balloon basket assembly, and four electrode delivery sheaths positioned radially, the Stretta device uses radiofrequency (RF) energy to increase the tone of the lower esophageal sphincter (LES). Its mechanism of action is unclear, but it is believed that the RF energy results in shrinkage of collagen fibers, resulting in elevation of postprandial LES pressure[152] and reduction of transient lower esophageal sphincter relaxations. Islam and colleagues studied the effects of the Stretta procedure on a small series of six pediatric patients (mean age 12 +/− 4 years), concluding that the procedure was safe and effective.[153] Five of the six patients were asymptomatic at 3 months, and three were able to discontinue antisecretory medication. Mean reflux score improved significantly after 6 months; however, pH studies were not done. Without significant improvements in acid exposure, the benefit of this procedure in children is questionable, because common indications for surgical management of pediatric GERD consist mainly of complications of esophageal acid exposure, such as esophagitis, pharyngitis, or aspiration, as opposed to minor GERD symptoms.

Also approved for use by the FDA in 2000, the EndoCinch system aims to reduce gastric reflux by pleating the gastroesophageal junction (GEJ). The 30- to 60-minute procedure begins with insertion of the Endocinch device through an overtube. Suction applied 1 to 2 cm below the squamocolumnar junction facilitates full-thickness placement of two adjacent sutures. The sutures are then "cinched" together or brought into approximation, to create a pleat. Usually several pleats are created, significantly narrowing the lumen at the GEJ. The resulting rosette of tissue (gastroplication) is intended to prevent reflux of gastric contents into the esophagus. Only one pediatric study describes the effects of the Endocinch system for treating GERD.[154] Seventeen patients with median age 12.4 years (range, 6.1 to 15.9 years) underwent gastroplication. All patients showed significant improvement in early postoperative assessments of symptom severity, symptom frequency, and quality of life. These effects persisted at 1-year follow-up in the majority of patients and were reflected in reduced pH indices. In adult patients, lack of long-term durability has been attributed to suture degradation and loss, both demonstrated on follow-up endoscopy.[155,156] The reason for the longer durability of this procedure in children compared with adults is unclear but may be a consequence of a greater ability to achieve full-thickness esophageal bites in the smaller patients.

The latest transoral endoscopic device on the market is the EsophyX (Endogastric Solutions, Redmond, Wash.), which is designed to achieve transoral incisionless fundoplication (TIF). The goal of this antireflux procedure is to endoluminally create an anteriorly placed 3- to 5-cm, 200- to 270-degree valve at the distal esophagus secured by special fasteners. The end result is creation of an antireflux barrier and reestablishment of the angle of His. The device does not have to be inserted and removed for each stitch, and its function allows reduction of a small hiatal hernia, although the crura remains unapproximated. Although adult studies have shown long-term reductions in proton pump inhibitor use, improved quality of life, and reduced esophageal acid exposure, data for the pediatric population is forthcoming.[157] Use of the device is limited only to larger children whose esophagi can accommodate a device that is 18 mm in diameter.

## SURGICAL ROBOTICS

Innovations in endoscopic technique and equipment continue to broaden the range of applications in minimal access surgery. However, many minimal access procedures have yet to replace the traditional open approach. Difficulties remain in achieving dexterity and precision of instrument control within the confines of a limited operating space. These difficulties are further compounded by the need to operate from a 2D video image. Robotic surgical systems have evolved to address these limitations.

Since their introduction in the late 1990s, the use of computer-enhanced robotic surgical systems has grown rapidly. Originally conceived to facilitate battlefield surgery, these systems are now used to enable complex minimal access surgical (MAS) procedures. In children, early reports described the feasibility of using surgical robots to complete common and relatively simple pediatric general surgical procedures.[158–160] More recently, the use of robotic surgical systems in human patients has been described in multiple surgical disciplines, including pediatric general surgery, pediatric urology, and pediatric cardiothoracic surgery.[161–163] In addition, the feasibility of complex, technically challenging procedures, such as robotic-assisted fetal surgery, has been reported in animal models.[164,165]

## Robotic Technology in Surgery

For several decades, robots have served in a variety of applications, such as manufacturing, deep-sea exploration, munitions detonation, military surveillance, and entertainment. In contrast, the use of robotic technology in surgery is still a relatively young field. Improvements in mechanical design, kinematics, and control algorithms originally created for industrial robots are directly applicable to surgical robotics.

The first recorded application of surgical robotics was for CT-guided stereotactic brain biopsy in 1987.[166] Since then, technologic advancements have led to the development of several different robotic systems. These systems vary significantly in complexity and function.

## Classification of Robotic Surgical Systems

One method of classifying robots is by their level of autonomy. Under this classification, there are currently three types of robots used in surgery: autonomous robots, surgical-assist devices, and teleoperators (Table 4-2).

An autonomously operating robot carries out a preoperative plan without any immediate control from the surgeon. The tasks performed are typically focused or repetitive but require a degree of precision not attainable by human hands. An example is the ROBODOC system (Curexo Technology, Fremont, Calif.) that is used in orthopedic surgery to accurately mill out the femoral canal for hip implants.[167] Another example is the CyberKnife system, previously referenced, which consists of a linac mounted on a robotic arm to precisely deliver radiotherapy to intracranial and spinal tumors.[168,169]

The second class of robot is the surgical-assist devices, where the surgeon and robot share control. The most well-known example of this group is the AESOP (*A*utomatic *E*ndoscopic *S*ystem for *O*ptimal *P*ositioning; formerly produced by Computer Motion, Goleta, Calif.). This system allows a surgeon to attach an endoscope to a robotic arm that provides a steady image by eliminating the natural movements inherent in a live camera holder. The surgeon is then able to reposition the camera by voice commands.

The final class consists of robots whose every function is explicitly controlled by the surgeon. The hand motions of the surgeon at a control console are tracked by the electronic controller and then relayed to the slave robot in such a manner that the instrument tips perfectly mirror every movement of the surgeon. Because the control console is physically separated from the slave robot, these systems are referred to as teleoperators. All the recent advances in robotic-assisted surgery have involved this class of machines.

**TABLE 4-2**
**Classification of Robotic Surgical Systems**

| *Type of System* | *Definition* | *Example* |
|---|---|---|
| Autonomous | System carries out treatment without immediate input from the surgeon | CyberKnife ROBODOC |
| Surgical-Assist | Surgeon and robot share control | Aesop |
| Teleoperators | Input from the surgeon directs movement of instruments | da Vinci System |

## Current Status of Robotic Technology Used in Pediatric Surgery

Currently, there is only one commercially available robotic surgical system—the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, Calif.). Though the da Vinci is popularly referred to as a surgical robot, this is a misnomer, because "robot" implies autonomous movement. The da Vinci does not operate without the immediate control of a surgeon. A better term may be "computer-enhanced telemanipulators." However, for the sake of consistency with published literature, this chapter will continue to refer to such systems as robots.

***The da Vinci Surgical System*** The da Vinci system is made up of two major components (Figs. 4-16 and 4-17).[162] The first component is the surgeon's console, which houses the visual display system, the surgeon's control handles, and the user interface panels. The second component is the patient side cart, which consists of two to three arms that control the operative instruments and another arm that controls the video endoscope.

The operative surgeon is seated at the surgeon's console, which can be located up to 10 meters away from the operating table. Within the console are located the surgeon's control handles, or masters, which act as high-resolution input devices that read the position, orientation, and grip commands from the surgeon's finger tips. This control system also allows for computer enhancement of functions, such as motion scaling and tremor reduction. The image of the operative site is projected to the surgeon through a high-resolution stereo display that uses two medical-grade cathode ray tube (CRT) monitors to display a separate image to each of the surgeon's eyes.

The standard da Vinci instrument platform consists of an array of 8.5-mm diameter instruments. These instruments provide 7 degrees of freedom through a cable-driven system.

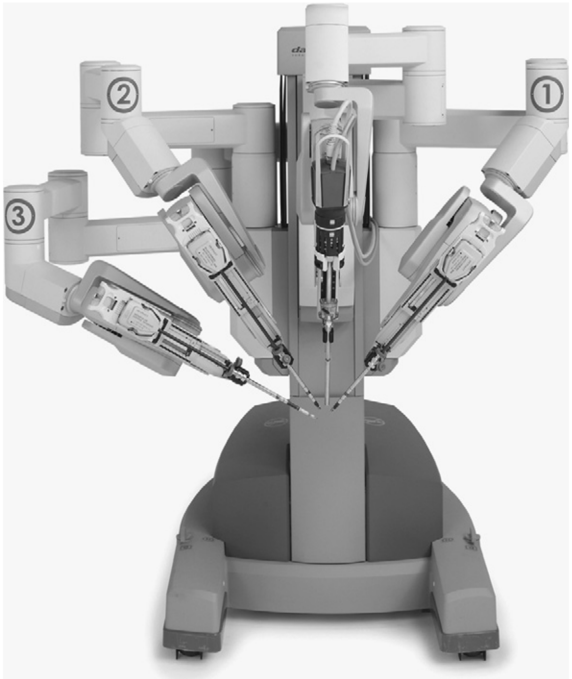

**FIGURE 4-16** The Intuitive Surgical da Vinci Si robotic surgical system (Courtesy Intuitive Surgical, Sunnyvale, Calif.)

FIGURE 4-17 The Intuitive Surgical da Vinci Si robotic surgical system. (Courtesy Intuitive Surgical, Sunnyvale, Calif.)

A set of 5-mm instruments are also available. These instruments use a "snake wrist" design and also provide 7 degrees of freedom (Fig. 4-18).

Since its inception in 1995, the da Vinci system has undergone several iterations. The current system, called the da Vinci Si, features high-definition optics and display as well as smaller and more maneuverable robotic arms. Other features include dual console capability for training purposes.

### Current Advantages and Limitations of Robotic Pediatric Surgery

The utility of the different robotic surgical systems is highly influenced by the smaller size of pediatric patients and the reconstructive nature of many pediatric surgical procedures. Overall, the advantages of the robotic systems stem from technical features and capabilities that directly address many of the limitations of standard endoscopic techniques and equipment. Unlike conventional laparoscopic instrumentation, which requires manipulation in reverse, the movement of the robotic device allows the instruments to directly track the movement of the surgeon's hands. Intuitive nonreversed instrument control is therefore restored, while preserving the minimal access nature of the approach. The intuitive control of the instruments is particularly advantageous for the novice laparoscopist.

In infants and neonates, the use of a magnified image via operating loupes or endoscopes is often necessary to provide more accurate visualization of tiny structures.[170,171] This enhanced visualization is taken a step further with robotic systems, because they are capable of providing a highly magnified, 3D image. The 3D vision system adds an additional measure of accuracy by enhancing depth perception and magnifying images by a factor of ten. The alignment of the visual axis with the surgeon's hands in the console further enhances hand–eye coordination to a degree uncommon in traditional laparoscopic surgery.

FIGURE 4-18 Articulated robotic instrument. (Courtesy Intuitive Surgical, Sunnyvale, Calif.)

Similarly, the presence of a computer control system enables electronic tremor filtration, which makes the motion of the endoscope and the instrument tips steadier than with the unassisted hand. The system also allows for variable motion scaling from the surgeon's hand to the instrument tips. For instance, a 3:1 scale factor maps 3 cm of movement of the surgeon's hand into 1 cm of motion at the instrument tip. In combination with image magnification from the video endoscope, motion scaling makes delicate motions in smaller anatomic areas easier and more precise.[160]

The da Vinci system uses instruments that are engineered with articulations at the distal end that increase their dexterity compared with traditional MAS tools. This technology permits a larger range of motion and rotation, similar to the natural range of articulation of the human wrist, and may be particularly helpful when working space is limited. The da Vinci instruments feature 7 degrees of freedom (including grip), while standard laparoscopic instruments are only capable of 5 degrees of freedom, including grip. This increased dexterity may be particularly advantageous during complex, reconstructive operations that require fine dissection and intracorporeal suturing.

Finally, by separating the surgeon from the patient, teleoperator systems feature ergonomically designed consoles that may decrease the fatigue often associated with long MAS procedures. This may become a more significant issue as the field of pediatric bariatric surgery develops because of the larger size and thicker body walls of bariatric patients.

Although robotic surgical systems provide several key advantages versus standard minimal access surgery, there are a number of technological limitations specific to pediatric surgery. First and foremost is the size of the robotic system. Compared with many pediatric surgical patients, the size of the da Vinci surgical cart may be overwhelming. This size discrepancy may restrict a bedside surgical assistant's access to the patient while the arms are in use, and may require the anesthesiology team to make special preparations to ensure prompt access to the patient's airway.[170]

The size and variety of available robotic instruments is limited compared with those offered for standard laparoscopy. Currently, the da Vinci system is the only platform undergoing further development at the industry level. A suite of 5-mm instruments with 7 degrees of freedom has been introduced for

use with this system. Although these instruments represent a significant improvement compared with the original 8.5-mm instruments regarding diameter, the number of instruments offered is still somewhat limited. Furthermore, these instruments use a new "snakewrist" architecture that requires a slightly larger amount of intracorporeal working room to take full advantage of their enhanced dexterity. Specifically, the instruments are limited by a greater than 10-mm distance from the distal articulating joint or wrist and the instrument tip.

There are a number of general limitations inherent to the available robotic surgical system that must be overcome before they are universally accepted in pediatric as well as adult surgery. These include the high initial cost of the robotic systems as well as the relatively high recurring costs of the instruments and maintenance.[162] In addition, this system does not offer true haptic feedback.[170] Even though such feedback is reduced in standard minimal access surgery compared with open surgery, it is further reduced or absent with a robotic interface. This disadvantage is partially compensated for by the improved visualization offered by the robotic systems, but it remains a potential drawback when precise surgical dissection is required.

The robotic systems require additional, specialized training for the entire operating room team. This translates into robotic procedure times that are predictably longer when compared with the conventional laparoscopic approach, at least until the surgical team becomes facile with the use of the new technology. Even with an experienced team, setup times have been reported to require an additional 10 to 35 minutes at the beginning of each robotic-assisted case.[170]

### Applications of Robotic Technology to Pediatric Surgery

To date, only a small body of literature regarding the application of robotic technology for pediatric surgical procedures has shown the feasibility of robotic-assisted surgery. A wide variety of abdominal and thoracic procedures have been reported in the fields of pediatric general, cardiothoracic, and urologic surgery. The bulk of the literature represents class IV evidence, consisting of case reports and case series with no class I evidence. In 2009, van Haasteren and colleagues[172] reviewed the literature and found a total of eight peer-reviewed case series and five studies comparing robotic surgery with open or conventional laparoscopic surgery. Several of the studies had a retrospective design, and there were no randomized studies. From their review, they concluded that the published literature demonstrates that robotic surgical systems can be safely used to perform a variety of abdominal and thoracic operations. They were not able to identify evidence that robotic-assisted surgery provided any improvement in clinical outcomes compared with conventional open or laparoscopic surgery.[172]

The first reports describing the use of robotic surgical systems for abdominal procedures in children were published in 2002,[158,160] and robotic-assisted surgery has only seen modest adoption in the field of pediatric general surgery. The cause of this is likely multifactorial and in many ways mirrors the adoption curve seen in adult general surgery. To date, robotic-assisted surgery has found the most widespread adoption in the field of adult urology, specifically for prostatectomies. This operation takes advantage of the strengths of the current robot, namely articulated instruments and 3D visualization that assist in the complex dissection and reconstruction required in a narrow space. It is also a single quadrant operation that does not require significant repositioning of either the patient or the robotic system once the procedure begins. Lastly, prostatectomies are a relatively high-volume operation that is reproducible. This leads to improved efficiency, because the operating room team has only one setup to master. In contrast, the field of pediatric general surgery is characterized by a wide variety of complex but low-volume operations performed in small children. There is no high-volume operation in pediatric general surgery that takes advantage of robotic assistance. In addition, the instrument size and haptic limitations of the current robotic system are not ideal for use in many of our smaller patients.[173] These issues will likely be addressed by further advancement of the technology, with evolved incarnations of robotic surgery possibly playing a larger role in pediatric general surgery in the future.

## Microtechnologies and Nanotechnologies—Size Matters

An arsenal of technology will emerge from material science and its application principles to microelectromechanical systems (MEMS)[174,175] and nanoelectromechanical systems (NEMS). Just as the electronics industry was transformed by the ability to manipulate electronic properties of silicon, the manipulation of biomaterials at a similar scale is now possible. For the last 40 years the common materials of stainless steel, polypropylene, polyester, and polytetrafluroethylene have been unchanged. A recent example of this potential is the use of nitinol (equiatomic nickel-titanium), a metal alloy with the property of shape memory.

An important concept and distinction in device manufacturing is that of the "top down" versus "bottom up" assembly. Top down refers to the concept of starting with a raw material and shaping it into a device. In a typical MEMS device, silicon is etched, heated, and manipulated to its final form. In the nascent field of nanotechnology, the underlying conceptual principle is that of self-assembly. Here component ingredients are placed together under optimal conditions and self assemble into materials. This process is much more one of biologic assembly.

### Microelectromechanical Systems

The evolution of surgical technology has followed the trends of most industries—the use of technology that is smaller, more efficient, and more powerful. This trend, which has application in the medical and surgical world, is embodied in MEMS devices.

Most MEMS devices are less than the size of a human hair, and although they are scaled on the micron level, they may be used singly or in groups. MEMS devices have been used for years in automobile airbag systems and in inkjet printers.

Because the medical community relies increasingly on computers to enhance treatment plans, it requires instruments that are functional and diagnostic. Such a level of efficiency lies at the heart of MEMS design technology, which is based

on creating devices that can actuate, sense, and modify the outside world on the micron scale. The basic design and fabrication of most MEMS devices resemble the fabrication of the standard integrated circuit, which includes crystal growth, patterning, and etching.[176]

MEMS devices have a particular usefulness in biologic applications because of their small volumes, low energy, and nominal forces.[177] Increased efficacy of instruments and new areas of application are also emerging from specific and successful biomedical applications of MEMS.[178] There are two basic types of MEMS devices: sensors and actuators. Sensors transduce one type of energy (such as mechanical, optical, thermal, or otherwise) into electrical energy or signals. Actuators take energy and transform it into an action.

### Sensors

Sensors transduce or transform energy into an electrical signal. The incoming energy may be mechanical, thermal, optical, or magnetic. Sensors may be active or passive systems. Active sensors can derive their own energy from an input signal, whereas passive sensors require an outside energy source to function. Almost all of these devices are in their developmental stage but give form to the concept.

***Data Knife and H-Probe Surgical Instruments*** MEMS devices are particularly suited to surgical applications, because their small dimensions naturally integrate onto the tips of surgical tools. One example is the “Data Knife” (Verimetra, Pittsburgh, Penn.), which uses microfabricated pressure sensors that are attached to the blade of a scalpel (Fig. 4-19). While cutting, the Data Knife pressure sensors cross reference with previously gathered ex vivo data to inform the surgeon about the type of tissue that is being divided. This information becomes particularly useful during endoscopic cases in which a sense of tactile feedback is reduced or lost entirely.

Verimetra’s H-probe uses similar sensors to “palpate” calcified plaques transmurally during coronary bypass surgery. The intention is to eliminate poor positioning of the bypass graft conduit by more precisely targeting an ideal anastomotic site before arteriotomy.

***Arterial Blood Gas Analyzer*** MEMS technology can be applied to the analysis of arterial blood gases. This MEMS-based analyzer was founded on established methods in infrared spectroscopy. It consists of an infrared light source, an infrared sensor, and an optical filter. The infrared light is passed through the filter, which is designed to monitor the infrared spectrums of oxygen, carbon dioxide, and other associated blood gases. Because most gases have a known infrared absorption, the sensor can be designed with specific values for infrared signatures.

Once again, because of microscaling techniques and because of the relatively small sample size, the test can be performed in less time than conventional arterial blood gas analysis. One specific example is an arterial blood gas catheter for monitoring blood in preterm infants, in which real-time data can be gathered by way of oxygen and carbon dioxide–specific sensors.

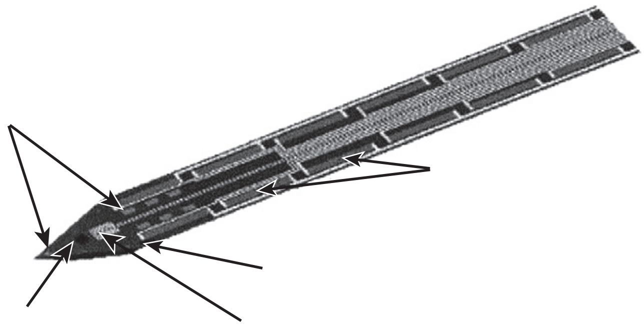

**FIGURE 4-19** Data Knife MEMS-based scalpel. (Courtesy of Verimetra, Pittsburgh, Penn.)

***Blood Pressure Sensor*** The biggest success story in medical MEMS technology is the disposable blood pressure sensor. Disposable blood pressure sensors replace reusable silicon-beam or quartz-capacitive pressure transducers that can cost as much as $600 and have to be sterilized and recalibrated for reuse. These expensive devices measure blood pressure with a saline solution–filled tube-and-diaphragm arrangement that must be connected directly to the arterial lumen. In the silicon MEMS blood pressure transducer, pressure corresponds to deflection of a micromachined diaphragm. A resistive element, a strain gauge, is ion implanted on the thin silicon diaphragm. The piezo-resistor changes output voltage with variations in pressure. Temperature compensation and calibration can be integrated in one sensor.

***Other MEMS Sensors in Medicine*** The Wheatstone bridge piezo-resistive silicon pressure sensor is a prime example of a MEMS device that is used commonly in medical applications. Able to measure pressures that range from less than 0.1 to more than 10,000 psi, this sensor combines resistors and an etched diaphragm structure to provide an electrical signal that changes with pressure. These types of sensors are used primarily in blood pressure monitoring equipment, but their use in the medical field extends to respiratory monitors, dialysis machines, infusion pumps, and medical drilling equipment. They are also used in inflatable hospital bed mattresses to signal an alarm upon detection of a lack of motion over a significant period of time.

### Actuators

An actuator is a fluid-powered or electrically powered device that supplies force and motion. There are several kinds of actuators used in MEMS devices. These include electrostatic, piezoelectric, thermal, magnetic, and phase recovery. Actuators in medicine are used in valves, accelerometers, and drug delivery systems. Future use to produce muscle activation or “artificial muscles” is predicted.

### Drug Delivery Systems

MEMS devices are used in drug delivery systems in the form of micropumps. A typical drug pump consists of a pump chamber, an inlet valve, an outlet valve, a deformable diaphragm, and an electrode. When a charge is applied to the electrode, the diaphragm deforms, which increases the volume in the pump chamber. The change in volume induces a decrease in pressure in the pump chamber. This opens the inlet valve. When the charge is terminated, the pressure returns to normal, by closing the inlet valve, opening the outlet valve, and allowing the fluid to exit. Other micropumps incorporate pistons or pressurized gas to open the outlet valves.

One of the more attractive applications for implantable pumps is insulin delivery. There are disadvantages of current insulin micropumps, most notably their expense. The drug supply must be refilled once every 3 months, and each pump costs between $10,000 and $12,000. Furthermore, insulin is unstable at core body temperature. Therefore an insulin analogue must be synthesized that would be stable at physiologic temperatures. Thinking forward, a biomechanical pancreas, which senses glucose and insulin levels and titrates insulin delivery, would be an interesting MEMS combination of a sensor and an actuator.

### Next Steps for MEMS

MEMS devices are in the same state today as the semiconductor industry was in the 1960s. Like the first semiconductors, MEMS devices are now largely funded by government agencies, such as the Defense Advanced Research Projects Agency (DARPA). Relatively few commercial companies have taken on MEMS devices as a principal product. However, no one could have predicted in 1960 that, 40 years later, a conglomerate of semiconductors would be on virtually every desktop in the United States. It is then not unreasonable to predict potential value, including surgical applications, for MEMS devices.

Indwelling microsensors for hormone and peptide growth factors might replace episodic examinations, lab determinations, or CT scans to monitor tumor recurrence. As more devices are fabricated, the design process becomes easier, and the next technology can be based on what was learned from the last. At some point in the future, we will view MEMS devices as common surgical modalities, smart instruments, inline laboratories, surveillance devices, and perhaps for cellular or even DNA insertion.

## NANOELECTROMECHANICAL SYSTEMS

Applications of nanotechnology and nanoelectromechanical systems in medicine and surgery have been recently reviewed.[175] Size does matter. In medicine and biology, the major advantage of decreasing size scale is the ability to enable materials or particles to find places in body compartments to which they could otherwise not be delivered. Current and future applications of surgical interest include coating and surface manipulation, the self-assembly or biomimicry of existing biologic systems, and targeted therapy in oncology.

### Coating and Surface Manipulation

Although most medical devices are composed of a bulk material, biologic incorporation or interaction occurs only at the thinnest of surfaces. To optimize this surface interaction, sintered orthopedic biomaterials have been developed. A thin layer of beads are welded or "sintered" by heat treatment on top of the bulk material.[179] This bead layer optimizes bone ingrowth, while the bulk material is responsible for the mechanical stability of the device. Hydroxyapatite-coated implants represent a biologically advanced coating of the device with ceramic hydroxyapatite,[180] thereby inducing bony ingrowth by mimicking the crystalline nature of bone (biomimicry). Future attempts involve coating with the RGD peptide, the major cell attachment site in many structural proteins.

Cardiovascular stents, and now drug-eluting stents, provide a similar example. The current generation of drug eluting stents has a micron-thick coating made of a single polymer that releases a drug beginning at the time of implantation.[181] The drug coating of rapamycin or paclitaxel diffuses slowly into the tissue microenvironment to prevent a fibrotic reaction. The future ideal stent will likely be engineered to optimize the bulk material and the coating. Indeed, the perfectly biocompatible material may be one in which a bulk material is artificial and the surface is seeded with the patient's own cells, for example, an endothelialized Goretex vascular stent.[182]

### Self Assembly

NEMS materials are produced from a self-directed or self-assembly process in which mixtures of materials are allowed to condense into particles, materials, or composites.[183] Thus NEMS processing starts with a nonsolid phase, typically a solution, and by manipulating the environment, materials are created.

Recently, biologic molecules such as proteins and DNA have been used to stabilize nanoparticle crystals and create materials with unique properties, opening the door to unlimited diversity in the next generation of nanoparticles and materials.[184,185] Such processes mimic nature's ability to produce materials such as pearls, coral, and collagen.

### NEMS in Oncology

More than in any other field, microscale and nanoscale technologies will provide the field of oncology with critical therapeutic advances. In considering the perverse biologic process of malignant transformation and spread, our current therapies are gross and nontargeted. Figure 4-20 depicts a complex nanoparticle[186] composed of an iron oxide core surrounded by silicon oxide shells. Ligands may be attached to the silicon oxide coating that may then target the iron oxide to a specific site. Such technology can be used for diagnostic purposes based on tumor permeability and therapeutic options.

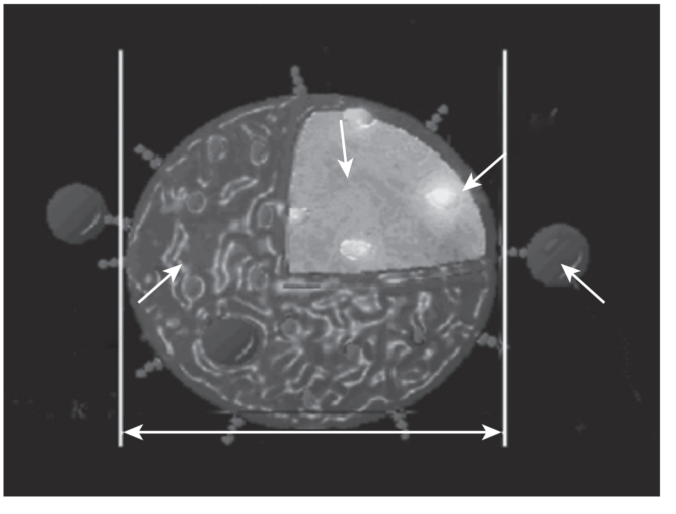

FIGURE 4-20 A schematic of a nanoparticle. An iron oxide core is surrounded by a silicon oxide shelf. Ligands attached to the silicon oxide can target the iron oxide to a specific site or potentially a tumor. The iron oxide can be heated in a magnetic field. Alternatively, the iron oxide may carry a toxin, a gene, or a pharmaceutical. Surface arrows highlight customized ligands while inner arrows point out therapeutic materials that can be placed in the iron oxide core.

Harisinghani and colleagues[186] used iron oxide nanoparticles to identify tumor metastases in lymph nodes of patients with prostate cancer. The authors demonstrated increased sensitivity and specificity in identifying nodes that ultimately contained tumor. Further work with magnetic nanoparticles functionalized with tumor-specific antibodies will enhance a specific uptake by tumors.

# Surgical Innovator

Most clinical innovations in surgery relate to a novel operation, a novel device, or both. Occasionally, the novel procedure or device is of the surgeon's own development. In all cases, the surgeon holds the responsibility of ensuring that the implementation of these innovations is done in an ethical fashion. There are guidelines that surgeons can follow to help them safely and ethically introduce innovative solutions to their practice.

## INNOVATIVE DEVICES

In the United States, pediatric research falls under the regulation of institutional review boards (IRBs), which serve the purpose of upholding the guidelines set forth by state and federal legislative bodies. The FDA regulates the use of all surgical devices.[187] Although the majority of pediatric surgeons will not design large clinical trials or novel devices, it is helpful to understand the regulatory processes when implementing new techniques or devices into one's practice.

The FDA categorizes new devices into three classes based on the potential risk incurred by using the device in humans. Class I devices pose minimal harm to the recipient and do not typically require premarket notification or approval (i.e., clinical data supporting safety and efficacy). Class II devices pose an intermediate level of potential harm but have demonstrated clinical efficacy comparable to similar existing devices. Class III devices pose significant potential harm to the recipient and require premarket approval with clinical data supporting safety and efficacy.

If a surgeon intends to study a novel device as part of a clinical trial in humans, the collection of preliminary data for non-FDA–approved devices is regulated by IRBs. If an IRB determines that the device provides insignificant risk to the study participants, the study may proceed. However, if an IRB concludes that the proposed study exposes the participants to significant risk, the FDA must approve an investigational device exemption prior to commencement of the study.[187]

If a device treats a condition that affects less than 4000 people per year in the United States, which applies to most pediatric conditions, it may qualify for humanitarian device exemptions (HDE). This allows approval of such devices when safety has been demonstrated and the probable benefits outweigh the risks of using the device.[187] HDE aids in disseminating high-impact technologies designed for rare conditions, technologies that would otherwise have delayed time to market because of the inability to properly power premarket clinical trials.

The pediatric surgeon using a novel non-FDA–approved device should obtain IRB approval. If there is sufficient patient risk associated with the use of the novel device, the investigator must obtain investigational device exemption from the FDA. Once clinical safety and efficacy are established, one can apply for FDA approval. If the device has significant potential benefit for an uncommon disease, the investigator has the option to apply for an HDE.

## INNOVATIVE PROCEDURES

An innovative procedure may be composed of a new way of surgically correcting a condition, with or without the use of a device not approved for that use. Minor modifications to existing procedures would not be included in this category. The off-label use of an adult device in children may or may not be seen as innovative, depending on the circumstances surrounding its use. In all cases, a reasoned approach, such as that outlined in Table 4-3, can help to ensure safe and effective implementation of the innovation.

The Department of Health and Human Services (DHHS) categorizes pediatric research into four successive categories based on the degree of risk and the potential benefit to the study participant.[188] The first three of these codes encompass studies with potential for benefit to the participant with relatively low levels of risk exposure. The fourth code includes research that exposes participants to the potential risk in the *absence* of direct or indirect benefit but that has the potential to benefit children in general. A study that falls under this category may not be approved solely by an IRB but must have the authorization of the Secretary of the DHHS.

All pediatric research proposals, regardless of which DHHS code they fall under, must demonstrate an appropriate process for obtaining both patient *assent* and parent/guardian *consent* as defined by The American Academy of Pediatrics Committee on Bioethics.[189] The currently accepted standard of care is to obtain patient assent prior to enrollment in a study when feasible (i.e., when the patient is developmentally capable of affirming participation after receiving a cognitive age-appropriate explanation of the study/procedure, risks, benefits, and alternative options). Parental permission/consent is required whenever possible (i.e., nonemergent settings) if the patient is a nonemancipated minor. Practically speaking, parental permission/consent involves all of the components of informed consent in an adult population.

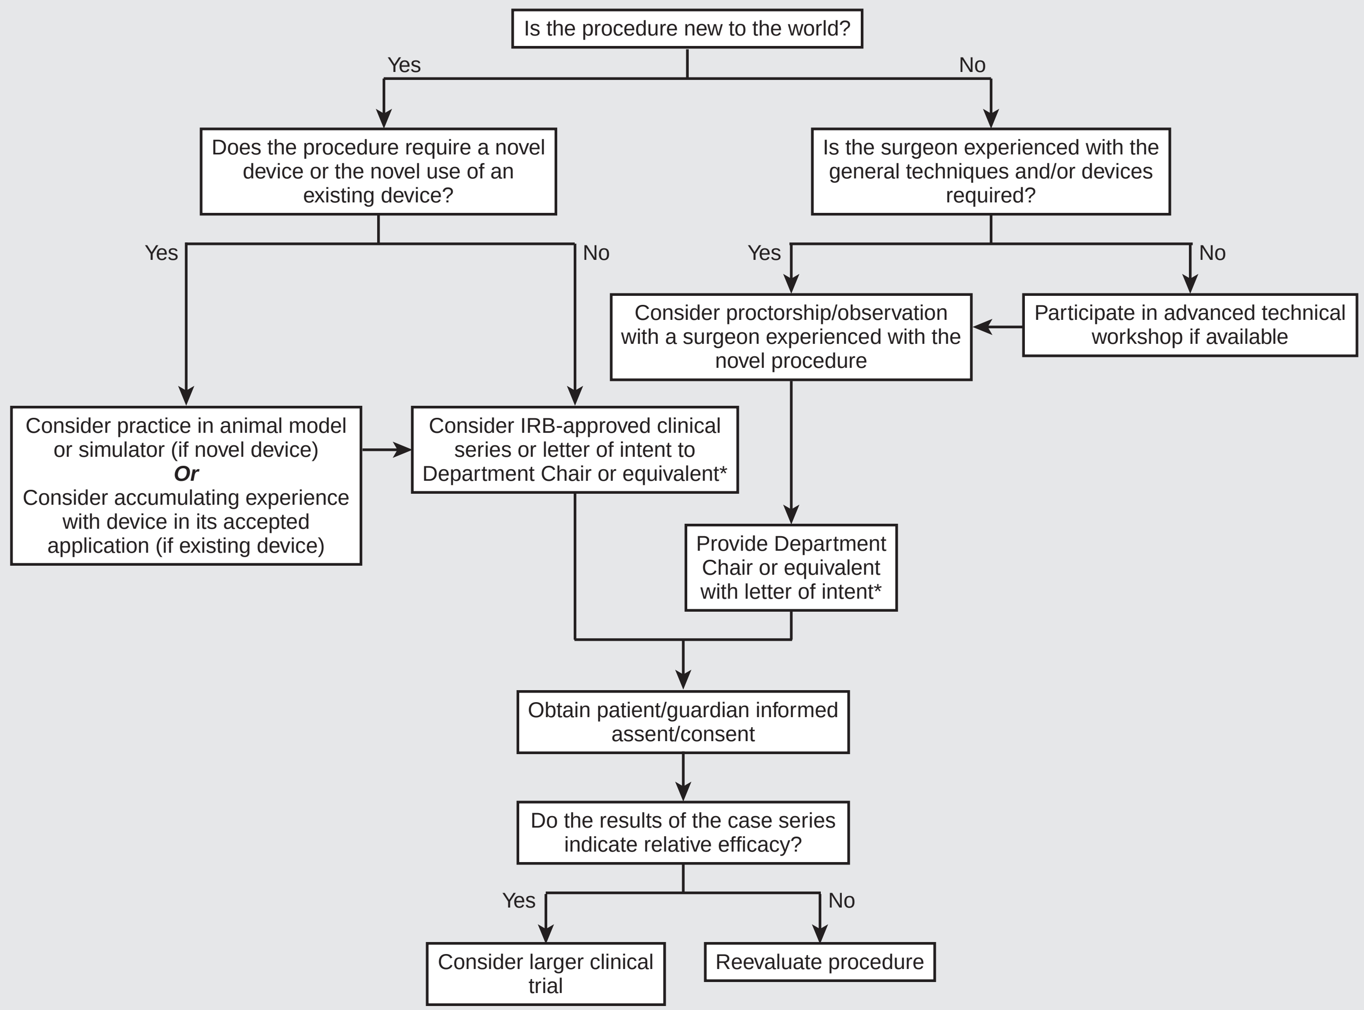
## PEDIATRIC DEVICE DEVELOPMENT

The medical device industry has shown little interest in pediatric device development because of small market sizes and regulatory hurdles.[190] Similarly, entrepreneurs trying to promote medical device concepts have had little success in getting their ideas funded through typical funding channels, such as venture capital, for these same reasons. The consequence is that pediatric surgeons and others performing pediatric procedures are left to use adult devices off-label in children, "jerry-rig" their own devices, or simply do without. All of these approaches potentially result in a substandard level of care for pediatric patients.

Recognizing the dire need for pediatric-specific devices and the lack of interest from medical device companies, medical practitioners have in recent years taken a more active role in pediatric device development. More focused efforts at pediatric specific medical device innovation have emerged, in response to the dearth of innovation for this population.

**TABLE 4-3**

**Approach to Introducing Innovative Procedures into Pediatric Surgical Practice**



*Letter should include description of existing foundational technique(s), a description of the novel technique, a summary of the published results comparing the novel technique to existing technique(s) if available, and a description of the preparation undertaken by the surgeon prior to attempting the novel procedure.

From Kastenberg Z, Dutta S: Guidelines for innovation in pediatric surgery. J Laparoendosc Adv Surg Tech A 2011;21:371–374.

In September 2007, President George W. Bush signed into law the *FDA Amendments Act of 2007*, which included *Title III: Pediatric Medical Device Safety and Improvement Act*. This Act, which was designed to improve the research, manufacture, and regulatory processes for pediatric medical devices, also aimed to establish nonprofit consortia to stimulate development of pediatric devices. As a consequence, the United States Congress charged the FDA with dispersing grant funds for the creation of pediatric device consortia (PDC), organizations devoted to creating a national platform for the development of pediatric-specific medical devices, and demonstrating the timely creation of such devices. The first of these consortia include the PDC at University of California, San Francisco (http://www.pediatricdeviceconsortium.org) led by Dr. Michael Harrison, the University of Michigan PDC (http://peddev.org) led by Dr. James Geiger, the Pediatric Cardiovascular Device Consortium at Boston Children's Hospital led by Dr. Pedro Del Nido, and the Multidisciplinary Initiative for Surgical Technology Research (MISTRAL; www.mistralpediatric.org), a collaborative effort between one of the authors (SD) representing Stanford University and SRI International, an engineering firm based in Menlo Park, Calif. Notably, three of these four consortia are led by pediatric general surgeons, attesting to the pioneering role our specialty can play in the advancement of pediatric medical technologies. These consortia have taken the lead in establishing formalized collaborative ventures that engage clinical and technical expertise in needs identification, foundational science research, and device design and prototyping. Going beyond the typical role of the academic institution, these collaborative groups are also identifying paths to market for the devices they develop through such strategies as spin-off companies or partnerships with commercialization entities.

Furthermore, the consortia provide pediatric surgeons-in-training an opportunity to immerse themselves in the innovation process, focusing specifically on the unique challenges of developing devices for children.

The market strategy for pediatric devices depends on the nature of the device. For example, many pediatric applications may require a device to be miniaturized for use in children. The technical solutions used to achieve this can then be applied in much larger adult markets. In areas such as minimal access surgery, smaller devices are also seen as beneficial for adult applications. This "trickle up" effect of the technology to adult applications can justify production of the device for pediatric markets because of the potential to also use it in much larger adult markets. Licensing to commercialization entities interested in applying the technology to adult markets may come with the caveat that they also address the pediatric need. In some circumstances where the device is quite specific to a rare pediatric condition, philanthropic support may be necessary to help it get to market, such as that by an individual or a foundation with particular interest in child health or the specific disease.

Device development can be seen as a form of translational science, where the basic research, design, prototyping, and testing of novel devices comprise unique intellectual contributions. Some institutions are beginning to recognize the scholarly potential for device innovation and crediting the researchers engaged in it, thus making it a potential basis for academic promotion. The measures of scholarly productivity may be different than traditional research tracks but nevertheless hold value for the academic institution. For example, device innovators may not be able to publish extensively because of concerns about protection of intellectual property (at least in the initial stages of device development), but the generation of grants, patents, and usable devices that positively impact healthcare can have great value for the institution.

# Innovative Surgical Training

The practice of surgery is a visual, cognitive, and manual art and science that requires the physician to process increasingly large amounts of information. Techniques are becoming more specific and complex, and decisions are often made with great speed and under urgent circumstances, even when rare problems are being addressed. Simulation and virtual reality (VR)[191,192] are two concepts that may reshape the way we think about surgical education, rehearsal, and practice.

## SURGICAL SIMULATION

Simulation is a device or exercise that enables the participant to reproduce or represent, under test conditions, phenomena that are likely to occur in actual performance. There must be sufficient realism to suspend the disbelief of the participant. Simulation is firmly established in the commercial airline business as the most cost-effective method of training pilots. Pilots must achieve a certain level of proficiency in the simulator before they are allowed to fly a particular aircraft and must pass regular proficiency testing in the simulator to keep their licenses. Military organizations use a similar method for training in basic flying skills and find simulation useful in teaching combat skills in complex tactical situations. Surgical simulation therefore has roots in the techniques and experiences that have been validated in other high-performance, high-risk organizations.

The expense and risk of learning to fly motivated Edward Link to construct a mechanical device he called "the pilot maker" (Link, http://www.link.com/history.html). The addition of instrument sophistication enables the training of individuals to fly in bad weather. At the onset of World War II, with an unprecedented demand for pilot trainees, tens of thousands were trained in Link simulators.[193]

The medical community is beginning to use simulation in several areas for training medical personnel, notably surgeons, anesthesiologists, phlebotomists, paramedics, and nurses. The ability of the simulator to drill rehearsed pattern recognition repetitively in clinical practice makes just as much sense for the surgical disciplines as it does for aviators. Surgical care entails a human risk factor, which is related to both the underlying disease and the therapeutic modality. Risk can be reduced through training. One of the ways to accomplish both of these goals is through simulation.

Simulation is loosely defined as the act of assuming the outward qualities or appearances of a given object or series of processes.[194] It is commonly assumed that the simulation will be coupled with a computer, but this is not requisite. Simulation is a technique, not a technology, used to replace or amplify real experiences with guided experiences that evolve substantial aspects of the real world in a fully interactive manner.[195] To perform a simulation, it is only necessary to involve the user in a task or environment that is sufficiently "immersive" so that the user is able to suspend reality to learn or visualize a surgical teaching point. The knowledge that is gained is then put to use in education or in the live performance of a similar task. Just as one can simulate a National Football League football game with a console gaming system, surgeons can learn to tie knots using computer-generated virtual reality, or simulate the actions of a laparoscopic appendectomy with the use of a cardboard box painted to resemble a draped abdomen.

### Visual Display Systems in Simulation

Simulator technology involves the design of training systems that are safe, efficient, and effective for orienting new trainees or providing advanced training to established clinicians. This involves teaching specific skills and generating scenarios for the simulation of critical or emergent situations. The entertainment industry is by far the main user and developer of visual displays. So much headway has been made in the advancement of visual technologies by the entertainment industry that many visual devices that are used in simulation are borrowed from these foundations. Considering that the graphic computing power of a $100,000 supercomputer in 1990 was essentially matched by the graphic capability of a $150.00 video game system in 1998, the available technology today is more than capable of representing a useful surgical simulation faithfully.[196]

Props are a key component of the visual act of simulation. Although laparoscopic surgical procedures can be represented on a desktop computer, a much more immersive experience can be carried out by involving monitors and the equipment used in an actual operating room. For example, mannequin simulators, although internally complex, can serve to complement the

simulation environment. Simulation of procedures, such as laparoscopic operations, should use displays similar to those used in the actual operating room.

Simulation of open procedures, on the other hand, requires systems that are presently in the developmental stages. The level of interaction between the surgeon and the simulated patient requires an immersive visualization system, such as a head-mounted display. The best approach for a developer of a simulator for open procedures would be to choose a system with good optical qualities and concentrate on developing a clear, stable image. Designs for this type of visualization include "see-through displays" in which a synthetic image is superimposed on an actual model.[176] These systems involve the use of a high-resolution monitor screen at the level of the operating table. The characteristics of the displayed image must be defined in great detail.

### Human/Simulator Interface and Tactile Feedback

Force feedback is the simulation of weight or resistance in a virtual world. Tactile feedback is the perception of a sensation applied to the skin, typically in response to contact. Both tactile and force feedback were necessary developments, because the user needs the sensation of touching the involved virtual objects. This so-called ***haptic loop***, or the human-device interface, was originally developed with remote surgical procedures in mind and has much to lend to the evolution of surgical simulation.

Technologies that can address haptic feedback are maturing, as noted by rapid development of haptic design industries in the United States, Europe, and Japan and in many university-based centers.[197] Haptic technologies are used in simulations of laparoscopic surgical procedures, but extending this technology to open procedures in which a surgeon can, at will, select various instruments will require a critical innovation.

### Image Generation

The generation of 3D, interactive, graphic images of a surgical field is the next level in surgical simulation. Seeing and manipulating an object in the real world is altogether different from manipulating the same object in virtual space. Most objects that are modeled for simulations are assumed to be solids. In human tissue, with the possible exception of bone, this is not the case. Many organs are deformable semisolids, with potential spaces. Virtual objects must mirror the characteristics of objects in the real world. Even with today's computing power, the task of creating a workable surgical surface (whether skin, organ, or vessel) is extremely difficult.

A major challenge in the creation of interactive surgical objects is the reality that surgeons change the structural aspects of the field through dissection. On a simulator, performing an incision or excising a problem produces such drastic changes that the computer program supporting the simulation is frequently incapable of handling such complexity. This also does not include the issue of blood flow, which would cause additional changes to the appearance of the simulated organ. Furthermore, the simulation would have to be represented in real time, which means that changes must appear instantaneously.

To be physically realistic, simulated surgical surfaces and internal organs must be compressible in response to pressure applied on the surface, either bluntly or by incision. Several methods of creating deformable, compressible objects exist in computer graphic design.

Frequently, simulator graphic design is based on voxel graphics. A voxel is an approximation of volume, much in the same way a pixel is an approximation of area. Imagine a voxel as a cube in space, with length, width, and depth. Just as pixels have a fixed length and width, voxels have a fixed length, width, and depth. The use of volume as the sole modality to define a "deformable object," however, does not incorporate the physics of pressure, stress, or strain. Therefore the graphic image will not reflect an accurate response to manipulation. The voxel method does not provide a realistic representation of real-time changes in the organ's architecture, which would occur after a simulated incision.

A more distinct approach to the solution for this problem is with the use of finite elements. Finite elements allow the programmer to use volume, pressure, stress, strain, and density as bulk variables. This creates a more detailed image, which can be manipulated through blunt pressure or incision. Real-time topologic changes are also supported.

For the moment, a good alternate solution to the problem is to avoid computational models. Some groups have used hollow mannequins with instruments linked to tracking devices that record position. Task trainers allow one to practice laparoscopic skills directly by the use of the equivalent of a cardboard box with ports to insert endoscopic tools. These tools are used to complete certain tasks, such as knot tying or object manipulation.

### Simulation in Education, Training, and Practice

Historically, surgical training has been likened to an apprenticeship. Residents learn by participating, taking more active roles in patient care or the operative procedure as their experience increases. Despite potential flaws, this model has successfully trained generations of surgeons throughout the world. Error and risk to patients are inherent in this traditional method of education, despite honest attempts at mitigation, and will always be a factor in the field of surgery, no matter how it is taught. New methods of surgical training exist, however, that can help to reduce error and risk to the patient.[198,199]

Training in simulated environments has many advantages. The first advantage is truly the crux of simulation: It provides an environment for consequence-free error, or freedom to fail. Simulator-based training incurs no real harm, injury, or death to the virtual patient. If a student transects the common duct during a simulated cholecystectomy, the student simply notes the technical error and learns from the mistake. Furthermore, simulations can be self directed and led by a virtual instructor or can be monitored and proctored by a real instructor. This means that the student can learn on his or her own time, outside of the operating room.[200]

Simulators are pliable tools. Depending on the assessment goals of a particular simulator, tasks can be modified to suit the educational target. For example, self-contained "box trainers," which are used to teach a particular dexterous skill, can be modified to be less or more difficult or to teach grasping skills versus tying skills. In more complex computer-based simulations, variables can be changed automatically by the computer or manually by the instructor, even during the simulation. These variables range from changes in the graphic overlay to the introduction of an unexpected medical emergency. Approaches to learning laparoscopic navigational skills within the human body have benefited considerably from

such techniques. A prime objective of surgical education is to learn how to function mentally and dexterously in a 3D environment. Surgical "fly-through" programs can be invaluable resources to learn this kind of special orientation inside the human body.[201]

Perhaps one of the greatest benefits of surgical simulation is the ability of early learners to become skilled in basic tasks that have not been previously presented in formal training. The orientation of medical students, now frequently excluded from patient care tasks, may aid in their engagement, education, and recruitment to surgical careers. Therefore the most consistent success has been the discovery that simulators are most beneficial to individuals with little or no previous experience in the simulated task.[202]

### Looking Forward

Simulation successes, particularly in the aviation industry, strongly suggest utility to medical and surgical applications. As with any form of new technology, advances depend on many factors. A product made solely for the sake of technology is doomed to fail; therefore the simulation market must be driven by clinical and educational need. In these early stages of surgical simulation, simpler, mannequin-based trainers have proven to be more useful. However, as graphic design and human interface technology evolve, simulations become more realistic, and equipment prices fall, more immersive computer-generated models will lead the way for this unique form of continuing medical education.

## VIRTUAL REALITY

Virtual reality (VR), although closely related to simulation, has many unique aspects. Simulation is the method for education and training; VR is the modality for making simulation look more real. VR, simply stated, is the creation of a 3D artificial environment with which a user in the real world may interact. VR, in contrast to simulation, almost always relies on computers and computer software to generate a virtual environment. Furthermore, an interface device is required to immerse the user.[203] This device could be as simple as a mouse or keyboard or as complex as VR-based goggles or headsets. The basic intention of VR is to divert the user's attention from the outside world to a manufactured, virtual world with detailed, interactive content based on visuals, sound, and touch. When optimized, such an experience would immerse the participants such that reality becomes this virtual environment.

Although the term *virtual reality* was introduced by Jaron Lanier in 1989, the concept as we currently know it emerged long before that time. In 1963, funding from the Advanced Research Projects Agency (ARPA) gave Ivan Sutherland the opportunity to create Sketchpad, one of the first graphics design tools. By this time, Sutherland was developing the head-mounted display (HMD), which heralded the theories and themes of modern immersive science (Fig. 4-21).

Sutherland used what he learned in his research with HMDs to create scene generators for Bell Helicopter Laboratories. With scene generation, computer graphics would replace the standard video camera–generated display used in the flight simulators manufactured by Bell Laboratories (Fig. 4-22). With his partner, David Evans, Sutherland founded Evans & Sutherland, Inc., which is currently based in Salt Lake City

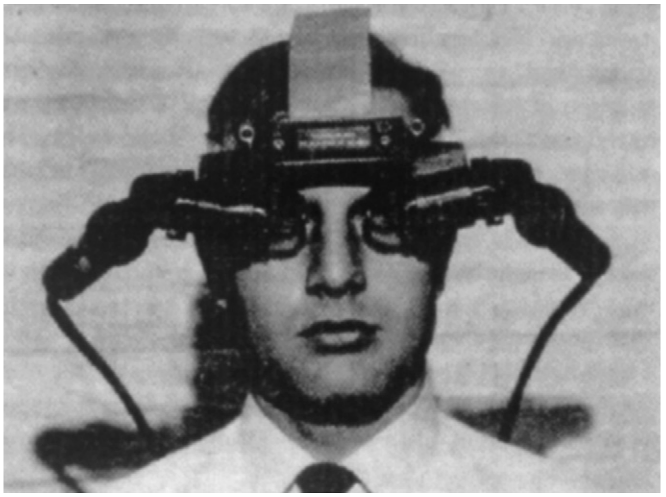


**FIGURE 4-21** Sutherland's head-mounted display. (From National Systems Contractors Association Multimedia Online Expo, "Science for the New Millenium.")

and designs several VR-based products. Sutherland's foray into medicine occurred in 1971, when he developed the first arterial anastomosis simulation. With the simultaneous development of computer interface tools, such as the mouse, VR immersion became possible, because the ordinary user could now interact easily with the computer in a manner that was more intuitive than a keyboard.

By the early 1970s, ARPA was forced to concentrate its research and development on weapons for the Vietnam conflict. This led to an exodus of talent from ARPA to Xerox, which had established the Palo Alto Research Center (PARC). During the 1970s, major advances in technology meant that computers were becoming more powerful, smaller, and cheaper. The personal computer, laser printer, and desktop architecture were all developed at Xerox PARC.[204]

After the Vietnam conflict, the technologies advanced in war were directed towards other industries. Science and, even more so, entertainment began to look at VR as a way to

enhance their respective businesses. VR has had obvious application in making blockbuster films with dazzling special effects (e.g., *Star Wars*, *The Terminator*, and *The Perfect Storm*). It was during the 1970s that many different industries began to see the applications and implications of VR. Three-dimensional mapping of genomes in DNA research led VR into medicine. For the first time, real-time modification of computer-aided design models became available. Thomas Zimmerman designed a "data glove," a type of human interface device, out of the desire to convert gestures into music by feeding these gestures directly into a computer, which could interpret the movements as sound. He patented the glove in 1982. The glove could interpret the wearer's hand movements and finger flexion, allowing them to interact with a 3D environment.

Jaron Lanier first combined the HMD and data glove in 1986, giving the world a more realistic version of immersive VR. This step meant that users could not only see the 3D environment but could also interact with it, feeling the objects and seeing themselves interacting in VR at the same time. Since these forefathers of VR presented their ideas and concepts to the world, there have been many groups, organizations, and individuals that have been interested in exploring and adding to the general knowledge of this field.

The evolution of VR for surgery began in the 1980s. It was quickly realized that simulation and VR for surgical procedures did not have to rely on an especially detailed graphic terrain, which was the case for complex professional flight simulators. In fact, even moderately detailed surgical VR systems could accomplish the purpose of "task training." This reinforced the fact that, for surgeons, one of the primary goals of training was to establish technical skills. Therefore simple graphic representations of two hollow tubes with an interface for needle holders and forceps would be enough to teach someone about the principles of bowel anastomosis. In the late 1980s, Scott Delp of Stanford University developed one of the first surgical VR-based simulators for lower extremity tendon transfers. In 1991, Richard Satava and Jaron Lanier designed the world's first intra-abdominal interactive simulation.

These seminal events in surgical VR were followed by more improved versions based on similar computer-assisted digitizing and rendering techniques. Although these early iterations lacked the computing power to combine maximum detail with surgical flexibility and dynamic change, they proved to be more than enough to establish the concept.

### Components of Virtual Reality

Construction of a virtual environment requires a computer system, a display monitor, an interface device, and compiler software. Surgical simulations and artificial environments are based on the same types of programming methods. Computational speed must be sufficient to power the graphics to deliver a minimum frame rate so that the user does not experience flicker or the perception of frames changing on the monitor. To accomplish this, the simulation should be delivered to the user's eye at no less than 30 Hz, or 30 frames per second. This is equivalent to most televisions. Five years ago, this kind of graphic generation required high-end graphics (Silicon Graphics, Mountain View, Calif.) or a workstation (SUN, Mountain View, Calif.). Now, dual-processor or single-processor personal computers can render graphics at this speed.

The software required to produce virtual worlds has specific requirements. First, the programmer must design the software to match the physical constraints of the real world. The heart, for example, cannot be allowed to float in thin air during a coronary bypass graft simulation. It must have some representation of gravity, compressibility, volume, and mass. These constraints, and more, must be considered for the virtual world to approach reality. Second, the software must be designed so that user interaction will be compiled and processed efficiently and accurately, so as not to become unstable to the user who is dynamically changing the simulation. Forceps pulling on tissue must appropriately deform the graphic representation of that tissue, for example. The software also must be able to communicate force feedback, through external devices, to the user in real time.

### Patient-Specific Virtual Reality

Surgical dissection, although second nature to a surgeon, is difficult to program into a computer system. The thousands of anatomic interactions can easily exceed the processor power; therefore digital rendering of patient data must be performed as efficiently as possible.

Patient-specific data for VR can come from several sources. MRI, magnetic resonance angiography, CT imaging, PET scanning, US scanning, and single photon emission CT imaging are among the common modalities. Traditionally, a physician mentally organizes these two-dimensional stacks of data, compiles it in his or her brain, and visualizes a 3D representation of the patient, not unlike the Visible Human data set (Fig. 4-23). With VR, these image stacks are meshed by the computer to realize the data in three dimensions automatically; this was previously a mental task, performed by the surgeon before an operation.[197]

Using different types of data sources, such as MRI or CT scanning, allows VR programmers to take advantage of the unique properties of each scanning method. CT scanning, for example, is particularly useful for scanning bones. MRI is more useful for soft tissue scanning. These properties can be combined to create a realistic VR image.

The manner in which these 3D images are represented within the system has a profound impact on the overall performance of the simulation. Patient data sets from CT scans, MRI, and other methods originate as voxels.[205,206] Voxel graphics are based on volume and result in an image that contains an infinite amount of data points. To compute changes in each point would put a tremendous strain on any computer. Other forms of VR rendering exist, however, to ease the strain on the system and to speed up the simulation.

### Surface Rendering

Rendering is the process of digitizing data into a computerized image by applying parameters to the data. To reduce the number of data points that require computation, surface rendering converts volume-based images into geometric primitives, which have far fewer data points.[207] This could be a patchwork of polygons that are based on the boundaries of different regions in the image. Boundary regions could be between fascia and fat or gray matter and white matter. Such separation requires knowledge of the properties of each region, because some blurring occurs in voxel images, such as CT scans. Shading algorithms can blend layers or regions so that the final product has a smooth appearance (Fig. 4-24). The number

**FIGURE 4-23** Visible Human Project. Reconstruction of a 3D model based on MRI and CT data. (Courtesy the National Library of Medicine Dataset.)

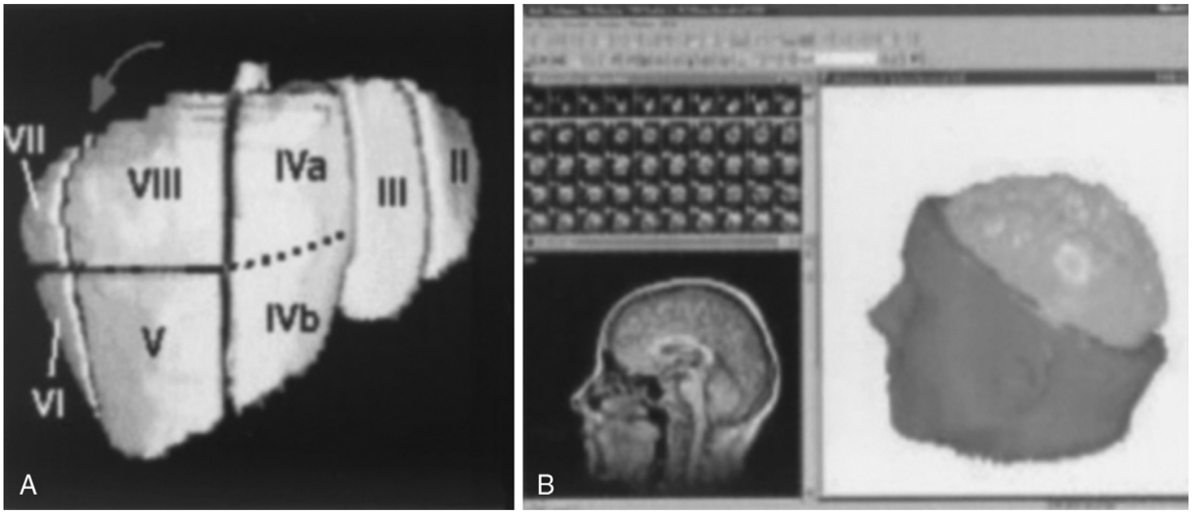

**FIGURE 4-24** Surface-rendered view of the liver (**A**) and brain (**B**). (Courtesy 3-D Doctor: 3-D Imaging, Rendering, and Measurement Software for Medical Images, Lexington, Mass.)

of geometric elements is extremely important in the surface method of VR. One must remember that each movement of the simulation by the user in virtual space requires a recalculation of each geometric object by the computer in real time. If there are too many polygons to reproduce quickly, then the simulation will "jerk," making it less real and perhaps unusable. When compared with voxel-based imagery, surface-rendered objects run unequivocally faster.

## Volume Rendering

Volume rendering requires special equipment to handle the immense amounts of data that must be compiled. This method works explicitly with volumetric data and renders them each time the data set is manipulated by the user. This is different from surface rendering in that surface rendering splits the volume into groups of polygonal surfaces. Surface-rendered objects are adequate when the surgeon wants to limit the inspection to the surface of an object, but as its name implies, surface rendering only displays the surface part of the data set. Currently, higher-end computer equipment, such as a graphics workstation, is necessary to render volume-based graphics.

## Finite Elements

Finite elements are based on geometric networks that are placed under the constraints of physics. Forces of pressure, elasticity, stress, and strain affect the shape and nature of

the object being manipulated. Such manipulation will affect not only the surface of the model but also the volume. When combined with a detailed graphic overlay, finite element models can provide the most accurate simulation to date.[206]

### Visual Displays

In a perfect world, VR can incorporate any, or all, of our five senses, but it usually relies most heavily on our most critical visual sense. The basics of our visual system can be categorized in three groups: depth perception, field of view, and critical fusion frequency.

Depth perception in humans is limited to approximately 30 meters, because the eyes are close together in relation to the distance being seen. VR systems must allow the user to reproduce these mechanisms, or proper depth cannot be achieved. The eye needs only a limited field of view to feel as though it is part of a virtual environment. Critical fusion frequency is the frequency at which static images, in rapid succession, appear to be a seamless stream of moving data. This is much like the old methods of animation in which shuffled flash cards gave the appearance of an animated cartoon. The approximate frequency for smooth video is approximately 30 to 40 Hz. Such displays must be capable of delivering a 3D image. The most dynamic form of VR visual display is the head mounted display. Although VR can be, and often is, represented on desktop monitors, the sense of immersion is not as complete when the participant is not in a closed system like an HMD. On a desktop monitor, a 3D environment is being projected on a 2D screen.

There are two basic methods of 3D visualization. The first method uses two separate displays, one to each eye, giving a stereoscopic effect. The second method uses a head-mounted tracking system that changes the perspective of the system to match the direction in which the user is looking. This tracking method must coordinate the movement of the user's head and hands.

Many different types of HMDs are available. The capabilities of a particular HMD depend on its final purpose. HMDs exist for personal video gaming, architecture, and missile guidance alike. There are also many modes of HMD instrumentation. Opaque displays, for example, completely occlude any visual contact with the outside world. Any visual input comes solely from the head-mounted video display.

Fakespace, Inc. (Menlo Park, Calif.) offers a binocular omni-orientation monitor (BOOM). This is a head-coupled display that is externally supported by a counterbalanced stand. Because this is not worn by the user and is supported by an external platform, the BOOM system can allow for additional hardware technology to be added to the system, thereby creating a very high-fidelity visual. Resolutions of 1280 × 1024, which are better than most computer monitors, are standard on the Fakespace system. The BOOM device is, of course, weightless to the user and relies on a motion-tracking system to keep face-forward perspective. The swivel stand allows for a superior degree of freedom (DOF) and field of view.

One of the more novel and immersive visual display systems is the Cave Automatic Virtual Environment (CAVE; Fakespace/Electronic Visualization Laboratories), which is a room-sized multiuser system. Graphics are projected stereoscopically onto the walls and the floor and are viewed with shutter glasses. Users wear position trackers that monitor the user's position within the CAVE by way of a supercomputer. Changes in perspective are constantly updated as the user moves around this "confined" space. Monocular head-mounted systems allow the wearer to have contact with the outside environment while data are delivered (Fig. 4-25). Surgical applications include the ability to perform an operation while simultaneously processing data about the patient's vital signs and imaging studies.

Virtual retinal displays scan light directly onto the viewer's retina. Because of this feature, the viewer perceives an especially wide field of view. Although still in development, retinal displays have so far been able to deliver resolutions close to human vision, while encased in a lightweight, portable system.[208] Virtual retinal displays have been developed at the University of Washington's Human Interface Technology laboratory.

### Input Devices

The best way to interact with the virtual world is with one's hands. It is both natural and intuitive. The DataGlove system (VPL Research, Redwood City, Calif.) (Fig. 4-26) is the archetypical system.

The DataGlove System frees up the user's hands from a keyboard. Commands are simplified, and tasks are carried out by rudimentary pointing or grasping in the virtual environment. Since the conception of the DataGlove, many manufacturers

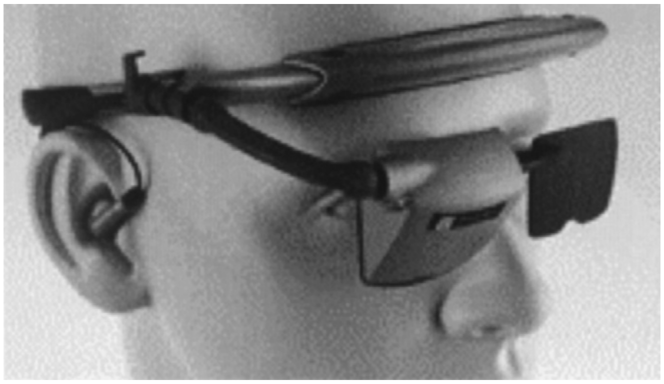

**FIGURE 4-25** eGlass II, with eye Blocker. (VirtualVision, Redmond, Wash.)

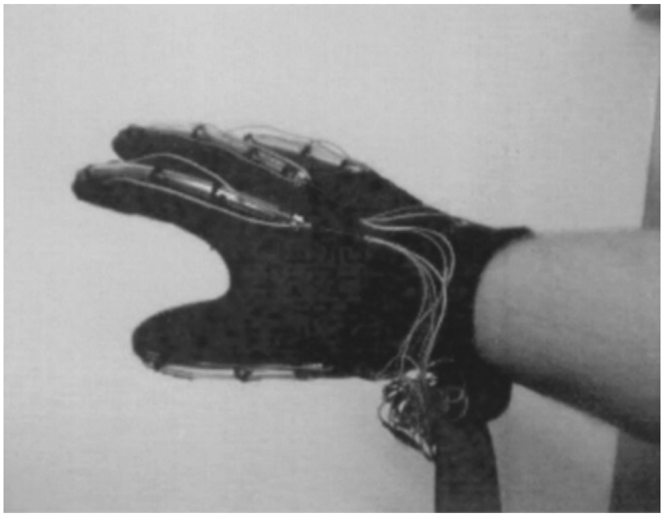

**FIGURE 4-26** Generic dataglove.

have developed similar interface products. Data gloves process information by many different methods. Some gloves use mechanical sensors or strain gauges over the joints of the hand to determine position. Other gloves use fiberoptic circuits to measure the change in light intensity and angle of the fiberoptic band as the hand flexes and extends. Trackers are also positioned on some gloves to monitor their position in free space. In any configuration, the data glove remains an intuitive solution to a complex problem.

### Force and Tactile Feedback

Force (resistance) and tactile (contact or touch) feedback could be the two most important goals of surgical VR, yet they are also among the most difficult to achieve. Surgeons rely on a keen sense of touch and resistance with the human environment, and without these senses, fidelity suffers. Laparoscopy is one example of how touch sense is displaced from the surgeon's hands.[209]

The tangible senses are very hard to generate artificially. Humans can easily judge the force with which to pick up a glass of water to bring it smoothly to the mouth. A computer, if incorrectly programmed, may mistake the picking up of a glass to the hoisting of a cinderblock, causing the virtual glass of water to be thrown completely across the room. Until recently, the one major component that was lacking in VR simulations was the sense of touch, or haptics.

Haptic feedback requires two basic features to render the sense of touch back to the user. First, the system needs a computer that is capable of calculating the interaction between the 3D graphics of the simulation and the user's hand, all in real time. Second, the loop requires some form of interface device (whether a joystick, a glove, or other device) for the user to be able to interact with the computer. The computer systems that support haptics are typically 3D graphics workstations with hardware video acceleration.[197,210] These systems are connected to an interface device, such as the popular PhanTOM joystick (SenseAble Technologies, Woburn, Mass.) (Fig. 4-27). Such joystick-based devices can function to provide up to six DOF. Again, the computer's visuals must refresh at a rate approximately 30 times per second to create a smooth simulation.

Like muscle linkages to bone, since all forces must be generated in relation to a point of fixation and an axis of motion, current force feedback systems require an exoskeleton of mechanical linkages. Force feedback systems currently use one of two approaches to this exoskeleton. The first system uses an exoskeleton that is mounted on the outside of the hand, similar to the ones used for electromechanical tracking. The linkages consist of several pulleys that are attached to small motors that use long cables. The motors are mounted away from the hand to reduce weight but can exert a force on various points of the fingers by pulling the appropriate cable. The second system consists of a set of small pneumatic pistons between the fingertips and a base plate on the palm of the hand. Forces can be applied to the fingertips only, by applying pressure to the pistons.

**FIGURE 4-27** PhanTOM interfaces. (SenseAble Technologies, Woburn, Mass.)

Because these systems reflect all their forces back to somewhere on the hand or wrist, they can allow you to grasp a virtual object and feel its shape but cannot stop you from passing your hand through that object. To prevent this, the exoskeleton must be extended to a base that is mounted on the floor through more linkages along the arm and body or an external system similar to a robot arm.

Multiple methods of generating force or tactile feedback have been developed. Piezoelectric vibration systems generate slight vibrations onto the user's fingertips when simulated contact is made. Electrotactile feedback works on the same principle of fingertip sensation, although there are no moving parts. A small current is passed over the skin surface in the case of virtual contact. Micropin arrays consist of a bed of fine pins that extend onto a fingertip to produce extremely fine details. Micropins can recreate the feeling of edges. Pneumatic feedback uses gloves with air pockets placed within the glove. These pockets inflate at the desired time to represent the sense of touching a surface. Temperature feedback uses heating coils on the hand to represent temperature change.

### Tracking in Virtual Reality

Virtual reality is based on spacial relationships. Even though the user is presented with a virtual representation of certain objects, the computer must know where the user is in relation to such objects. Otherwise, the user's hand, for example, would pass through a virtual glass rather than grasping it. Some VR systems solve this problem by following, or tracking, the critical interface points between the user and the computer. Tracking systems are placed on helmets and gloves so that the computer knows when to react. Several tracking methods exist.[202]

Mechanical tracking systems are physically in connection with the user's interface. The user's helmet is tethered at one end and interfaced with the computer at the other. This direct connection is fast, but the subject is always attached to the system, which limits movement.

Cameras in conjunction with small flashing beacons placed on the body can be used as a method for optical tracking. Multiple cameras taking pictures from different perspectives can analyze the configuration of the flashing light-emitting diodes on the body. These pieces of 2D data are compiled into a single 3D image. Such processing takes time, a critical drawback of optical tracking. Magnetic-field signals can be used; source elements placed on the hand can be tracked with a sensor. Disadvantages include interference from nearby magnetic sources and a maximum useable distance.

Acoustic trackers use high-frequency sound to triangulate to a source within the work area. These systems rely on line-of-sight between the source and the microphones and can suffer from acoustic reflections if they are surrounded by hard walls or other acoustically reflective surfaces. If multiple

acoustic trackers are used together, they must operate at nonconflicting frequencies, a strategy also used in magnetic tracking.

### Challenges of Virtual Reality

As with any emerging technology, there is an ebb and flow of hype and hope.[210] VR is no exception. In order to exceed the hype, areas that have the greatest room for improvement are graphics and haptic feedback. Because of the massive processing power that is required to create a full VR production, one must currently trade off graphic detail for performance. Currently, this means VR is defined by the phrase, "It can be good, fast, and cheap; pick two." This results in simulations that have a cartoon quality, so that they may have a reasonable run time. Even with a forced reduction in graphic detail, there is still a slight perception of delay, or lag, in the time between user interface and VR reaction. The visual representation of an incision is still very difficult to achieve accurately.

Haptic feedback requires equal computing power (if not more) and can cause instabilities or inaccuracies in the system. Many VR forced feedback systems can be forced to fail, by "pushing through" the force feedback and ruining the illusion.

### Virtual Reality Preoperative Planning

Beyond simple task training, one of the great advantages and goals of VR is the ability to plan and perform an operation on patient-specific data before actually performing the operation on the same human being. This goes far beyond early learning on a generic task or human. Surgeons, when planning an operation, traditionally compile data such as CT scans or MRIs, along with patient examinations and charts, into a solution envisioned in their head. It takes years of experience and training to master such visualization, especially when it comes to translating multiple 2D images into a 3D paradigm.

For many surgical specialties, VR techniques can assemble patient-specific data into graphic "before and after" images, which can be manipulated by the surgeon before the operation so that the outcome of the case may be predicted. These outcomes would be based on decisions that the surgeon would make during the operation. Furthermore, as more procedures are developed, VR preplanning can be used as a research model based on actual patient data that would be used to predict the outcome of a novel surgical application. VR enhancement also preemptively speeds up decision processes for complicated cases by providing the surgeon with a preplanned outline of the procedure, thereby making the hospital system more efficient. VR preoperative planning is available for general surgery, vascular surgery, plastic surgery, neurosurgery, and orthopedic surgery.

Craniofacial reconstructive surgery is a difficult task. The surgeon who is asked to handle a difficult or even routine operation of this kind reconstructs 3D data from 2D CT or MRI scans. No matter how experienced the surgeon, the predictions of outcomes in plastic reconstructions are limited, at best, with the use of this traditional method. As a result, the preoperative plan is often modified in the operating room during the operation. For these reasons, rehearsal and preparation with VR have been applied with increasing frequency in this area.[211,212]

There are many methods of computer-assisted planning for craniofacial surgery, but most produce a 3D interactive image that can predict the outcome of the case based on what the surgeon does on a workstation ahead of time. This process starts with a patient-specific CT or MRI scan that is cut in transverse sections, as is the case in facial reconstruction for trauma or malformation.[213] Once the images are scanned from the patient, they are segmented and specified into bone and soft tissue windows. This results in a mass of 2D cuts that must be rendered into a 3D environment. Patient-specific CT images are typically processed on a graphics workstation.

The University of Erlangen in Germany has demonstrated a method with "marching cubes" for 2D to 3D reconstruction from CT scans.[214] In this process, a CyberWare (Cyberware, Monterey, Calif.) scanner is used to scan the patient's skin surface features, which are compressed to reduce the volume of data. The skin and bone windows are compiled similarly into a 3D image. This image may be cut at any plane to focus on a particular area of interest. Keeve and colleagues[211] simulated a Dal-Pont osteotomy of the mandible using this technique. After the 3D image is rendered, any number of cutting, moving, and manipulating steps may be performed, which will predict the reconstructive outcome in the operating room (Fig. 4-28). "Before and after" pictures of actual patients with this type of computer-aided design models for facial reconstruction yield positive results.

The National Biocomputational Center at Stanford University uses a slightly different rendering paradigm that is based on CT images, called virtual environment for surgical planning and analysis (VESPA). Montgomery and colleagues[213] developed VESPA for use in craniofacial reconstruction, as well as breast

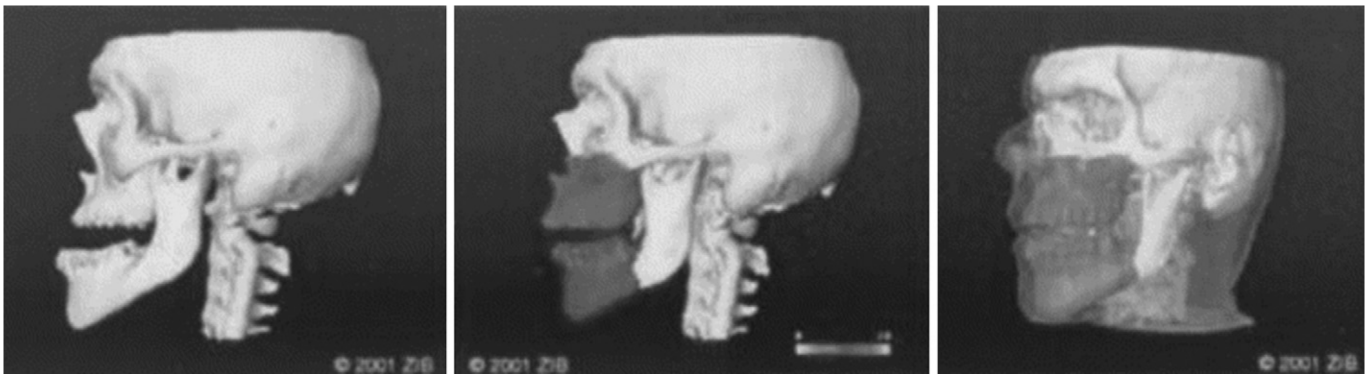

**FIGURE 4-28** 3D planning of a high Le Fort I-Osteotomy (Konrad-Zue-Zentrum for Informationstechnik, Berlin, Germany). (Courtesy SenseAble Technologies, Woburn, Mass.)

surgery, soft tissue reconstruction, and repair of congenital defects. Once CT images are acquired, voxel-based or volume-based images are focused down the area of interest, which results in very specific, segmented data. 3D images are broadcast onto a high-definition CRT monitor, and the user, who is wearing tracked CrystalEyes (StereoGraphics, San Rafael, Calif.) shutter glasses and a FasTrak (Polhemus, Colchester, Vt.) stylus for user input, can view and manipulate the virtual object.

The complexity of facial reconstructive surgery almost demands this kind of preoperative power, because conventionally there is only so much planning and prediction that can be performed by the surgeon who uses 2D conventions. Preplanning will allow the physician and the patient to view precise outcomes; this not only reassures both parties but also allows for reduced anesthesia times.

### Virtual Reality–Based Three-Dimensional Surgical Simulators

The actual practice of surgical procedures is a highly visual and, subsequently, manual task with constant visual and haptic feedback and modification.[215] This represents a formidable challenge. To create a VR surgical simulator for education or practice, the programmers must develop a system that adequately represents the surgical environment; it must react to the surgical changes (e.g., incision, dissection, resection) that the surgeon imparts to the operative field and must give the surgeon appropriate forced feedback. These prerequisites must be accomplished in a manner that is transparent to the surgeon (i.e., the virtual operation room should mimic a real operating room). Depending on the target audience and application, many surgical simulators have been developed. VR surgical simulators have been applied to open surgical procedures, laparoscopic surgery, and remote telepresent surgery.

The Karlsruhe "VEST" Endoscopic Surgery Trainer (IT VEST Systems AG, Bremen, Germany) is likely the most developed surgical endoscopic simulator (Fig. 4-29). This device mimics the surgically draped human abdomen and allows for the insertion of multiple laparoscopic instruments and an endoscopic camera. Force feedback is provided and applied to the laparoscopic instruments. Visual displays are generated with proprietary KISMET (Kinematic Simulation, Monitoring, and Off-Line Programming Environment for Telerobotics) 3D generation surgical environments.[216] This software affords the user high-fidelity immersion into a virtual laparoscopic scenario of a minimally invasive cholecystectomy, complete with real-time tissue dynamics and kinematic tissue response to user interaction. The laparoscopic instruments are tracked with sensors, to mimic the same DOF of actual endoscopic tools that are placed into a human abdominal cavity. This system is processed by a graphics workstation and has the ability to support total immersion goggles and telepresence training. As computing and graphic power become more developed, the graphic representations will become more detailed and hopefully approach that of the video monitors in an actual operating room.

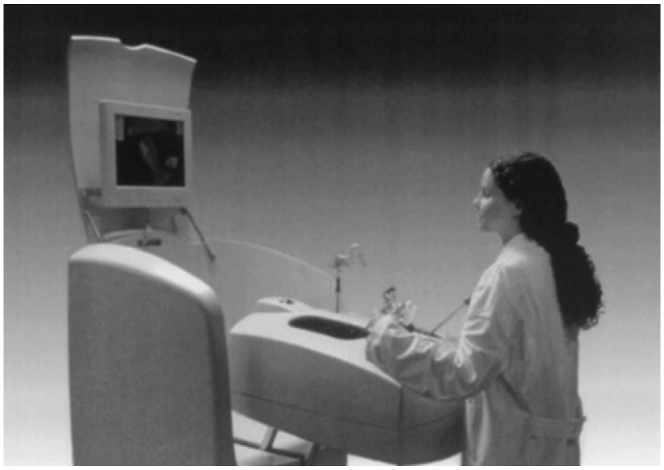

**FIGURE 4-29** VEST/LapSim One endoscopic surgical trainer. (IT VEST Systems AG, Bremen, Germany). (Courtesy of IT VEST Systems AG.)

Other surgical simulation systems are also available. Boston Dynamics (Cambridge, Mass.) has developed an anastomosis simulation with Pennsylvania State University based on force feedback surgical instruments and 3D vision with shutter goggles. This system allows the user to place sutures in a bowel or vessels to simulate the delicate nature of anastomosis. A "surgical report card" is a unique implementation in this system, which analyzes the surgeon's performance in real time. Comments on performance include time, accuracy, angle of needle insertion, and tissue damage.[217]

Virtual reality simulators for bronchoscopy, catheter insertion, and endoscopy are so real that residents and fellows use these to get exposure to procedures not already in their arsenal of experience. Stanford University has used the BronchSim and CathSim devices (Immersion Medical Technologies, Gaithersburg, Md.) and the VR Med Upper GI simulator (Fifth Dimension Technologies, Pretoria, South Africa) to evaluate surgical procedure training. A study that involved the BronchSim device that was conducted at Stanford University consisted of three sections: practice, navigation and visualization, and diagnosis and therapy. The subject was introduced to the bronchoscope and the simulation by a narrative from the training staff, which was supplemented by four videos on basic bronchoscopy, which were supplied with the Immersion Medical Technologies software. One of the tasks involved diagnosing an intraluminal bronchial wall tumor from CT scans and plain radiographs of the chest, then using the provided biopsy tool to safely take a sample of the tumor and control hemorrhage. The BronchSim device was able to distinguish between experts and novices, and subjective data from Likert questionnaires suggested an increase in procedural ability and familiarity in bronchoscopy. Similar educational studies were completed with the same internal structure for evaluation. These studies returned equally encouraging results.

With the advent of computer-assisted medicine, VR training tools have never been so accessible to medical educational programs as they are today. Our results, and the results of many others, suggest that surgical education that incorporates VR systems can be used in a training program, for both medical students and residents entering careers for which this procedure might be performed. Experience suggests that many VR simulator interfaces are realistic enough to serve not only as a teaching tool but also as a method for honing present skills.

## SIMULATION IN SURGICAL EDUCATION

Current training in surgery is focused on core knowledge, patient care, team training, and procedural skills. Surgical simulators can be used to enhance each of these components.

Simulation can be used for skills training, patient treatment, and crisis training in primary and continuing education for both residents and practicing surgeons.

Surgical simulation has been adopted by several surgical centers and residency programs through the formation of “simulation centers.” Mannequin simulators are being used to train surgical interns and residents in crisis treatment, and as a formal credentialing method for certain aspects of advanced cardiac life support (ACLS) and advanced trauma life support (ATLS).

As an example of mannequin-based core knowledge training, a simulation of initial burn surgical treatment has been developed. Treatment of acute burn injury is a core surgical skill, and proper treatment ranks in urgency with the care of a myocardial infarction. Despite the expertise needed to treat burns, only 20% of surgical residencies have a formal burn rotation.

The METI (Medical Education Technologies, Incorporated, Sarasota, Fla.) human patient simulator (HPS), a life-sized male mannequin model that is linked to a customizable computer system, was used. The HPS has been proven to simulate normal and pathologic states reliably and is certified for ATLS and ACLS credentialing. Simulated output is through standard bedside monitoring equipment, spontaneous respiration, eye opening, pulses, voice response, and robotic limb motion. The test scenario demonstrated a 40%, third-degree burn. Initially, expert intensive care and burn surgeons were asked to validate the scenario for accuracy and relevancy. Next, senior surgery residents were exposed to the 30-minute simulation. Lickert scale questionnaires and expert debriefings were provided to each of the subjects. Each resident’s performance was filmed for expert review by an attending physician. The computer-driven response of the HPS was based on the residents’ ability to perform ATLS, while simultaneously treating the burned patient with fluids, intubation, and escharotomy.

Attending physicians responded that the proposed scenario accurately reflected the key treatment points for ATLS protocols and burn treatment. These experts also perceived that residents who were exposed to the simulation could function as a physician responder in a similar situation. After being debriefed, each subject was more confident with burn treatment, fluid calculation, intubation and ventilator management, and thoracic and extremity escharotomies. Burn treatment simulation can teach residents to process situations that are not experienced in training and can function as a credentialing platform for new faculty. This first validation of simulated burn training with the HPS suggests a feasible solution to a serious educational dilemma.

Also popular are surgical “fly-through” VR-based tools that are designed to provide a medical student or resident with a first exposure to surgical anatomic relationships in three dimensions. Projects that involve the virtual human male have taken advantage of the data sets that were acquired from this model to create a virtual human anatomy resource in which the student may approach any anatomic structure from any angle or route. The Visible Human Project data sets can be rendered in three dimensions to create virtual detailed fly-through movies. These fly-throughs can be modified to demonstrate the before and after effects of many common surgical procedures and to provide an “endoscopic” view of the abdominal cavity. As more surgical procedures are developed that require more detailed and specific knowledge of surgical relationships, and as the time for surgical education continues to decrease, VR fly-throughs will provide an efficient solution to the education problem.

## TRAINING THE MINIMAL ACCESS THERAPIST

Because of the overlap between IGT, endoscopy, and surgery, interspecialty battles over the control of this field are to some extent inevitable. There is, however, a move toward the concept of a “minimal access therapist,” an individual with training in minimal access surgery, endoscopy, and imaging, and one who can independently deliver complex minimal access care.[82,218] How such a minimal access therapist will be trained and credentialed remains to be seen, but the development of this field will require the cooperation of surgeons, endoscopists, and radiologists. Simulation and the use of virtual reality will likely play a role. Pediatric surgery is already seeing a move in this direction as minimal access pediatric surgeons embrace the use of intraoperative US, fluoroscopy, and therapeutic endoscopy.

The vision for the integrated environment in which the minimal access therapist will work is radically different from the conventional operating room. Most notably, the surgeon’s view of the operative field will be complemented by augmented reality visualization in which the surgeon is aided by images showing what is beyond the visible surface. Instrumentation combining features of laparoscopic tools with endoscopic tools will be used, potentially with robotic guidance. The overall goal is to integrate preoperative and intraoperative imaging data with a robotic-assisted platform into a unified surgical delivery system.

## TRAINING THE SURGICAL INNOVATOR

Technology continues to advance rapidly, becoming more complex and interdisciplinary; at the same time, clinical surgery has become increasingly demanding, requiring intense focus. As a result, the gap between technical advances and creative surgeons is growing. This chapter is an attempt to narrow that gap.

If, indeed, change is constant, and that constant cycling has advanced our field, then it is incumbent upon us as a specialty to understand, thoughtfully incorporate, and even direct the useful change of surgical innovation. Surgeons are undeniably uniquely positioned and privileged to contribute to this cycle, but the growing gap creates a special field of knowledge perhaps requiring a specialized education program.

Formal education programs that teach the process of innovation to young surgeons are appearing across the country. One example is the Biodesign Program at Stanford University, a 2-year fellowship in surgical innovation offered to graduate level engineering students and residents. In the first year, fellows participate in didactic courses that teach the practical issues in needs assessment, technology solutions, intellectual property, ownership, the FDA approval process, and the underpinning economics of this process. A team-based project course is a large component of the first year. A second year is spent further developing an identified project. At the completion of the program the fellow has the requisite skills to become a significant contributor to the next cycle of surgical innovation in children and in adults. Depending on the prior background of the fellow, a Masters degree in bioengineering

is also achievable. Now in its 10th year, more than 80 graduates are now dispersed around the world, including one of the authors (RKW).

The Biodesign Program is part of a campus-wide interdisciplinary program entitled "Stanford's Bio-X Initiative" involving over 500 scientists from the life sciences, engineering, chemistry, and physics, with broad research themes in biocomputation, biophysics, genomics and proteomics, regenerative medicine, and chemical biology. Networks such as Bio-X focus explicitly on technology transfer to bring innovations bidirectionally to the bedside-to-bench cycle. This represents a unique academic program focused on the invention and implementation of new health-care technologies through interdisciplinary research and education at the emerging frontiers of engineering and the biomedical sciences.

## Conclusion

If pediatric surgery is to remain an active participant in the endless cycle of change, then an acknowledgement of the role of technology in advancing our care and a desire to actively embrace and drive the process forward in an ethical fashion is essential. To sit on the sideline is to invite a slow and agonizing death of us as individuals and, more critically, of our field and our responsibility to it. This two-volume text is a tribute to those who came before us and, in the space of less than 50 years, defined our specialty. We, as stewards of this generation, must be architects of the next 50 years.

CHAPTER 5

# Prenatal Diagnosis and Fetal Therapy

Hanmin Lee, Shinjiro Hirose, and Michael R. Harrison

As the field of fetal diagnosis and therapy expands, pediatric surgeons are increasingly involved in the management of surgical anomalies before birth. Advances in imaging and sampling of the fetus have increased the accuracy of the diagnosis of many anomalies and improved stratification of disease severity. These advances in prenatal diagnosis have led to improved perinatal care. Severe lesions detected early enough may lead to counseling and termination of pregnancy. Most correctable defects are best managed by optimizing location, mode and timing of delivery, and postnatal care of the infant (Table 5-1). Some prenatally diagnosed conditions have progressive and severe sequelae and may be treated with fetal intervention. Some attempts at fetal therapy have resulted in tremendous success, whereas many others have resulted in unclear or no improvement.

Finally, serial study of affected fetuses may help unravel the developmental pathophysiology of some surgically correctable lesions and thus lead to improved treatment before or after birth. It is important that surgeons familiar with the management of lesions after birth be involved in management decisions and family counseling.[1]

In this chapter we review the current techniques of fetal diagnosis and intervention and specific fetal anomalies that have particular interest to pediatric surgeons.

## Fetal Diagnosis

Over the past 4 decades, fetal diagnosis has improved tremendously. Obstetricians are now able to accurately detect many genetic anomalies prenatally and are able to detect many anatomic abnormalities by fetal ultrasonography (US), echocardiography, and magnetic resonance imaging (MRI). In this section we discuss invasive and noninvasive methods of diagnosis of fetal anomalies.

### BIOCHEMICAL SCREENING

An elevated alpha fetoprotein (AFP) level in maternal serum and amniotic fluid is a reliable indicator of a fetal abnormality. Although used to screen for neural tube defects, AFP is also elevated in defects such as omphalocele, gastroschisis, and sacrococcygeal teratoma, in which transudation of fetal serum is increased. AFP is the major glycoprotein of fetal serum and resembles albumin in molecular weight, amino acid sequence, and immunologic characteristics. The AFP level in fetal serum reaches a peak of 3 mg/mL at 13 to 15 weeks of gestation. AFP concentration in amniotic fluid follows a curve similar to that of fetal serum, but at a 150-fold dilution. Maternal serum levels continue to rise throughout pregnancy until the middle of the third trimester. Typically AFP is measured in the second trimester at 15 to 18 weeks. Measuring other markers—inhibin, estriol, and human chorionic gonadotropin—enhances aneuploidy screening. Testing of these four markers is referred to as a *quad screen.*

Increasingly screening for aneuploidy is being performed in the first trimester because of the results of the First and Second Trimester Evaluation of Risk (FASTER) trial. The FASTER trial compared the accuracy of second-trimester serum quad screening to first-trimester triple screening consisting of maternal serum testing for pregnancy-associated plasma protein A (PAPP-A) and free beta-human chorionic gonadotropin (beta-hCG) combined with an ultrasonographic examination to determine the fetal nuchal translucency. The sensitivity and specificity of detecting trisomy 21 in this study by noninvasive first-trimester screening were found to be comparable to noninvasive quad screening performed in the second trimester.[2]

### FETAL SAMPLING

Cells can be obtained for karyotyping and DNA-based diagnosis of many genetic defects and inherited metabolic abnormalities. Amniocentesis in the middle of the second trimester has been the most common method of fetal sampling. Chorionic villus sampling (transvaginal or transabdominal) as early as 10 weeks of gestation has become used increasingly because complication rates for the procedure are now comparable to those of amniocentesis.[3] Thus current first-trimester noninvasive screening or chorionic villus sampling, or both, give women earlier information with which to make decisions concerning their pregnancies.

Powerful new sorting techniques now allow isolation of fetal cells and free fetal DNA in the maternal circulation, allowing noninvasive genetic testing for fetal diseases by maternal blood sampling.[4,5] Increased access to fetal genetic

**TABLE 5-1**
**Prenatal Diagnosis and Management**

| |
|---|
| **Defects Usually Managed by Pregnancy Termination** |
| Anencephaly, hydranencephaly, alobar holoprosencephaly |
| Severe anomalies associated with chromosomal abnormalities (e.g., trisomy 13) |
| Bilateral renal agenesis, infantile polycystic kidney disease |
| Severe untreatable inherited metabolic disorders (e.g., Tay-Sachs disease) |
| Lethal bone dysplasias (e.g., thanatophoric dysplasia, recessive osteogenesis imperfecta) |
| **Defects Detectable In Utero but Best Corrected After Delivery Near Term** |
| Esophageal, duodenal, jejunoileal, and anorectal atresias |
| Meconium ileus (cystic fibrosis) |
| Enteric cysts and duplications |
| Small intact omphalocele and gastroschisis |
| Unilateral multicystic dysplastic kidney, hydronephrosis |
| Craniofacial, limb, and chest wall deformities |
| Simple cystic hygroma |
| Small sacrococcygeal teratoma, mesoblastic nephroma, neuroblastoma |
| Benign cysts (e.g., ovarian, mesenteric, choledochal) |
| **Defects That May Lead to Cesarean Delivery** |
| Conjoined twins |
| Giant or ruptured omphalocele, gastroschisis |
| Severe hydrocephalus; large or ruptured meningomyelocele |
| Large sacrococcygeal teratoma or cervical cystic hygroma |
| Malformations requiring preterm delivery in the presence of inadequate labor or fetal distress |
| **Defects That May Lead to Induced Preterm Delivery** |
| Progressively enlarging hydrocephalus, hydrothorax |
| Gastroschisis or ruptured omphalocele with damaged bowel |
| Intestinal ischemia and necrosis secondary to volvulus or meconium ileus |
| Progressive hydrops fetalis |
| Intrauterine growth retardation |
| Arrhythmias (e.g., supraventricular tachycardia with failure) |
| **Defects That May Require EXIT Procedure** |
| Congenital high airway obstruction syndrome (CHAOS) |
| Large cervical tumors (e.g., teratoma) |
| Masses obstructing trachea or mouth (e.g., cystic hygroma) |
| Conditions requiring immediate ECMO cannulation |
| Chest mass preventing lung expansion |

ECMO, extracorporeal membrane oxygenation.

material, combined with advances in the human genome project, has led to testing of greater numbers of genetic abnormalities prenatally. Increasingly, single nucleotide polymorphism arrays are being developed to genetically characterize diseases further and will clearly augment testing for aneuploidy in the future.[6]

## FETAL IMAGING

### Ultrasonography

Fetal anatomy, normal and abnormal, can be accurately delineated by US. This noninvasive technique appears to be safe for both the fetus and the mother and is now routinely applied in most pregnancies. Most anatomic surveys are performed in the middle of the second trimester between 18 and 20 weeks' gestation. The scope and reliability of the information obtained are directly proportional to the skill and experience of the ultrasonographer and ultrasonologist. For example management of a fetal defect requires a thorough evaluation of the fetus for other abnormalities because malformations often occur as part of a syndrome.

Real-time US may yield important information on fetal movement and fetal vital functions (heart rate, breathing movements) that reflect fetal well-being. Serial US evaluation is particularly useful in defining the natural history and progression of fetal disease. Further, US can stratify the severity of a disease. For instance details of the ultrasonogram that correlate with outcome include presence or absence of associated anomalies, presence or absence of hydrops fetalis, presence or absence of liver herniation into the chest, and relative lung size. The details of a complete anatomic survey are extensive and are covered elsewhere.[1] Finally, real-time US is critical for guidance during fetal interventions. It may be the only method of guidance in some procedures such as needle aspiration for fetal fluid or tissue sampling. For fetal endoscopic or open fetal procedures, US not only gives valuable information about the fetus but also gives information about the uterus, particularly placental location.

### Echocardiography

The field of echocardiography has seen rapid growth in the past 10 years because of advances in ultrasound technology and increasing experience with the assessment of the normal and abnormal fetal heart. Most structural cardiac anomalies can be detected prenatally.[7–9] Many abnormalities of interest to pediatric surgeons, such as congenital diaphragmatic hernia (CDH) and omphalocele, have a high incidence of associated structural cardiac anomalies, and the identification of these anomalies can affect postnatal outcome and prenatal counseling. The determination of cardiac function has played a significant role in predicting outcome for fetal anomalies that may cause cardiac dysfunction, such as sacrococcygeal teratoma and congenital pulmonary adenomatoid malformations, as well as twin anomalies that are less familiar to pediatric surgeons such as twin-twin transfusion syndrome (TTTS) and twin reversed arterial perfusion (TRAP) sequence. Further, fetal cardiac monitoring by perioperative echocardiography has been used to monitor the fetal response to surgery.[10] Finally, because the natural history of cardiac anomalies are now better understood,[9] ameliorating or reversing their progressive effects with fetal intervention by echocardiographic guidance has been attempted.[11–13]

### Magnetic Resonance Imaging

Although US remains the primary mode of imaging the fetus, magnetic resonance imaging (MRI) is used increasingly for a variety of abnormalities to evaluate the fetal spine, brain, and body. MRI has proved to be a valuable imaging technique because of the high resolution capabilities that are complementary to US, which is less costly and more accessible, and as a real-time modality that can show motion and changes over time. There are no known adverse effects of MRI on the fetus when it is performed with MRI scanners that are 1.5 T or less.[14] Figure 5-1 shows an ultrasonographic image of a CDH, and Figure 5-2 shows an MRI image of a CDH.

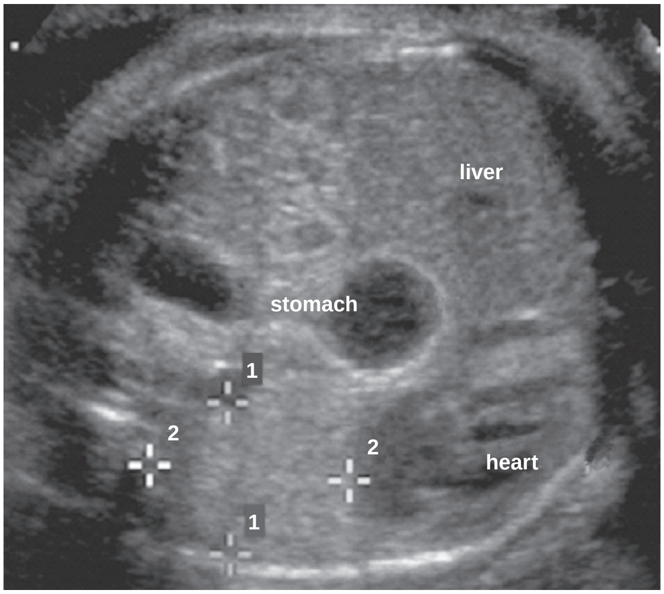

**FIGURE 5-1** Transaxial ultrasonographic image of the chest in a fetus with a left diaphragmatic hernia (liver, stomach, and heart labeled). Measurements of the right lung (*1* and *2*) are made using electronic calipers to calculate the LHR.

**TABLE 5-2**

**Fetal Conditions That May Require Prenatal Medical Treatment**

| *Defects* | *Treatment* |
|---|---|
| Erythroblastosis fetalis (erythrocyte deficiency) | Erythrocytes—intraperitoneal or intravenous |
| Pulmonary immaturity (surfactant deficiency) | Glucocorticoids—transplacental |
| Metabolic block (e.g., methylmalonic acidemia, multiple carboxylase deficiency) | Vitamin $B_{12}$—transplacental<br>Biotin—transplacental |
| Cardiac arrhythmia (supraventricular tachycardia) | Digitalis—transplacental<br>Propranolol—transplacental<br>Procainamide—transplacental |
| Endocrine deficiency (e.g., hypothyroidism, adrenal hyperplasia) | Thyroid—transamniotic<br>Corticosteroids—transplacental |
| Nutritional deficiency (e.g., intrauterine growth retardation) | Protein-calories—transamniotic or intravenous |

## Fetal Access

Although most prenatally diagnosed anatomic malformations are best managed by appropriate medical and surgical therapy after maternal transport and delivery, a few simple anatomic abnormalities that have predictable devastating developmental consequences may require correction before birth.[15] In the 1980s the developmental pathophysiology of several potentially correctable lesions was worked out in animal models; the natural history was determined by serial observation of human fetuses; selection criteria for intervention were developed; and anesthetic, tocolytic, and surgical techniques for hysterotomy and fetal surgery were refined.[1,15–20]

This investment in basic and clinical research has benefited an increasing number of fetal patients with a few relatively rare defects and will benefit many more as new forms of therapy—including stem cell transplantation, tissue engineering, and gene therapy—are applied to a wide variety of anatomic and biochemical defects. Some milestones in this development of fetal therapy appear in Table 5-2.

The technical aspects of hysterotomy for open fetal surgery that evolved over 30 years of experimental and clinical work are presented in Figure 5-3.[1] Because the morbidity of hysterotomy (particularly preterm labor) is significant, videoendoscopic fetal surgery (FETENDO) techniques that obviate the need for a uterine incision were developed (Fig. 5-4).[21] Percutaneous fetoscopic intervention has been applied clinically for diagnostic biopsies, laser ablation of

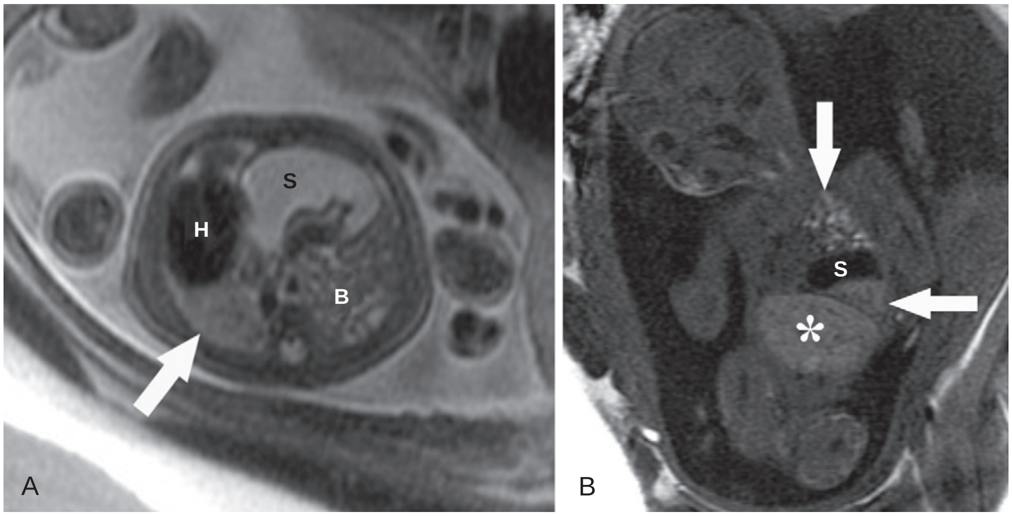

**FIGURE 5-2** **A,** Axial ssFSE T2-weighted image of a fetus at 24 weeks' gestation with a left-sided congenital diaphragmatic hernia (CDH). The heart *(H)* and right lung *(arrow)* are displaced to the right. The left lung is not visible, and instead the left side of the chest contains herniated stomach *(S)* and bowel *(B)*. **B,** Sagittal spoiled gradient-echo T1-weighted magnetic resonance image shows the stomach *(s)* in the left side of the chest. Note the liver *(asterisk)* is of relatively high signal intensity, facilitating the identification of the herniated left lobe *(horizontal arrow)* in the left side of the chest. The herniated bowel loops *(vertical arrow)* in the left side of the chest are also of relatively high signal intensity.

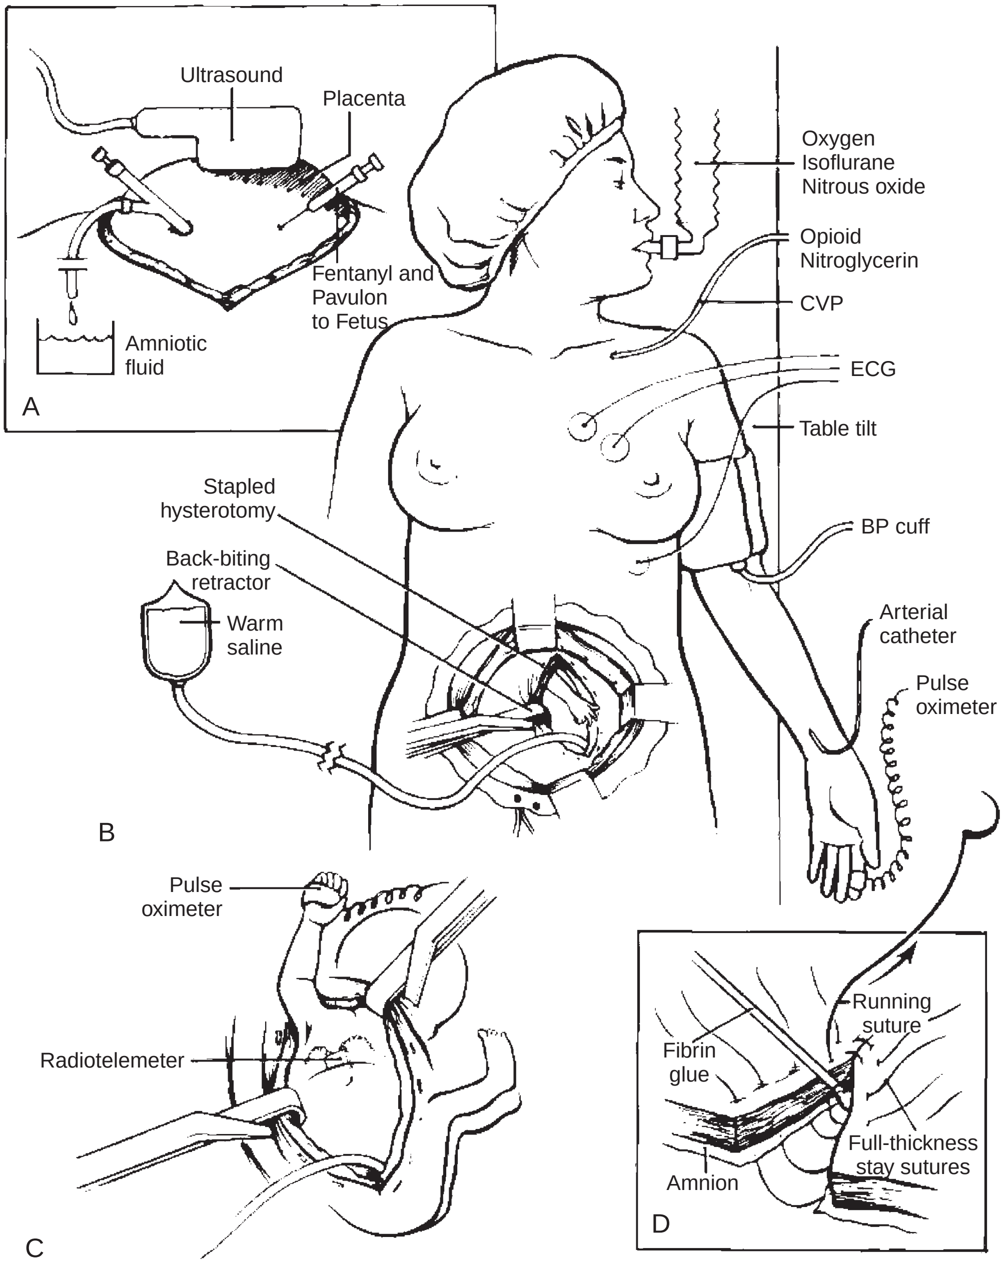

**FIGURE 5-3** Summary of open fetal surgery techniques. **A,** Uterus is exposed through a low transverse abdominal incision. Ultrasonography is used to localize the placenta, inject the fetus with narcotic and muscle relaxant, and aspirate amniotic fluid. **B,** The uterus is opened with staples that provide hemostasis and seal the membranes. Warm saline solution is continuously infused around the fetus. Maternal anesthesia, tocolysis, and monitoring are shown. **C,** Absorbable staples and back-biting clamps facilitate hysterotomy exposure of the pertinent fetal part. A miniaturized pulse oximeter records pulse rate and oxygen saturation intraoperatively. A radiotelemeter monitors fetal electrocardiogram *(ECG)* and amniotic pressure during and after operation. **D,** After fetal repair the uterine incision is closed with absorbable sutures and fibrin glue. Amniotic fluid is restored with warm lactated Ringer solution. BP, blood pressure; CVP, central venous pressure.

placental vessels in twin-twin transfusion syndrome,[22] fetal cystoscopy and urinary tract decompression,[23,24] cord ligature or division in anomalous twins,[25,26] division of amniotic bands, and tracheal occlusion for CDH.[27] Percutaneous ultrasonographically guided intervention has been applied to placement of catheter shunts (bladder, chest),[24,28] vascular access (heart,[29] umbilical vessels), radiofrequency ablation of large tumors or anomalous twins,[30] aspiration of fluid from fetal body cavities,[28] and administration of drugs or cells directly to the fetus.[31]

## Management of Mother and Fetus

Breaching the uterus, whether by puncture or incision, incites uterine contractions. Despite technical advances, disruption of membranes and preterm labor are the Achilles' heel of fetal therapy. Although halogenated inhalation agents provide satisfactory anesthesia for mother and fetus, the depth of anesthesia necessary to achieve intraoperative uterine relaxation

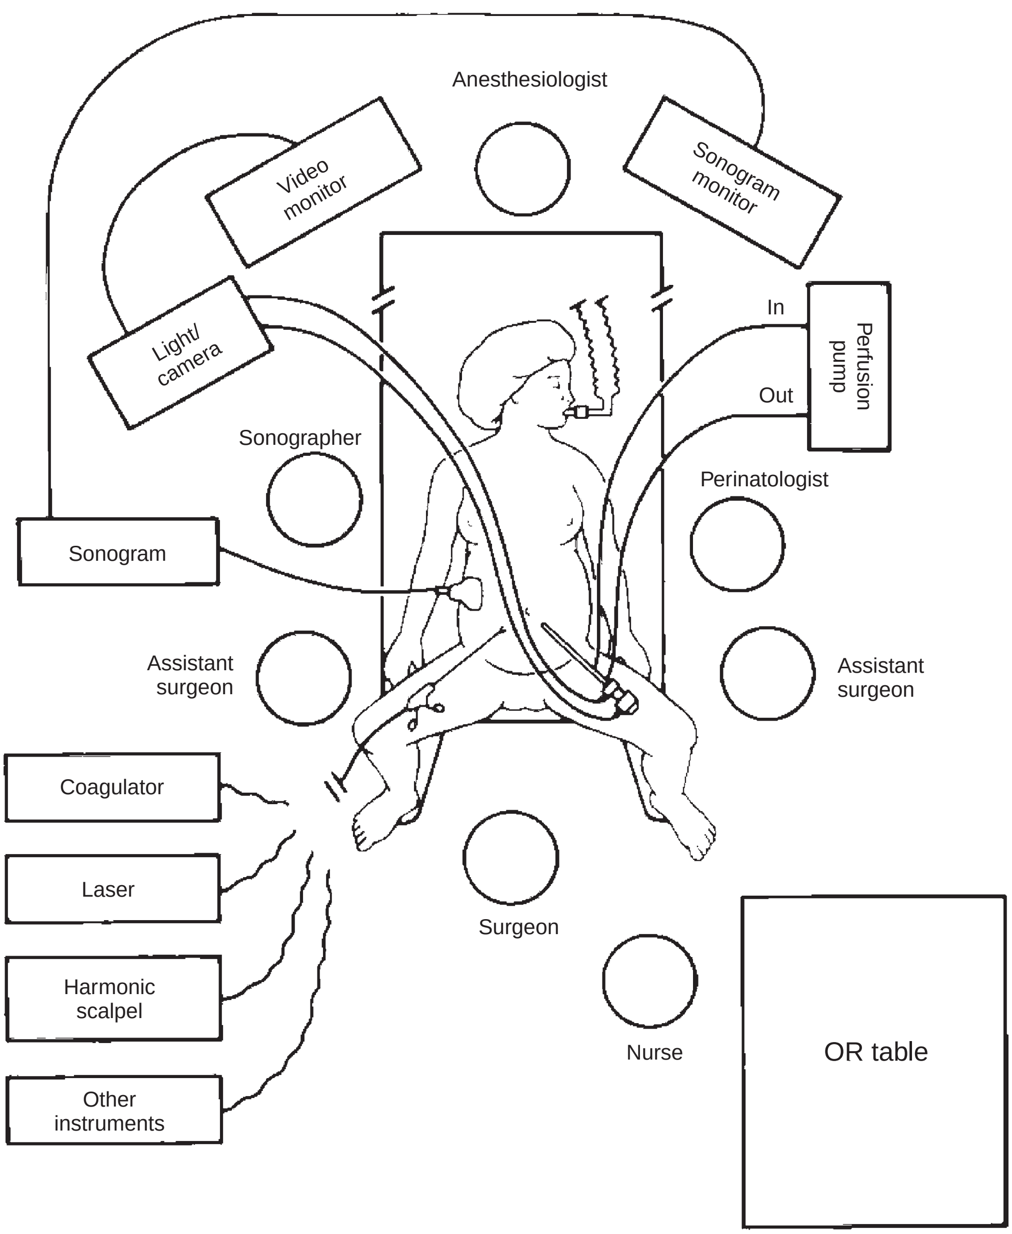

**FIGURE 5-4** Drawing of the operating room set-up. Note that there are two monitors at the head of the table: one for the fetoscopic picture and the other for the real-time ultrasonographic image.

can produce fetal and maternal myocardial depression and affect placental perfusion.[10] Indomethacin can constrict the fetal ductus arteriosus and the combination of magnesium sulfate and betamimetics can produce maternal pulmonary edema. The search for a more effective and less toxic tocolytic regimen led to the demonstration in monkeys that exogenous nitric oxide ablates preterm labor induced by hysterotomy.[32] Intravenous nitroglycerin is a potent tocolytic but requires careful control to avoid serious complications.[1]

Postoperative management is dictated by the degree of intervention. Open fetal surgery by maternal laparotomy and hysterotomy is usually performed with the patient under general anesthesia. Fetal well-being and uterine activity are recorded externally by tocodynamometer. Extensive monitoring, both fetal and maternal, continues postoperatively. Patient-controlled analgesia or continuous epidural analgesia, or both, ease maternal stress and aid tocolysis. After contractions are controlled, monitoring and tocolysis continue and fetal sonograms are obtained at least weekly. Open hysterotomy requires cesarean delivery in this and future pregnancies because of the potential for uterine rupture.[33,34] The most common immediate maternal complication is pulmonary edema due to the administration of perioperative tocolytic agents and intravenous fluids. The incidence was as high as 28% in previous experiences, but with refinement of surgical techniques and tocolytic management the incidence is now approximately 5%.[35] Bleeding that requires transfusion is an infrequent but significant complication of open fetal surgery. Preterm labor and membrane rupture are the most significant complications throughout the remainder of the pregnancy. Close monitoring for contractions, amount of amniotic fluid, membrane disruption,

and cervical shape and length must be performed throughout pregnancy.

Patients who undergo percutaneous procedures, performed either with fetoscopic guidance or with image guidance using 1- to 3-mm-diameter devices, usually receive regional or local anesthesia. The requirement for tocolytic therapy is significantly less than for open fetal surgery, and most patients can be safely discharged from the hospital within 24 to 48 hours after the procedure.[35] Maternal bleeding and pulmonary edema are rare. However membrane rupture and preterm labor remain significant complications,[22] and close monitoring is required throughout the remainder of pregnancy.

# Risks of Maternal-Fetal Surgery

The risk of the procedure for the fetus is weighed against the benefit of correction of a fatal or debilitating defect. The risks and benefits for the mother are more difficult to assess. Most fetal malformations do not directly threaten the mother's health, yet she must bear significant risk and discomfort from the procedure. She may choose to accept the risk for the sake of the unborn fetus and to alleviate the burden of raising a child with a severe malformation.

There is a paucity of published data on the maternal impact of fetal surgical interventions.[34] We analyzed maternal morbidity and mortality associated with different types of fetal intervention (open hysterotomy, different endoscopic procedures, and percutaneous techniques) to quantify this risk. We performed a retrospective evaluation of a continuous series of 187 procedures performed between July 1989 and May 2003 at the University of California, San Francisco (UCSF) Fetal Treatment Center.

Fetal surgery was performed in 87 patients by open hysterotomy, 69 patients underwent endoscopic techniques, and 31 patients underwent percutaneous techniques. There was no maternal mortality. Endoscopic procedures, even with laparotomy, showed statistically significantly less morbidity compared with the open hysterotomy group regarding cesarean section as the mode of delivery (94.8% versus 58.8%; $P < 0.001$), requirement for intensive care unit (ICU) stay (1.4% versus 26.4%; $P < 0.001$), length of hospital stay (7.9 days versus 11.9 days; $P = 0.001$), and requirement for blood transfusions (2.9% versus 12.6%; $P = 0.022$). It was not significant for premature rupture of membranes, pulmonary edema, abruptio placentae, postoperative vaginal bleeding, uncontrollable preterm labor leading to preterm delivery, or interval from fetal surgery to delivery. In more recent series, however, the incidence of pulmonary edema after percutaneous fetal endoscopic surgery has been low.[22] The group that had percutaneous procedures had the least morbidity.[35]

Our study of maternal outcome confirmed that fetal surgery can be performed without maternal mortality. Short-term morbidity can be serious, with impact on maternal health, length of pregnancy, and survival of the fetus.

Because midgestation hysterotomy is not performed in the lower uterine segment, delivery after fetal surgery and all future deliveries should be by cesarean section. In our series uterine disruptions occurred in subsequent pregnancies; uterine closure and neonatal outcome were excellent in both cases. Finally, the ability to carry and deliver subsequent infants does not appear to be jeopardized by fetal surgery.[33]

### PRENATAL DIAGNOSIS DICTATES PERINATAL MANAGEMENT

The nature of the defect determines perinatal management (see Table 5-1).[1] When serious malformations that are incompatible with postnatal life are diagnosed early enough, the family has the option of terminating the pregnancy. Most correctable malformations that can be diagnosed in utero are best managed by appropriate medical and surgical therapy after delivery near term; prenatal diagnosis allows delivery at a center where a neonatal surgical team is prepared. Elective cesarean delivery rather than a trial at vaginal delivery may be indicated for fetal malformations that cause dystocia or that will benefit from immediate surgical repair in a sterile environment.

Early delivery may be indicated for fetal conditions that require treatment as soon as possible after diagnosis, but the risk of prematurity itself must be carefully considered. The rationale for early delivery is unique to each anomaly but the principle remains the same: continued gestation will have progressive ill effects on the fetus. In some cases the function of a specific organ system is compromised by the lesion (e.g., hydronephrosis) and will continue to deteriorate until the lesion is corrected. In some malformations, the progressive ill effects on the fetus result directly from being in utero (e.g., the bowel damage in gastroschisis from exposure to amniotic fluid).

Some fetal deficiency states may be alleviated by treatment before birth (Table 5-3). For example blood can be transfused into the fetal peritoneal cavity or directly into the umbilical artery, and antiarrhythmic drugs can be given transplacentally to convert fetal supraventricular tachycardia. When the necessary substrate, medication, or nutrient cannot be delivered across the placenta, it may be injected into the amniotic fluid from which it can be swallowed and absorbed by the fetus. In the future it is possible that deficiencies in cellular function will be corrected by providing the appropriate stem cell graft or the appropriately engineered gene.[31,36]

# Fetal Anomalies

The only anatomic malformations that warrant consideration are those that interfere with fetal organ development and that if alleviated would allow normal development to proceed (Table 5-4). Initially a few life-threatening malformations were studied intensively and successfully corrected. Over the past two decades an increasing number of fetal defects have been defined and new treatments devised.[1,18] As less invasive interventional techniques are developed and proved safe, a few nonlethal anomalies (e.g., myelomeningocele) have become candidates for fetal surgical correction.[37–39] Finally, stem cell transplantation, gene therapy, and tissue engineering should open the door to treatment of a variety of inherited disorders.[31,36,40,41] In the next section of this chapter, we give an overview of fetal anomalies that may be amenable to fetal intervention as well as fetal anomalies that are of specific interest to pediatric surgeons.

### URINARY TRACT OBSTRUCTION

Fetal urethral obstruction produces pulmonary hypoplasia and renal dysplasia, and these often-fatal consequences can be ameliorated by urinary tract decompression before birth.[24]

The natural history of untreated fetal urinary tract obstruction is well documented, and selection criteria based on fetal urine electrolyte and ß$_2$-microglobulin levels and the ultrasonographic appearance of fetal kidneys have proved reliable.[24] Of all fetuses with urinary tract dilatation, as many as 90% do not require intervention. However fetuses with bilateral hydronephrosis due to urethral obstruction in whom oligohydramnios subsequently develops require treatment. If the lungs are mature the fetus can be delivered early for postnatal decompression. If the lungs are immature the bladder can be decompressed in utero by a vesicoamniotic shunt placed percutaneously using ultrasonographic guidance or by fetoscopic vesicostomy.[24,28] Fetal cystoscopic ablation of posterior urethral valves has also been reported, with the potential benefit of maintenance of the normal physiologic state of fetal bladder filling and emptying.[23,42]

Experience treating several hundred fetuses in many institutions suggests that selection is good enough to avoid inappropriate intervention and that restoration of amniotic fluid can prevent the development of fatal pulmonary hypoplasia. It is not yet clear how much renal function damage can be reversed by decompression. In one retrospective series of fetuses treated with vesicoamniotic shunting for lower urinary tract obstruction, survival at 1 year was 91%, with two neonatal deaths from pulmonary hypoplasia. There was a 39% incidence of prune belly syndrome, more than 50% demonstrated some renal dysfunction, and 33% required renal replacement. Approximately half of the children had persistent respiratory problems, musculoskeletal problems, and frequent urinary tract infections. Nearly two thirds of them had poor growth.[43] Identifying fetuses who may consistently have renal benefit from fetal intervention is likely contingent on the development of more sensitive biomarkers for early fetal renal dysfunction.

## AIRWAY OBSTRUCTION

The tracheal occlusion strategy for fetal CDH required development of techniques to safely reverse the obstruction at birth. The ex utero intrapartum treatment (EXIT) procedure is a technique in which the principles of fetal surgery (anesthesia for mother and fetus, complete uterine relaxation, and maintenance of umbilical circulation to support the fetus) are used during cesarean delivery to allow the airway to be secured while the fetus remains on maternal bypass. The EXIT procedure has been used successfully to reverse tracheal occlusion, repair the trachea, secure the airway by tracheotomy, resect large cervical tumors, place vascular cannulas for immediate extracorporeal membrane oxygenation (ECMO) (EXIT to ECMO), and manage laryngeal obstruction in congenital high airway obstruction syndrome (CHAOS).[44–46]

The EXIT procedure provides a wonderful opportunity for surgeons, perinatologists, neonatologists, and anesthesiologists to learn to work together, and this should be one of the first procedures done in developing a fetal treatment center.

## CONGENITAL PULMONARY AIRWAY MALFORMATION

Although congenital pulmonary airway malformation (CPAM), traditionally referred to as congenital cystic adenomatoid malformation (CCAM), often presents as a benign pulmonary mass in infants and children, some fetuses with large lesions die in utero or at birth from hydrops and pulmonary hypoplasia. The pathophysiologic characteristics of hydrops and the feasibility of resecting the fetal lung have been studied in animals. Experience managing more than 200 patients suggests that

most lesions can be successfully treated after birth and that some lesions resolve before birth. Although only a few fetuses with very large lesions experience hydrops before 26 weeks of gestation, these lesions may progress rapidly and the fetuses die in utero.[47]

Careful ultrasonographic surveillance of large lesions is necessary to detect the first signs of hydrops because fetuses in whom hydrops develops can be successfully treated by emergency resection of the cystic lobe in utero.[48] Size of the CPAM is an important determinant of outcome and the most commonly used metric is the CCAM volume ratio (CVR). CVR is a ratio of the volume of CPAM/fetal head circumference, and higher CVR has been shown to produce a higher incidence of

the development of hydrops fetalis and perinatal mortality.[49] That study also found that microcystic CPAMs tend to plateau in size at 26 to 28 weeks of gestation, whereas macrocystic CPAMs may grow rapidly throughout gestation. Fetal pulmonary lobectomy for fetuses with microcystic CPAM and hydrops fetalis has proved surprisingly simple and quite successful at two large fetal surgery centers, although there is a high likelihood for preterm labor and premature delivery.[44] In 2003, we reported our initial experience with maternal corticosteroid administration for fetuses with microcystic CPAM lesions and hydrops, showing reversal of hydrops and survival in patients.[50] The cumulative data for treatment of 37 fetuses with large microcystic CPAMs at three centers showed 87% overall survival and 80% survival for those with hydrops (16/20 patients).[51] The effect of the steroids on the CPAM is unclear and difficult to elucidate as there is no sufficient animal model for microcystic CPAM. However some have speculated that CPAM represents an arrested state of normal lung development that has been characterized by increased cell proliferation and decreased apoptosis.[52]

We hypothesized that administration of maternal corticosteroids may drive maturation of microcystic CPAM tissue into more mature pulmonary tissue, decreasing proliferation of the lesions. The experience of treating large fetal macrocystic CPAM with maternal steroid administration has not been successful.[53] For lesions with single large cysts thoracoamniotic shunting has been the best option.[54]

## CONGENITAL DIAPHRAGMATIC HERNIA

The history of the evolution of fetal diagnosis and therapy for CDH outlines many of the successes and disappointments of the field. Prenatal diagnosis is now made routinely for CDH.

CDH can now be diagnosed accurately by midgestation, and the severity can be reasonably stratified by fetal US, MRI, and echocardiography. The diagnosis of fetal CDH is usually made by second-trimester anatomic ultrasonographic survey. Typical findings include mediastinal shift with abdominal viscera in the thorax. Careful attention is paid to the presence of other anomalies that can significantly affect the outcome for patients with CDH, including cardiac anomalies, aneuploidy, and other genetic syndromes such as Fryns syndrome. The most consistent prognostic factor for isolated CDH is presence or absence of liver herniation into the chest.[55] For prenatally diagnosed CDH, the presence of liver herniated into the chest is correlated with decreased survival compared with patients without liver herniation. Attempts at further stratifying the severity of CDH by determining relative lung size have met with variable success. The primary ultrasonographic measurement is lung/head ratio (LHR). To determine LHR a two-dimensional measurement of the lung is made at the level of the four-chambered view of the heart (numerator) and is compared with the head circumference to control for differences in gestational age and fetal size. LHR in the presence of liver herniated into the chest has been shown to have close correlation to survival in several single-institution series as well several multi-institutional series.[55,56] LHR shows substantial variability among ultrasonologists and requires an ultrasonologist with extensive experience in evaluating fetuses with CDH. LHR without liver herniation has not been shown to correlate with outcome.

Lung volume on MRI is the other primary measurement to determine severity of fetal CDH. Three-dimensional interpretation of fetal MRI data is performed and compared with nomograms for fetal lung volume to calculate the percentage of expected lung volume.[57] Some centers have found ultrasonographic measurements to be more predictive of outcome, whereas others have found MRI measurements to be more predictive.

Fetuses without liver herniation and with a favorable LHR (>1.4) have low mortality after term delivery at tertiary centers. However fetuses with liver herniation and a low LHR have high mortality and morbidity despite recent advances in intensive neonatal care, including ECMO, nitric oxide inhalation, high-frequency ventilation, and delayed operative repair of the diaphragmatic hernia.[19,58–63] The fundamental problem in newborns with CDH is pulmonary hypoplasia. Research in experimental animal models and later in human patients over 2 decades has aimed to improve growth of the hypoplastic lungs before they are needed for gas exchange at birth. Anatomic repair of the hernia by open hysterotomy proved feasible but did not decrease mortality and was abandoned.[64,65] Fetal tracheal occlusion was developed as an alternative strategy to promote fetal lung growth by preventing normal egress of lung fluid. Occlusion of the fetal trachea was shown to stimulate fetal lung growth in a variety of animal models.[66–68] Techniques to achieve reversible fetal tracheal occlusion were explored in animal models and then applied clinically, evolving from external metal clips placed on the trachea by open hysterotomy or fetoscopic neck dissection to internal tracheal occlusion with a detachable silicone balloon placed by fetal bronchoscopy through a single 5-mm uterine port.[69–71]

Our initial experience suggested that fetal endoscopic tracheal occlusion improved survival in human fetuses with severe CDH.[71–73] To evaluate this novel therapy we conducted a randomized controlled trial comparing tracheal occlusion with standard care.[74] Survival with fetal endoscopic tracheal occlusion (73%) met expectations (predicted 75%) and appeared better than that of historical controls (37%) but proved no better than that of concurrent randomized controls. The higher than expected survival in the standard care group may be because the study design mandated that patients in both treatment groups be delivered, resuscitated, and intensively managed in a unit experienced in caring for critically ill newborns with pulmonary hypoplasia.[74]

Attempts to improve outcome for severe CDH by treatments either before or after birth have proved double-edged swords. Intensive care after birth has improved survival but has increased long-term sequelae in survivors and is expensive.[19,59–61,63] Intervention before birth may increase lung size but prematurity caused by the intervention itself can be detrimental.[65,72,75–77] In our study newborns with severe CDH who had tracheal occlusion before birth were born on average at 31 weeks as a consequence of the intervention. The observation that their rates of survival and respiratory outcomes (including duration of oxygen requirement) were comparable to infants without tracheal occlusion who were born at 37 weeks suggests that tracheal occlusion improved pulmonary hypoplasia, but the improvement in lung growth was affected by pulmonary immaturity related to earlier delivery.[74]

The current results underscore the role of randomized trials in evaluating promising new therapies. This is the second National Institutes of Health (NIH)-sponsored trial studying a new prenatal intervention for severe fetal CDH. The first trial showed that complete surgical repair of the anatomic defect (which required hysterotomy), although feasible, was no better than postnatal repair in improving survival and was ineffective when the liver as well as the bowel were herniated.[65] That trial led to the abandonment of open complete repair at our institution and subsequently around the world. Information derived from that trial regarding measures of severity of pulmonary hypoplasia (including liver herniation and the development of the LHR) led to the development of an alternative physiologic strategy to enlarge the hypoplastic fetal lung by temporary tracheal occlusion[73,76,77] and to the development of less invasive fetal endoscopic techniques that did not require hysterotomy to achieve temporary reversible tracheal occlusion.[21,69,71]

Our ability to accurately diagnose and assess severity of CDH before birth has improved dramatically. Fetuses with CDH who have associated anomalies do poorly, whereas fetuses with isolated CDH, no liver herniation, and an LHR greater than 1.4 have an excellent prognosis (100% in our experience). In this study fetuses with an LHR between 0.9 and 1.4 had a chance of survival greater than 80% when delivered at a tertiary care center. The small number of fetuses with an LRH less than 0.9 had a poor prognosis in both treatment groups and should be the focus of ongoing study.[74] Further, animal models have shown that reversal of tracheal occlusion before delivery may minimize the damage to type II pneumocytes and surfactant production that prolonged tracheal occlusion may cause.[78]

With the advent of further miniaturized fetoscopic equipment, the group in Leuven, Belgium has led efforts to perform percutaneous temporary fetoscopic tracheal occlusion for isolated severe (liver herniation into chest, LHR <1.) CDH. They have reported 50% survival with gestational age at delivery of 34 weeks in fetuses undergoing temporary tracheal occlusion compared with survival of less than 15% in a cohort of fetuses with similar prenatal variables.[79] The European experience now consists of more than 200 patients with temporary tracheal occlusion, and a prospective randomized trial comparing that strategy to standard postnatal care is under way in Europe.[80] The low survival of patients with standard postnatal care in Europe has been criticized, as survival in that cohort in the United States at certain tertiary centers has been significantly higher. UCSF currently is conducting a safety and feasibility trial for temporary percutaneous fetoscopic tracheal occlusion for severe CDH with oversight by the US Food and Drug Administration (FDA).

## Myelomeningocele

Myelomeningocele is a devastating birth defect with sequelae that affect both the central and peripheral nervous systems. Altered cerebrospinal fluid dynamics result in the Chiari II malformation and hydrocephalus. Damage to the exposed spinal cord results in lifelong lower extremity neurologic deficiency, fetal and urinary incontinence, sexual dysfunction, and skeletal deformities. This defect carries enormous personal, familial, and societal costs, as the near-normal life span of the affected child is characterized by hospitalization, multiple operations, disability, and institutionalization. Although it has been assumed that the spinal cord itself is intrinsically malformed in children with this defect, recent work suggests that the neurologic impairment after birth may be due to exposure and trauma to the spinal cord in utero and that covering the exposed cord may prevent the development of the Chiari malformation.[37,39,81]

Since 1997 more than 200 fetuses have undergone in utero closure of myelomeningocele by open fetal surgery. Preliminary clinical evidence suggests that this procedure reduces the incidence of shunt-dependent hydrocephalus and restores the cerebellum and brainstem to a more normal configuration.[39] However clinical results of fetal surgery for myelomeningocele are based on comparisons with historical controls, examine only efficacy not safety, and lack long-term follow-up.

The NIH has funded a multicenter randomized clinical trial (Management of Myelomeningocele Study [MOMS]) of 200 patients that will be conducted at three fetal surgery units: the University of California, San Francisco; the Children's Hospital of Philadelphia; and Vanderbilt University Medical Center, along with an independent data and study coordinating center, the George Washington University Biostatistics Center. Since the inception of the trial Vanderbilt has dropped out as a surgical site.

Primary objectives of this randomized trial are (1) to determine if intrauterine repair of fetal myelomeningocele at 19 to 26 weeks' gestation using a standard multilayer closure improves outcome, as measured by death or the need for ventricular decompressive shunting by 1 year of life, compared with standard postnatal care and (2) to determine if intrauterine repair of myelomeningocele can improve motor function as well as cognitive function as measured by the Bayley Scales of Infant Development mental development index at 30 months' corrected age.[82] The study was closed to new patient enrollment on December 7, 2010, after 183 patients had been randomized because of the efficacy of prenatal repair. Specifically, prenatal repair of spina bifida reduced the need for ventricular shunting to treat hydrocephalus and improved motor outcomes including the ability to walk at 30 months of age.[98] Prenatal repair of MMC was also associated with significant maternal and neonatal risks, including premature birth and uterine scar issues.

### SACROCOCCYGEAL TERATOMA

Most neonates with sacrococcygeal teratoma survive and malignant invasion is unusual. However the prognosis of patients with sacrococcygeal teratoma diagnosed prenatally (by ultrasonography or elevated AFP levels) is less favorable. There is a subset of fetuses (fewer than 20%) with large tumors in whom hydrops develops from high-output failure secondary to extremely high blood flow through the tumor. Because hydrops progresses rapidly to fetal death, frequent ultrasonographic follow-up is mandatory. Excision of the tumor reverses the pathophysiology if it is performed before the mirror syndrome (maternal eclampsia) develops in the mother.[1,83] Attempts to interrupt the vascular steal by ablating blood flow to the tumor by alcohol injection or embolization have not been successful. Ultrasonographically guided radiofrequency ablation of the vascular pedicle has worked but with unacceptable damage to adjacent structures.

## Gastroschisis

Patients born with gastroschisis require immediate surgical intervention after birth with either primary or staged closure of the abdominal wall. Despite closure of the abdominal wall defect, many infants face prolonged difficulty with nutrient absorption and intestinal motility. At birth, the intestines of these patients are frequently thickened and covered by a fibrinous "peel." Mesenteric shortening and intestinal atresia may also be present. The bowel damage may be due to constriction of the mesentery (like a napkin ring), causing poor lymphatic and venous drainage from the bowel, or to an inflammatory reaction to various substances in the amniotic fluid bathing the bowel.[84]

With advances in neonatal care, survival for gastroschisis is now more than 90% in most series.[84–86] Serial amniotic fluid exchange has been used to dilute putative inflammatory mediators and thus prevent bowel damage.[87] However our ability to select fetuses with damaged bowels is limited, and the volume of exchange may be inadequate to alter outcome.

Despite high survival rates the complications of gastroschisis remain severe. Gastroschisis is one of the leading causes of short-bowel syndrome and one of the leading indications for small bowel transplantation. The main challenge in fetal treatment of gastroschisis has been identifying biomarkers to distinguish the small subset of fetuses who will have poor outcomes for both counseling and potential treatment. Unfortunately most attempts at predicting outcome by prenatal markers have been unsuccessful. The only prenatal marker that has been reproducible has been multiple intra-abdominal dilated loops of intestine on prenatal US.[88,89]

## INTESTINAL ABNORMALITIES

Nearly all abnormalities of fetal intestines are best managed postnatally. However pregnant women are frequently referred to pediatric surgeons for consultation. A common ultrasonographic finding is that of echogenic bowel, seen in up to 1.4% of all second-trimester ultrasonograms.[90] The vast majority of fetuses with echogenic bowel as an isolated anomaly have no clinical sequelae. However the presence of echogenic bowel does increase the risk of aneuploidy. Further, echogenic bowel can herald the presence of bowel injury from a variety of causes. The workup for echogenic bowel may include a detailed ultrasonogram of the fetus and an amniocentesis for karyotype for evidence of cytomegalovirus, toxoplasmosis, and parvovirus. Cystic fibrosis (CF) carrier testing for both parents and maternal serologic testing for recent cytomegalovirus and toxoplasmosis may also be performed. Follow-up with serial growth scans is recommended because these fetuses are potentially at risk for poor growth.

Evidence of frank bowel perforation is suggested by prenatal ultrasonographic findings of ascites, abdominal calcifications, pseudocysts, dilated loops of intestine, or polyhydramnios. The causes of bowel perforation in utero are similar to postnatal causes and are familiar to pediatric surgeons. They include intestinal atresias, meconium ileus, midgut volvulus, and intestinal ischemia. The majority of fetuses with evidence of bowel perforation usually require no surgery postnatally. However fetuses with pseudocysts or diffuse ascites are at higher risk for postnatal surgery and the possibility of long-term intestinal complications.[91]

Dilatation of intestine as an isolated finding usually indicates jejunal-ileal atresia. Without evidence of perforation, volvulus, or other complications, postnatal management results in excellent outcome.[92]

## ANOMALIES OF MONOCHORIONIC TWINS

Identical twins may have separate placentas (dichorionic) or share a placenta (monochorionic). Monochorionic twins may have unequal blood flow or unequal shares of the placenta and are at risk for discordant growth or more severe anomalies such as TTTS and TRAP sequence, two of the anomalies of monochorionic twinning that frequently require fetal surgery. Consultation for complications in monochorionic twins represents the most frequent consultation to fetal diagnosis and treatment centers. Further, the laser treatment for TTTS described later on is the most common fetal surgery performed both in the United States and worldwide.

## TWIN-TWIN TRANSFUSION SYNDROME

Branches of umbilical arteries and veins from one twin connect with branches of umbilical arteries and veins from the other twin on the surface of the placenta in all monochorionic twin pregnancies. In normal monochorionic twin pregnancies, the flow of blood is relatively balanced from one twin to the other.

TTTS is a complication of monochorionic multiple gestations resulting from an imbalance in blood flow through these vascular communications, or chorioangiopagus. This net imbalance in flow results in one twin (the "recipient") getting too much blood and becoming at risk for high-output cardiac failure and the other twin (the "donor) getting too little blood flow and becoming at risk for hypovolemia and hypoperfusion. Further, vascular mediators such as endothelin may exacerbate cardiac dysfunction in the recipient twin and cause progressive cardiac failure.[93]

It is the most common serious complication of monochorionic twin gestations, affecting between 4% and 35% of monochorionic twin pregnancies, or approximately 0.1 to 0.9 per 1000 births each year in the United States. Yet despite the relatively low incidence, TTTS disproportionately accounts for 17% of all perinatal mortality associated with twin gestations. Previously, standard therapy was limited to serial amnioreduction, which appears to improve the overall outcome but has little impact on the more severe end of the spectrum in TTTS. In addition survivors of TTTS treated by serial amnioreduction have an 18% to 26% incidence of significant neurologic and cardiac morbidity. Selective fetoscopic laser photocoagulation of chorioangiopagus has emerged as the gold standard for treatment of TTTS as demonstrated in a randomized trial in Europe.[22] This prospective randomized controlled trial compared fetoscopic laser coagulation of intertwin vessels to amnioreduction for severe TTTS, with the main outcome variable being survival of at least one twin. Survival of at least one twin was higher in the laser group compared with the amnioreduction group (76% versus 56%), with a decreased incidence of neurologic complications in the laser group. The authors concluded that laser coagulation for severe TTTS was superior to amnioreduction.[22]

## TWIN REVERSED ARTERIAL PERFUSION SEQUENCE

Acardiac/acephalic twinning is a rare anomaly in which a normal "pump" twin perfuses an acardiac twin, resulting in TRAP sequence. TRAP sequence in acardiac monochorionic twin gestations compromises the viability of the morphologically normal pump twin. Selective reduction and obliteration of blood flow in the acardiac twin has been accomplished by a variety of techniques, including fetectomy; ligation, division, and cauterization of the umbilical cord; and obliteration of the circulation in the anomalous twin by alcohol injection, electrocautery, or radiofrequency ablation.[25,26] We have pioneered a technique using radiofrequency technology with ultrasonographic guidance. We have used a 14-gauge or 17-gauge radiofrequency ablation (RFA) probe placed percutaneously into the body of the acardiac twin with real-time ultrasonographic guidance, which effectively obliterates the blood supply of the acardiac fetus and protects the pump twin.[26,94] Using this technique survival in monochorionic diamniotic TRAP pregnancies was 92%, with a mean gestational age of 36 weeks. The natural history of TRAP sequence has been reported at greater than 50% mortality.[95] Recently the North American Fetal Therapy Network presented a national registry of 98 pregnant women with TRAP sequence treated by RFA and found an 80% overall survival from 12 centers.[96]

## INHERITED DEFECTS CORRECTABLE BY FETAL STEM CELL TRANSPLANTATION

Various inherited defects that are potentially curable by hematopoietic stem cell (HSC) transplantation (e.g., immunodeficiencies, hemoglobinopathies, and storage diseases) can now be detected early in gestation. Postnatal bone marrow transplantation is limited by donor availability, graft rejection, graft-versus-host disease, and patient deterioration before transplantation, which often begins in utero. Transplantation of fetal HSCs early in gestation may circumvent these difficulties.[36,40,41]

The rationale for in utero rather than postnatal transplantation is that the preimmune fetus (<15 weeks) should not reject the transplanted cells, and the fetal bone marrow is primed to receive HSCs that migrate from the fetal liver. Thus myeloablation and immunosuppression may not be necessary. In addition in utero transplantation allows treatment before fetal health is compromised by the underlying disease. The disadvantage of treatment in utero is that the fetus is difficult to access for diagnosis and treatment. Definitive diagnosis using molecular genetic techniques requires fetal tissue obtained by transvaginal or transabdominal chorionic villus sampling, amniocentesis, or fetal blood sampling. Delivering even a small volume (<1 mL) of cells to an early-gestation fetus by intra-abdominal or intravenous injection requires skill and carries significant risks. The greatest potential problem with in utero transplantation of HSCs is that the degree of engraftment or chimerism may not be sufficient to cure or palliate some diseases. In diseases such as chronic granulomatous disease and severe combined immunodeficiency, relatively few normal donor cells can provide sufficient enzyme activity to alleviate symptoms. However a significantly higher degree of donor cell engraftment and expression in the periphery might be necessary to change the course of diseases such as ß-thalassemia or sickle cell disease. For diseases that require a high percentage of donor cells, a promising strategy is to induce tolerance in utero for subsequent postnatal booster injections from a living relative. The optimal source of donor HSCs for in utero transplantation is not known. Donor cells can be obtained from adult bone marrow or peripheral blood, from neonatal umbilical cord blood, or from the liver of an aborted fetus.

Clinical experience with fetal HSC transplantation is limited. Although engraftment has been successful in cases of severe combined immunodeficiency syndrome, for most other diseases low levels of engraftment after injection have limited clinical efficacy.[31,40,41]

## PAST AND FUTURE OF FETAL INTERVENTION

Although only a few fetal defects are currently amenable to surgical treatment, the enterprise of fetal surgery has produced some unexpected spin-offs that have interest beyond this narrow therapeutic field. For pediatricians, neonatologists, and dysmorphologists, the natural history and pathophysiologic features of many previously mysterious conditions of newborns have been clarified by following the development of the disease in utero. For obstetricians, perinatologists, and fetologists, techniques developed during experiments in lambs and monkeys will prove useful in managing other high-risk pregnancies. For example an absorbable stapling device developed for fetal surgery has been applied to cesarean sections; radiotelemetric monitoring has applications outside fetal surgery; and videoendoscopic techniques have allowed fetal manipulation without hysterotomy. These techniques will greatly extend the indications for fetal intervention. Finally, the intensive effort to solve the vexing problem of preterm labor after hysterotomy for fetal surgery has yielded new insight into the role of nitric oxide in myometrial contractions and has spawned interest in treating spontaneous preterm labor with nitric oxide donors.

Fetal surgical research has yielded advances in fetal biology with implications beyond fetal therapy. The serendipitous observation that fetal incisions heal without scarring has provided new insights into the biological characteristics of wound healing and has stimulated efforts to mimic the fetal process postnatally. Fetal tissue seems biologically and immunologically superior for transplantation and gene therapy, and fetal immunologic tolerance may allow a wide variety of inherited nonsurgical diseases to be cured by fetal HSC transplantation.

The great promise of fetal therapy is that for some diseases the earliest possible intervention (before birth) produces the best possible outcome (the best quality of life for the resources expended). However the promise of cost-effective preventive fetal therapy can be subverted by misguided clinical applications—for example, a complex in utero procedure that only half saves an otherwise-doomed fetus for a life of intensive (and expensive) care. Enthusiasm for fetal interventions must be tempered by reverence for the interests of the mother and her family, by careful study of the disease in experimental fetal animals and untreated human fetuses, and by a willingness to abandon therapy that does not prove both therapeutically effective and cost-effective in properly controlled trials. Advances must be achieved in a thoughtful manner that balances the potential benefits with the attendant risks, including those to the most important patient, the pregnant woman.

CHAPTER 6

# Neonatal Physiology and Metabolic Considerations

Agostino Pierro, Paolo De Coppi, and Simon Eaton

Advances in neonatal intensive care and surgery have significantly improved the survival of neonates with congenital or acquired abnormalities. This has been matched by an improvement in our understanding of the physiology of infants undergoing surgery and their metabolic response to starvation, anesthesia, operative stress, and systemic inflammation.[1] Newborn infants who undergo surgery are not just small adults; their physiology in terms of thermoregulation and fluid and caloric needs can be very different, particularly if the neonate is premature or has intrauterine growth retardation (IUGR). This chapter focuses on the physiology and metabolism of newborn infants undergoing surgery, with particular emphasis on the characteristics of preterm neonates. In this chapter we discuss fluid and electrolyte balance, neonatal energy metabolism and thermoregulation, and the metabolism of carbohydrate, fat, and protein. In addition, we present the current knowledge on the neonatal response to operative trauma and sepsis, which represent two of the major factors that alter their physiology.

## Premature, Small for Gestational Age, and Neonates with Intrauterine Growth Retardation

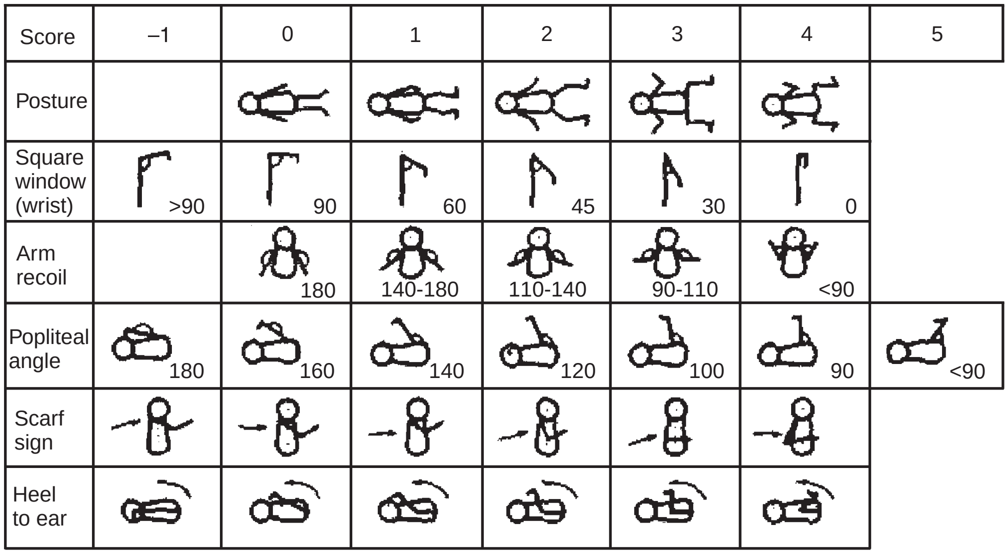
The greatest growth rate occurs during fetal life. In fact the passage from one fertilized cell to a 3.5-kg neonate encompasses an increase in length of 5000-fold, an increase in surface area of $61 \times 10^6$, and an increase in weight of $6 \times 10^{12}$. The greatest postnatal growth rate occurs just after birth. It is not unusual in neonates undergoing surgery to notice a period of slow or arrested growth during critical illness or soon after surgery.

Neonates can be classified as premature, term, or postmature according to gestational age. Any infant born before 37 weeks of gestation is defined as premature, term infants are those born between 37 and 42 weeks of gestation, and post-term neonates are born after 42 weeks of gestation. Previously any infant weighing less than 2500 g was termed premature. This definition is inappropriate because many neonates weighing less than 2500 g are mature or postmature but are small for gestational age (SGA); they have different appearance and different problems than do premature infants. The gestational age can be estimated antenatally or in the first days after birth using the Ballard score (Fig. 6-1).[2] By plotting body weight versus gestational age (Fig. 6-2),[3] newborn infants can be classified as small, appropriate, or large for gestational age. Head circumference and length are also plotted against gestational age to estimate intrauterine growth (Fig. 6-3).[3] Any infant whose weight is below the 10th percentile for gestational age is defined as SGA. Large for gestational age infants are those whose weight is above the 90th percentile for gestational age (see Fig. 6-2).[3] In general preterm infants weigh less than 2500 g, have a crown-heel length less than 47 cm, a head circumference less than 33 cm, and a thoracic circumference less than 30 cm. The preterm infant has physiologic handicaps due to functional and anatomic immaturity of various organs. Body temperature is difficult to maintain, there are commonly respiratory difficulties, renal function is immature, the ability to combat infection is inadequate, the conjugation and excretion of bilirubin is impaired, and hemorrhagic diathesis is more common.

Premature infants are usually further assigned to subgroups on the basis of birth weight as follows:

1. Moderately low birth weight (birth weight between 1501 and 2500 g): This group represents 82% of all premature infants. The mortality rate in this group is 40 times that in term infants.
2. Very low birth weight (birth weight between 1001 and 1500 g): This group represents 12% of premature infants. The mortality rate in this group is 200 times that in full-term newborns.
3. Extremely low birth weight (birth weight less than 1000 g): These neonates represent 6% of premature births but account for a disproportionate number of newborn deaths. The mortality rate is 600 times that in term infants.

The definition of IUGR is often confused and unclear in the medical literature. IUGR is usually defined as a documented decrease in intrauterine growth noted by fetal ultrasonography. IUGR can be temporary, leading to a normal-sized neonate at birth. There are two types of IUGR: symmetric and



Physical Maturity

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| Skin | Sticky, friable, transparent | Gelatinous, red, translucent | Smooth, pink, visible veins | Superficial peeling and/or rash; few veins | Cracking, pale areas; rare veins | Parchment, deep cracking; no vessels | Leathery, cracked, wrinkled |
| Lanugo | None | Sparse | Abundant | Thinning | Bald areas | Mostly bald | |
| Plantar surface | Heel-toe 40-50 mm: –1 <40 mm: –2 | >50 mm, no crease | Faint red marks | Anterior transverse crease only | Creases anterior $^2/_3$ | Creases over entire sole | |
| Breast | Imperceptible | Barely perceptible | Flat areola, no bud | Stippled areola, 1–2 mm bud | Raised areola, 3–4 mm bud | Full areola, 5–10 mm bud | |
| Eye/ear | Lids fused loosely: –1 lightly: –2 | Lids open; pinna flat; stays folded | Slightly curved pinna; soft; slow recoil | Well-curved pinna; soft but ready recoil | Formed and firm, instant recoil | Thick cartilage, ear stiff | |
| Genitals (male) | Scrotum flat, smooth | Scrotum empty, faint rugae | Testes in upper canal, rare rugae | Testes descending, few rugae | Testes down, good rugae | Testes pendulous, deep rugae | |
| Genitals (female) | Clitoris prominent, labia flat | Clitoris prominent, small labia minora | Clitoris prominent, enlarging minora | Majora and minora equally prominent | Majora large, minora small | Majora cover clitoris and minora | |

asymmetric. Symmetric IUGR denotes normal body proportions (small head and small body) and is considered a more severe form of IUGR.[4] Asymmetric IUGR denotes small abdominal circumference, decreased subcutaneous and abdominal fat, reduced skeletal muscle mass, and head circumference in the normal range. Infants with asymmetric IUGR show catch-up growth more frequently than do infants with symmetric IUGR, although 10% to 30% of all infants with IUGR remain short as children and adults. Premature infants are expected to have catch-up growth by 2 years of age. Those born after 29 weeks of gestation usually exhibit catch-up growth, whereas those born before 29 weeks of gestation are more likely to have a decreased rate of length and weight gain, which may be noted in the first week after birth and last up to 2 years.[5–7]

## Predicting Neonatal Mortality

Various factors contribute to the mortality of neonates. The most common factors are listed in Table 6-1. Although neonatal mortality decreased markedly as a result of improvements in care, it appears to have reached a plateau[8] at which small improvements in neonatal care may be offset by other secular trends such as increases in premature birth. Birth weight and gestational age are strong indicators of mortality, but ethnicity is also a factor (Fig. 6-4).[9] The survival of neonates of 500 g and 22 weeks' gestational age approaches 0%. With increasing gestational age, survival rates increase to approximately 15% at 23 weeks, 56% at 24 weeks, and 79% at 25 weeks of gestation. Scoring systems to predict mortality would be particularly useful in neonatal surgery to plan treatment, to counsel parents, and to compare outcomes between different centers.

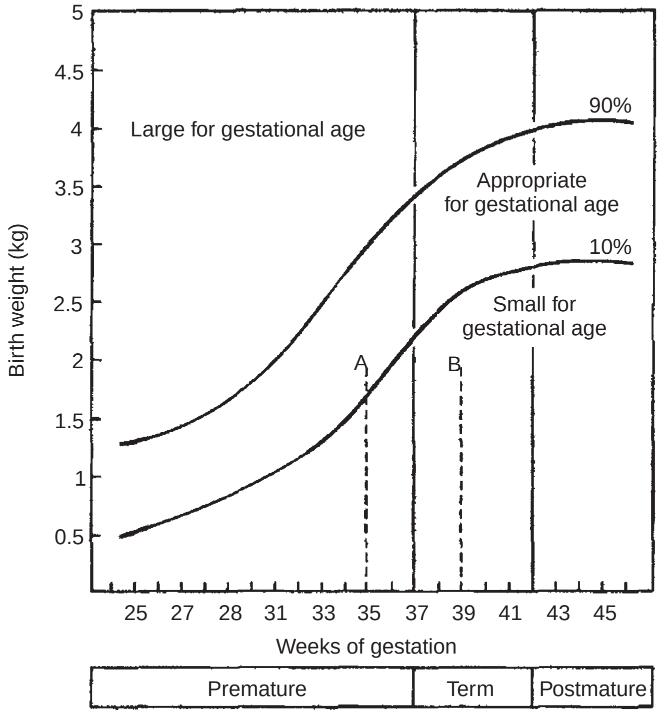

**FIGURE 6-2** Level of intrauterine growth based on birth weight and gestational age of live-born, single white infants. (From Disturbances in newborns and infants. In Beers MF, Berkow R [eds]: The Merck Manual of Diagnosis and Therapy, 17th ed. White House Station, NJ, Merck Research Laboratories, 1999, pp 2127–2145.)

However these scoring systems have not been developed and validated in neonatal surgery. Generic scoring systems for neonates are available but these do not take into consideration the anatomic abnormality requiring surgery. They are based on physiologic abnormalities such as hypotension-hypertension, acidosis, hypoxia, hypercapnia, anemia, and neutropenia (Score for Neonatal Acute Physiology [SNAP]) or clinical parameters such as gestational age, birth weight, anomalies, acidosis, and fraction of inspired oxygen ($F_{IO_2}$) (Clinical Risk Index for Babies [CRIB]).[10,11] CRIB includes 6 parameters collected in the first 12 hours after birth, and SNAP has 26 variables collected during the first 24 hours, and there have been various modifications to these scoring systems (e.g., CRIB-II, SNAP-II).[12] The authors have recently used[13] a modified organ failure score (Table 6-2) based on the Sepsis-related Organ Failure Assessment (SOFA) in use in adults and children to monitor the clinical status of neonates with acute abdominal emergencies who require surgery. Combining the surgeon's judgment and an objective score may produce an accurate assessment of the clinical progress of critically ill neonates and estimate their risk of mortality.

**TABLE 6-1**

| Respiratory distress syndrome | Meconium aspiration |
| Intraventricular hemorrhage | Birth asphyxia, trauma |
| Infection | |
| Bronchopulmonary dysplasia | |

# Fluid and Electrolyte Balance

## BODY WATER COMPOSITION

The content and distribution of intracellular and extracellular water in the human body is defined as total body water (TBW) and it changes with age. TBW also varies with body fat content. Fat cells contain very little water; therefore children with more body fat have a lower proportion of body water than

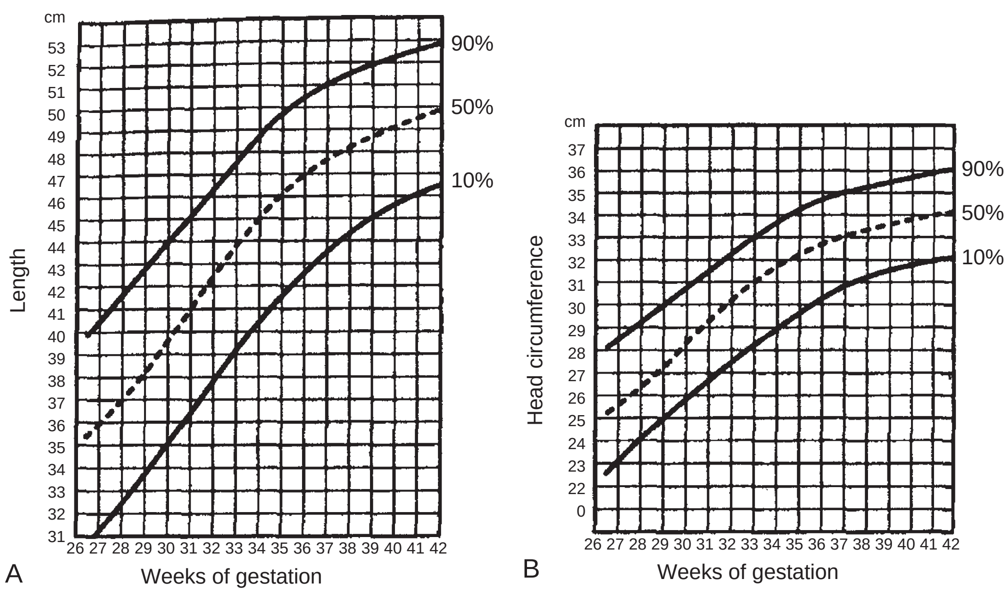

**FIGURE 6-3** Level of intrauterine growth based on gestational age, body length **(A)**, and head circumference **(B)** at birth. (From Disturbances in newborns and infants. In Beers MF, Berkow R [eds]: The Merck Manual of Diagnosis and Therapy, 17th ed. White House Station, NJ, Merck Research Laboratories, 1999, pp 2127–2145.)

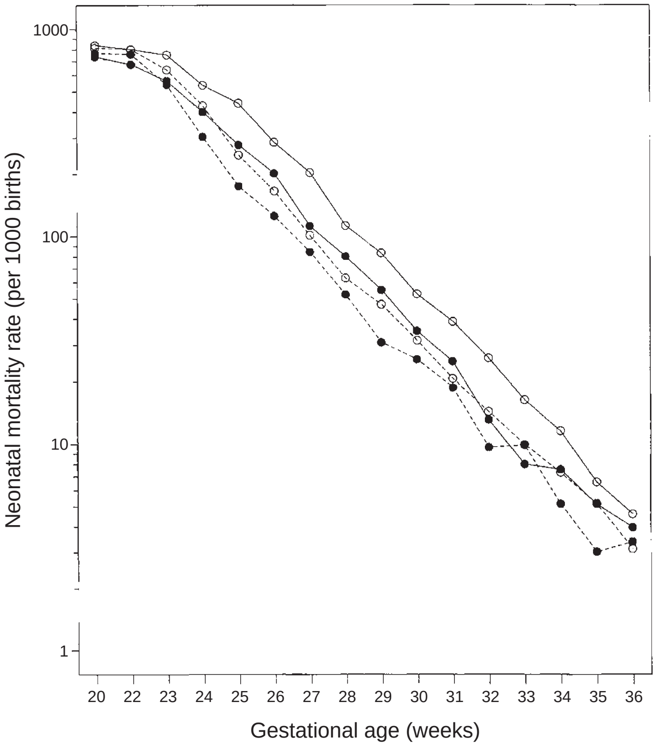

**FIGURE 6-4** Neonatal mortality, by gestational age, for black (•) and white (○) infants in the United States. Solid lines denote data for 1989; dashed lines are for 1997. Data shown are for less than 37 weeks' gestation only. (From Demissie K, Rhoads GG, Ananth CV, et al: Trends in preterm birth and neonatal mortality among blacks and whites in the United States from 1989 to 1997. Am J Epidemiol 2001;154:307-315.)

children with less fat. The water in body tissues includes the intracellular fluid, which represents the water contained within the cells, and extracellular fluid. Extracellular fluid is further subdivided into intravascular fluid (plasma), interstitial fluid (fluid surrounding tissue cells), and transcellular fluid (e.g., cerebrospinal, synovial, pleural, peritoneal fluid). During the first trimester, when only 1% of body mass is fat, 90% of body mass is TBW, with 65% of body mass made up of extracellular fluid.[14] However these ratios alter throughout gestation as the amount of body protein and fat increases. TBW as a proportion of body mass declines and is approximately 70% to 80% by term.[15] TBW continues to decline during the first year of life reaching 60% of total body mass, which is consistent with adult age. This is accompanied by a decrease in the extracellular compartment fluid (ECF)/intracellular compartment fluid (ICF) ratio. The ECF is 60% of total body mass at 20 weeks' gestation, declining to 40% at term, whereas ICF increases from 25% at 20 weeks' gestation to 35% of body mass at term and then to 43% at 2 months of age. Because extracellular fluid is more easily lost from the body than intracellular fluid and infants have a larger surface area/body mass ratio, they are more at risk of dehydration than are older children and adults.

Among preterm infants, those who are SGA have a significantly higher body water content (approximately 90%) than appropriate for full-term infants (approximately 80%).[16] Blood volume can be estimated as 106 mL/kg in preterm infants, 90 mL/kg in neonates, 80 mL/kg in infants and children and about 65 mL/kg in adults.[17,18] Adequate systemic perfusion depends on adequate intravascular volume, as well as many other factors. However infants and children can compensate for relatively large losses in circulating volume, and signs and symptoms of shock may be difficult to detect if a child has lost less than 25% of the circulating volume. The movement of fluid between the vascular space and the tissues depends on osmotic pressure, oncotic pressure, hydrostatic pressure, and changes in capillary permeability. Understanding these factors is important when trying to anticipate changes in the child's intravascular volume.[19]

## NEONATAL FLUID BALANCE

Before labor, pulmonary fluid production decreases while existing fluid is reabsorbed, and efflux through the trachea increases and accelerates during labor, thereby drying out the lungs. During labor, arterial pressure increases and causes shifts in plasma from the vascular compartment and a slight rise in hematocrit values. Placental transfusion can occur if

**TABLE 6-2**
**Modified Organ Failure Score***

To calculate the aggregate score, the worst value of each parameter in each time interval will be recorded. MAP = Mean Arterial Pressure

*$P$ < .05 vs. preoperative sample.
From Hall NJ, Eaton S, Peters MJ, et al: Mild controlled hypothermia in preterm neonates with advanced necrotizing enterocolitis. Pediatrics 2010;125:e300-e308.

there is delayed clamping of the cord and the neonate is placed at or below the level of the placenta, resulting in up to 50% increase in red blood cells and blood volume. This polycythemia may have severe consequences such as neurologic impairment, thrombus formation, and tissue ischemia.[20] One day postpartum the neonate is oliguric. Over the following 1 to 2 days, dramatic shifts in fluid from the intracellular to extracellular compartment result in a diuresis and natriuresis that contributes to weight loss during the first days of life. This is approximately 5% to 10% in the term neonate and 10% to 20% in the premature newborn. The proportion of contributions from ECF and ICF to fluid loss is controversial and the mechanism is yet to be determined. This diuresis occurs regardless of fluid intake or insensible losses and may be related to a postnatal surge in atrial natriuretic peptide.[21] Limitations in the methodology of measuring ECF and ICF have limited our understanding of the processes. It has been demonstrated however that large increases in water and calorie intake are required to reduce the weight loss. Higher caloric intake alone reduces weight loss but the ECF still decreases. Subsequent weight gain appears to be the result of increases in tissue mass and ICF per kilogram of body weight but not ECF per kilogram of body weight. By the fifth day postpartum, urinary excretion begins to reflect the fluid status of the infant.

## RENAL FUNCTION

The kidneys in neonates have small immature glomeruli and for this reason the glomerular filtration rate (GFR) is reduced (about 30 mL/min/1.73m$^2$ at birth to 100 mL/min/1.73m$^2$ at 9 months). Eventually renovascular resistance decreases, resulting in a rapid rise in GFR over the first 3 months of life followed by a slower rise to adult levels by 12 to 24 months of age. Premature and low-birth-weight infants may have a lower GFR than term infants, and the initial rapid rise in GFR is absent.

Urine osmolality is controlled by two mechanisms. Urine is concentrated in the loop of Henle using a countercurrent system dependent on the osmolality of the medullary interstitium. In neonates, the low osmolality in the renal medulla means the countercurrent system is less effective and urine concentration capacity is between 50 and 700 mOsm/kg compared with 1200 mOsm/kg in the adult kidney; therefore there is less tolerance for fluid imbalance.

## COMMON FLUID AND ELECTROLYTE DISTURBANCES AND THEIR TREATMENT

### Sodium

Serum sodium is the major determinant of serum osmolality and therefore extracellular fluid volume. Urinary sodium excretion is dependent on the GFR and therefore is low in neonates when compared with adults. Normal neonatal serum sodium levels are 135 to 140 mmol/L, controlled by moderating renal excretion. During the period of oliguria on the first day of life, sodium supplementation is not normally required. The normal maintenance sodium requirement after normal diuresis is 2 to 4 mmol/kg/day.

***Hyponatremia*** Hyponatremia is defined when serum sodium concentrations are less than 135 mmol/L. Treatment depends on the fluid status of the patient and in case of hypovolemia or hypervolemia, fluid status should be corrected first. When normovolemic, serum sodium levels should be gradually corrected with NaCl infusion, but at a rate not exceeding 0.8 mEq/kg/hr. Symptoms are not reliable for clinical management because they are not often apparent until serum sodium levels fall to less than 120 mmol/L, and their severity is directly related to the rapidity of onset and magnitude of hyponatremia. If not promptly recognized, hyponatremia may manifest as the effects of cerebral edema: apathy, nausea, vomiting, headache, fits, and coma. Urine sodium concentrations can be useful to help determine the underlying cause of hyponatremia because the kidneys respond to a fall in serum sodium levels by excreting more dilute urine, but the secretion of antidiuretic hormone (ADH)/vasopressin in response to hypovolemia affects this. Urine sodium concentrations less than 10 mmol/L indicates an appropriate renal response to euvolemic hyponatremia. However if the urinary sodium concentration is greater than 20 mmol/L this can indicate either sodium leakage from damaged renal tubules or hypervolemia.

***Hypernatremia*** Hypernatremia (serum sodium concentrations >145 mmol/L) may be due to hemoconcentration/excessive fluid losses (e.g., diarrhea). Symptoms and clinical signs include dry mucous membranes, loss of skin turgidity, drowsiness, irritability, hypertonicity, fits, and coma. Treatment is again by correction of fluid status with appropriate electrolyte-containing solutions. Other causes of hypernatremia are renal or respiratory insufficiency, or it can be related to drug administration.

### Potassium

In the 24 to 72 hours postpartum, a large shift of potassium from intracellular to extracellular compartments occurs, resulting in a rise in plasma potassium levels. This is followed by an increase of potassium excretion until the normal serum concentration of 3.5 to 5.8 mmol/L is achieved. Therefore supplementation is not required on the first day of life, but after neonatal diuresis a maintenance intake of 1 to 3 mmol/kg/day is required.

***Hypokalemia*** Hypokalemia is commonly iatrogenic, either due to inadequate potassium intake or use of diuretics but can also be caused by vomiting, diarrhea, alkalosis (which drives potassium intracellularly) or polyuric renal failure. As a consequence, the normal ion gradient is disrupted and predisposes to muscle current conduction abnormalities (e.g., cardiac arrhythmias, paralytic ileus, urinary retention, and respiratory muscle paralysis). Treatment employs the use of KCl.

***Hyperkalemia*** Hyperkalemia can be iatrogenic or due to renal problems but can also be caused by cell lysis syndrome (e.g., from trauma), adrenal insufficiency, insulin-dependent diabetes mellitus, or severe hemolysis or malignant hyperthermia. As in hypokalemia, hyperkalemia alters the electrical gradient of cell membranes and patients are vulnerable to cardiac arrhythmias, including asystole. Treatment is with insulin (plus glucose to avoid hypoglycemia) or with salbutamol.

### Calcium

Calcium plays important roles in enzyme activity, muscle contraction and relaxation, the blood coagulation cascade, bone metabolism, and nerve conduction. Calcium is

maintained at a total serum concentration of 1.8 to 2.1 mmol/L in neonates and 2 to 2.5 mmol/L in term infants and is divided into three fractions. Thirty percent to 50% is protein bound and 5% to 15% is complexed with citrate, lactate, bicarbonate, and inorganic ions. The remaining free calcium ions are metabolically active and concentrations fluctuate with serum albumin levels. Hydrogen ions compete reversibly with calcium for albumin-binding sites and therefore free calcium concentrations increase in acidosis. Calcium metabolism is under the control of many hormones but primarily 1,25-dihydroxycholecalciferol (gastrointestinal absorption of calcium, bone resorption, increased renal calcium reabsorption), parathyroid hormone (bone resorption, decreased urinary excretion), and calcitonin (bone formation and increased urinary excretion). Calcium is actively transported from maternal to fetal circulation against the concentration gradient, resulting in peripartum hypercalcemia. There is a transient fall in calcium postpartum to 1.8 to 2.1 mmol/L and a gradual rise to normal infant levels over 24 to 48 hours.

***Hypocalcemia*** In addition to the physiologic hypocalcemia of neonates which is usually asymptomatic, other causes of hypocalcemia are hypoparathyroidism, including DiGeorge syndrome, and parathyroid hormone insensitivity in infants of diabetic mothers, which may also be related to hypomagnesemia. Clinical manifestations are tremor, seizures, and a prolonged QT interval on electrocardiography.

***Hypercalcemia*** This is less common than hypocalcemia but can result from inborn errors of metabolism such as familial hypercalcemic hypocalcuria or primary hyperparathyroidism. Iatrogenic causes are vitamin A overdose or deficient dietary phosphate intake. Less common causes in children are tertiary hyperparathyroidism, paraneoplastic syndromes, and metastatic bone disease.

### Magnesium

As an important enzyme cofactor, magnesium affects adenosine triphosphate (ATP) metabolism and glycolysis. Only 20% of total body magnesium is exchangeable with the biologically active free ion form. The remainder is bound in bone or to intracellular protein, RNA, or ATP, mostly in muscle and liver. Gastrointestinal absorption of magnesium is controlled by vitamin D, parathyroid hormone, and sodium reabsorption. As previously stated, hypomagnesemia is often related to hypocalcemia and should be considered.

### Acid-Base Balance

Acidosis (pH <7.35) and alkalosis (pH >7.45) can be generated by respiratory or metabolic causes. When the cause is respiratory—$Pa_{CO_2}$ >45 mm Hg (acidosis) or <35 mm Hg (alkalosis)—treatment is with appropriate respiratory support. In case of metabolic causes—bicarbonate <21 mmol/L (acidosis) or > 26 mmol/L (alkalosis)—it is useful to check the anion gap $[Na^+ - (Cl^- + HCO_3^-)$, which is normally 12 ± 2 mEq/L] to understand the underlying cause. Treatment should be directed toward any underlying cause, for example, metabolic acidosis caused by dehydration or sepsis. The slow infusion of buffers such as sodium bicarbonate or tris-hydroxymethylaminomethane (THAM, a sodium-free buffer) should be used as therapeutic adjuncts. The amount of sodium bicarbonate required can be calculated using the following equation:

$$NaHCO_3 \text{ (mmol)} = \text{base excess} \times \text{body weight (kg)}$$

Acid-base balance is maintained by a complex system achieved by intracellular and extracellular buffer systems, respiration, and renal function. Intracellular systems consist of conjugate acid-base pairs in equilibrium as shown by the following equation (A = acid, H = proton):

$$HA \leftrightarrow H^+A^-$$

The pH can be derived from the Henderson-Hasselbalch equation:

$$pH = \frac{pK + \log[A^-]}{[HA]}$$

where pK is the dissociation constant of the weak acid, $[A^-]$ is the concentration of the dissociated acid, and [HA] is the concentration of the acid. The most important of these systems is the carbonic anhydrase system:

$$CO_2 + H_2O \leftrightarrow H^+ + HCO_3{}^-$$

Extracellular buffer systems are similar but the proton is loosely associated with proteins, hemoglobin, or phosphates and take several hours to equilibrate.

Respiratory compensation occurs through the carbonic anhydrase system, ridding the body of carbon dioxide and thereby shifting equilibrium to the left of the reaction and reducing the number of protons. The extent of the shift is influenced by the active transport of bicarbonate across the blood-brain barrier, thereby triggering central respiratory drive.

Normal extracellular pH is maintained at 7.35 to 7.45. Normal metabolic processes produce carbonic acid, lactic acid, ketoacids, phosphoric acid, and sulfuric acid, all of which are either excreted or controlled by a number of buffer systems.

In the neonate, loss of the contribution of the fetomaternal circulation and maternal respiratory and renal compensation mechanisms force adaptation and maturation. There is a suggestion that increased sensitivity of the respiratory centers to fluctuations in pH changes allow the neonate to control acid-base balance more. Increases in the intracellular protein mass allow greater intracellular buffering. The extracellular buffer systems are already functional.

Respiratory compensation becomes active as respiration is established. It relies on pulmonary function and lung maturity, and therefore neonates with lung disease may have impaired respiratory compensation. Carbon dioxide passes freely across the blood-brain barrier, allowing almost immediate response to respiratory acidosis from respiratory drive centers. The response to metabolic acidosis is delayed because interstitial bicarbonate requires a few hours to equilibrate with the cerebral bicarbonate.

Renal compensation is the most important mechanism available to the neonate for acid-base balance. Adjustments in urine acidity have been seen as soon as a few hours postpartum but it takes 2 to 3 days for it to fully mature. Consequent to the changes in renal function and perfusion described previously, the ability of the neonate to handle acid-base balance is limited in the first few days of life. Proximal tubules are responsible for the reabsorption of 85% to 90% of filtered bicarbonate but function less efficiently in

the premature neonate. Reabsorption can also be affected by some drugs used in neonates. Dopamine inhibits sodium/proton pump activity in the proximal tubules and therefore decreases the amount of bicarbonate that is reabsorbed. The remaining bicarbonate reabsorption takes place in the distal tubules, but they differ from the proximal tubules in their absence of carbonic anhydrase. Aldosterone is the most important hormone affecting distal tubular function and stimulates proton excretion in the distal tubules. However the distal nephrons of the premature infant are developmentally insensitive to aldosterone. Protons are excreted in the urine as phosphate, sulfate, and ammonium salts. This increases with age and gestation. However the introduction of phosphate-containing drugs increases phosphate delivery to the distal tubules and therefore can increase the capacity to excrete $H^+$. Dopamine decreases the reabsorption of protons in the distal tubules thereby increasing proton excretion.

### Intravenous Fluid Administration

***Fluid Maintenance*** Fluid administration varies with age as a consequence of the variation of TBW composition and the different compensatory mechanisms. Newborns can have a very wide range of maintenance requirements, depending on clinical conditions. In addition, especially in preterm infants, fluid administration should also allow for physiologic weight loss over the first 7 to 10 days of life (up to a maximum of 10% of birth weight), always maintaining a urine output of greater than or equal to 0.5 mL/kg/hr (Table 6-3).

Not only the amount of fluids but also the type of fluid administered varies according to age. In newborns, 10% dextrose solution is recommended. Sodium supplementation is not usually required in the first 24 hours (low urine output), and after that time can be given at 2 to 4 mmol/kg/day (adjusted primarily based on serum sodium values and changes in weight). Potassium (1 to 3 mmol/kg/day) and calcium (1 mmol/kg/day) are usually added after the first 2 days of life. In infancy and childhood various intravenous solutions are used (Table 6-4); probably the most common is 5% dextrose with one-half normal saline. Potassium is not usually necessary, except if intravenous fluid is given for a longer time. Fluids can be administered intravenously with peripherally or centrally placed catheters. In newborns, or in other situations in which dextrose is administered at more than 10%, peripheral administration is not recommended because of complications due to hyperosmolar solutions.

**TABLE 6-3**
**Normal Maintenance Fluid Requirements**

| | | |
|---|---|---|
| Premature infant | 1st day of life | 60-150 mL/kg/day |
| | 2nd day of life | 70-150 mL/kg/day |
| | 3rd day of life | 90-180 mL/kg/day |
| | >3rd day of life | Up to 200 mL/kg/day |
| Term infant | 1st day of life | 60-80 mL/kg/day |
| | 2nd day of life | 80-100 mL/kg/day |
| | 3rd day of life | 100-140 mL/kg/day |
| | >3rd day of life | Up to 160 mL/kg/day |
| Child > 4 weeks of age, up to 10 kg | | 100 mL/kg/day |
| Child from 10-20 kg | | 1000 mL + 50 mL/kg/day for each kg over 10 |
| Child >20 kg | | 1500 mL + 20 mL/kg/day for each kg over 20 |

## Energy Metabolism

Energy provides the ability to do work and is essential to all life processes. The unit of energy is the calorie or joule (J). One calorie = 4.184 J. One calorie equals the energy required to raise 1 g of water from 15° to 16° centigrade. The most widely used medical unit of energy is the kilocalorie (kcal), which is equal to 1000 calories. One joule equals the energy required to move 1 kilocalorie the distance of 1 meter with 1 newton of force. The first law of thermodynamics states that energy cannot be created or destroyed. Thus:

$$\text{Energy in} = \text{Energy out} + \text{Energy stored}$$

In the case of a neonate this can be expressed as:[22]

$$\begin{aligned}\text{Energy intake} = {} & \text{Energy losses in excreta} + \text{Energy stored} \\ & + \text{Energy of tissue synthesis} \\ & + \text{Energy expended on activity} \\ & + \text{Basal metabolic rate}\end{aligned}$$

### ENERGY INTAKE

The principal foodstuffs are carbohydrates, fats, and proteins (see later). The potential energy that can be derived from these foods is energy that is released when the food is completely absorbed and oxidized. The metabolizable energy is somewhat less than the energy intake, since energy is lost in the feces in the form of indigestible elements and in the urine in the form of incompletely metabolized compounds such as urea from amino acids or ketone bodies from fats.

**TABLE 6-4**
**Common Intravenous Fluids**

| *Intravenous fluid* | *Glucose (g/100 mL)* | *$Na^+$ (mEq/L)* | *$K^+$ (mEq/L)* | *$Cl^-$ (mEq/L)* | *Osmolality (mOsm/L)* |
|---|---|---|---|---|---|
| 5% dextrose | 5 | — | — | — | 252/277 |
| 10% dextrose | 10 | — | — | — | 505/556 |
| Normal saline (0.9% NaCl) | — | 154 | — | 154 | 308 |
| ½ Normal saline (0.45% NaCl) | — | 77 | — | 77 | 154 |
| 5% dextrose with ½ normal saline | 5 | 77 | — | 77 | 406 |
| 5% dextrose with ¼ normal saline | 5 | 34 | — | 34 | 329 |
| Lactated Ringer solution | 0 | 130 | 4 | 109 | 273 |
| Hartmann's solution | 0 | 131 | 5 | 111 | 278 |

Thus metabolizable energy can be calculated as the following equation:

$$\text{Metabolizable energy} = \text{Energy intake} - \text{Energy losses in urine and stool}$$

The foodstuffs are metabolized through a variety of complex metabolic pathways. Complete metabolism of a food requires that it be oxidized to carbon dioxide, water, and in the case of proteins urea and ammonia. This metabolism takes place according to predictable stoichiometric equations.[23] The energy liberated by oxidation is not used directly but is used to create high-energy intermediates, from which the energy can be released where and when it is required. The main intermediates are ATP (all cell types) and creatine phosphate (muscle and brain) but there are others.

These intermediates store the energy in the form of a high-energy phosphate bond. The energy is released when the bond is hydrolyzed. Formation of these high-energy intermediates may result directly from a step in a metabolic pathway. More often however they are created indirectly as the result of oxidative phosphorylation in mitochondria, the process by which a compound is oxidized by the sequential removal of hydrogen ions, which are then transferred through a variety of flavoproteins and cytochromes until they are combined with oxygen to produce water. This process releases large amounts of energy, which is used to form the high-energy phosphate bonds in the intermediates. Thus the energy in food is used to produce high-energy intermediates, the form of energy that is used for all processes of life. This process is the main oxygen-consuming process in the body, and the continual requirement for ATP for all energy requiring processes explains why oxygen delivery to the mitochondria of every cell is crucial for survival of these cells and ultimately the body as a whole.

Respiratory quotient is calculated as carbon dioxide production divided by oxygen consumption and varies with the substrate that is being oxidized. It has a numeric value of 1.0 for glucose oxidation and 0.70 to 0.72 for fat oxidation, depending on the chain length of fat oxidized. Thus the respiratory quotient, measured by indirect calorimetry, reflects the balance of substrate use. This situation is complicated however by partial oxidation of, for example, fats to ketone bodies or carbohydrate conversion to lipids, which will give a respiratory quotient greater than 1. Tables of precise respiratory quotient values for individual carbohydrates, fats, and amino acids are available.[23]

Birth represents a transition from the fetal state, in which carbohydrate is the principal energy substrate (approximately 80% of energy expended) to the infant state, in which both carbohydrate and fat are used to provide energy.[24] This transition is evidenced by the change in respiratory quotient, which declines from 0.97 at birth to 0.8 by 3 hours of age,[25,26] such that fat provides around 60% to 70% of energy expenditure. This is probably due to the fact that newborns have some initial difficulty in obtaining enough exogenous energy to meet their energy needs and are thus more dependent on their endogenous energy stores. Thereafter the respiratory quotient has been shown to increase slightly during the first week of life,[26–28] which suggests that newborns may preferentially metabolize fat in the first instance. Low-birth-weight infants have a respiratory quotient higher than 0.9 because of their limited fat stores and dependence on exogenous glucose.[29]

## ENERGY STORAGE

Although glucose is an essential source of energy, the circulation only contains approximately 200 mg glucose at birth in a term infant, which is only enough to support whole-body requirements for 15 minutes. The body does not store glucose directly because of osmotic problems, but glucose can be indirectly stored in the liver, kidneys, and muscles (and to a lesser degree in other cells) as glycogen. Muscle glycogen can only be used in situ, but liver and kidney glycogen can be used to produce glucose for metabolism in other sites. Glycogen stores in a term infant approximate 35 g (~140 kcal), enough to sustain energy requirements for between 12 and 24 hours. Energy is stored mainly as fat, which has two advantages. First, there is more energy stored per gram of fat (9 kcal/g) than glycogen (4 kcal/g). Second, although fat is stored as globules in adipose tissue and requires little hydration (~15% of its own mass in water), glycogen is stored as a hydrated polymer and so requires four times its own mass in water. Taking both these factors into consideration, 9.4 times as much glycogen mass (with its associated water) would need to be stored as the equivalent caloric amount of fat. A term infant has about 460 g of fat, which is capable of yielding 4140 kcal of energy on oxidation, enough energy for a 21-day fast. Protein largely performs functions other than energy storage, although some of the 525 g of protein (~60% intracellular; ~40% extracellular) in a term infant can be used as a source of energy during severe fasting, yielding 4 kcal/g. The serious consequences of oxidizing protein include wasting, reduced wound healing, edema, failure of growth/neurologic development, and reduced resistance to infection. The relative amounts of fat and carbohydrate stored as a proportion of body mass alter in the last trimester of gestation as the relative hydration decreases, so preterm infants have much lower caloric reserves than do term infants (Fig. 6-5).

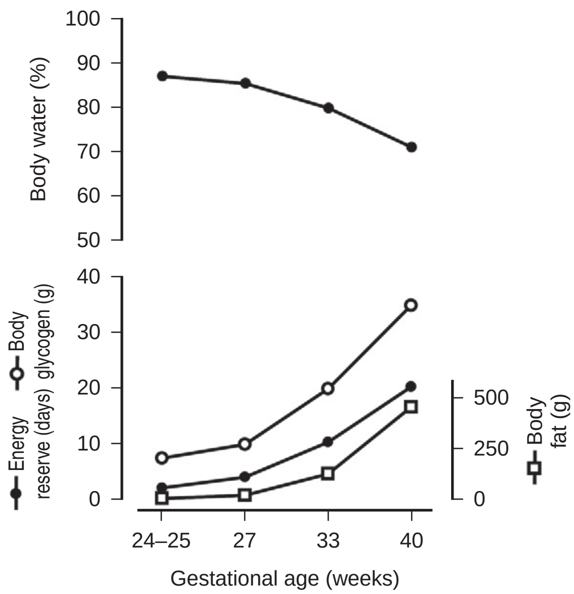

**FIGURE 6-5** Body water and energy stores according to gestational age.

## ENERGY OF GROWTH AND TISSUE SYNTHESIS

In stable mature adults little energy is needed for growth. However in neonates the energy requirements for growth are considerable. In infants up to 50% of the energy intake can be used for growth.[22,30] The energy required to lay down tissue stores includes two components: (1) the energy stored within the tissue itself (i.e., 9 kcal/g of fat, 4 kcal/g of carbohydrate or protein) and (2) the energy investment needed to convert the food into storable and usable substrates. Studies have shown this additional investment to be on the order of 5% to 30% of the energy value of the tissue.[31] The rate of growth of premature infants is on the order of 17 to 19 g/kg/day,[32] whereas that of full-term infants is 4 to 8 g/kg/day.[33] In addition, in rapidly growing premature infants more of the weight gain is as protein. Although protein has a lower energy value per unit weight than does fat, it requires a greater energy investment. Thus the energy cost of growth is much greater in the premature infant largely due to the rate of protein accretion.[34–37] In rapidly growing premature infants, this metabolic cost of growth has been estimated to be 1.2 kcal/g of weight gained, which represents about 30% of total energy expenditure.[34,37]

## ENERGY LOSSES

Infants lose energy in the excreta. Because of the immaturity of the gut and kidney and potentially inadequate supply of bile acids, stool and urine losses may be proportionally higher than in adults. This is especially true for infants undergoing surgery or those with gastroenterologic problems. Conversely parenterally fed infants have low or absent energy losses in stools, although there may be urinary losses.

## ENERGY USED IN ACTIVITY

Studies have shown that energy expenditure varies considerably with changes in the activity of the infant. Vigorous activity such as crying may double energy expenditure,[36] but because most of the time is spent sleeping,[36] the energy expended on activity is less than 5% of the total daily energy expenditure.[22] Studies have shown that daily energy expenditure is related to both the duration and level of activity.[27,35]

## BASAL METABOLIC RATE AND RESTING ENERGY EXPENDITURE

Basic metabolic rate represents the amount of energy used by the body for homeostasis: maintaining ion gradients, neurologic activity, cell maintenance, synthesis of extracellular proteins such as albumin, and so on. Because of ethical considerations, it is not possible to completely starve a newborn for the 14 hours required for a measurement of basal metabolic rate. As a result resting energy expenditure (REE) is much more commonly used as the basis of metabolic studies. REE is influenced by a number of factors, including age, body composition, size of vital organs, and energy intake.

### Age

The REE of a full-term, appropriate-for-gestational-age infant increases from 33 kcal/kg/day at birth, to 48 kcal/kg/day by the end of the first week of life.[38,39] It then remains constant for 1 month before declining. REE is higher in premature and SGA infants than in full-term and appropriate-for-gestational age infants.[40] The differences discussed probably reflect changes in body composition,[38] although it has been suggested that the increase in basal metabolism during the first week of life may represent increased enzyme activity in functioning organs.[41]

### Body Composition

During the first weeks of life infants lose body water. This is accompanied by a well-recognized loss of body weight.[25] Immediately before birth, a term infant is approximately 75% water, but by 1 month of age the water content has reduced to 45%.[42,43] Thus the increase in REE observed during the first weeks of life may reflect the relative increase in body tissue and the relative decrease in body water. These differences in body composition also result in an alteration in the ratio of basal metabolic rate/nonprotein energy reserve (Fig. 6-6).

### Size of Vital Organs

The brain, liver, heart, and kidneys account for up to 66% of basal metabolic rate in adults yet make up only 7% of total body weight. In infants these organs, particularly the brain, account for a greater proportion of body weight. It is believed that the brain alone may account for 60% to 65% of basal metabolic rate during the first month of life. In premature and SGA infants, the vital organs are less affected by intrauterine and extrauterine malnutrition than are other organs.[38,40] Thus their contribution to basal metabolism is even greater.[32] The brain alone may account for up to 70% of basal metabolism.[44] Premature and SGA infants also tend to have a greater proportion of metabolically active brown adipose tissue than relatively inactive white adipose tissue.[36] By contrast full-term appropriate-for-gestational age infants may have only 40 g of brown adipose tissue yet have 520 g of white adipose tissue.[38]

### Dietary Intake

REE of infants is related to caloric intake and weight gain. A significant linear correlation of increasing REE with increasing energy intake has been demonstrated.[30] REE increased by 8.5 kcal/kg/day after a meal, which was equivalent to 5.7% of the gross energy intake, which correlates well with the energy cost of growth.[30] Salomon and colleagues[45]

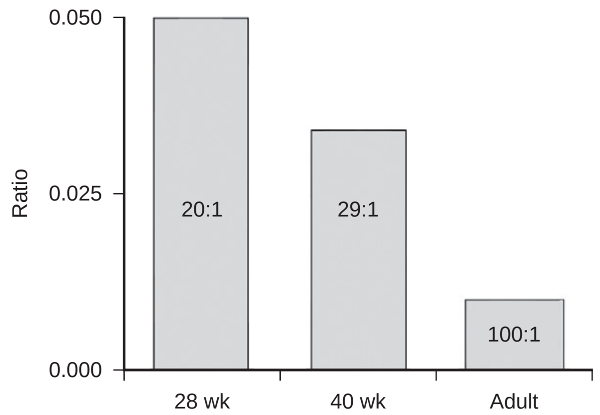

FIGURE 6-6 Ratio of basal metabolic rate/nonprotein energy reserve.

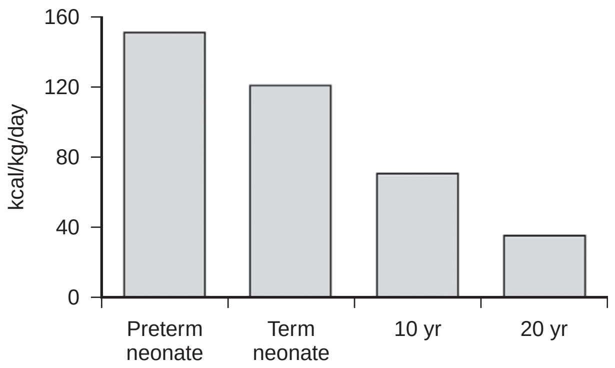

FIGURE 6-7 Energy requirements from the neonatal period to adulthood.

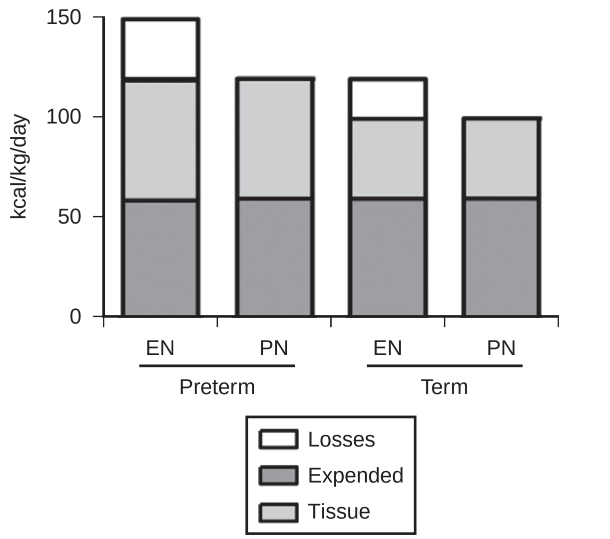

FIGURE 6-8 Partition of energy metabolism in preterm and term infants receiving enteral nutrition (EN) or parenteral nutrition (PN). *Expended* includes basal metabolic rate, activity, the energy expended in laying down new tissue, and thermoregulation, *tissue* is the amount of energy actually stored in new tissue, *losses* include losses in stool and so on. Data from references 22, 36, 48, 49 and 52.

measured the diet-induced thermogenesis of each dietary constituent in infants. They found that amino acids increased REE by 11% (4.4% of caloric intake), fat increased REE by 8% (3% of caloric intake), and glucose did not increase REE at all. This study is somewhat at odds with the results of other studies that have shown that REE increases considerably after a glucose load, particularly at high doses.[46,47]

The energy metabolism of neonates is different from that of adults and children and this reflects the special physiologic status of the neonate. Newborns have a significantly higher metabolic rate and energy requirement per unit body weight than do children and adults: the total energy requirement for an extremely low-birth-weight (i.e., <1000 g) preterm infant fed enterally is 130 to 150 kcal/kg/day[48] and that of a term infant is 100 to 120 kcal/kg/day compared to 60 to 80 kcal/kg/day for a 10-year old child and 30 to 40 kcal/kg/day for a 20-year old individual (Fig. 6-7).[49–51] The partition of this energy is also different from that of adults. Of the 100 to 120 kcal/kg/day required by the term infant, approximately 40 to 70 kcal/kg/day is needed for maintenance metabolism, 50 to 70 kcal/kg/day for growth (tissue synthesis and energy stored), and up to 20 kcal/kg/day to cover energy losses in excreta.[22,35,36] Newborns receiving total parenteral nutrition require fewer calories (110 to 120 kcal/kg/day for a preterm infant and 90 to 100 kcal/kg/day for a term infant[52]) because of the absence of energy losses in excreta and the fact that energy is not required for thermoregulation when the infant is in an incubator. These data are summarized in Fig. 6-8.

Several equations have been published to predict energy expenditure in adults.[53] In stable neonates undergoing surgery, REE can be predicted from parameters such as weight, heart rate, and age using the following equation:[54]

$$\begin{aligned}\text{Resting energy expenditure (cal/min)}\\ &= -74.436 + (34.661 \times \text{body weight in kilograms})\\ &\quad + (0.496 \times \text{heart rate in beats/minute})\\ &\quad + (0.178 \times \text{age in days})\end{aligned}$$

$$(r = 0.92; F = 230.07; \text{significance } F < 0.00001).$$

The major predictor of REE in the preceding equation is body weight, which is also the strongest individual predictor of REE and represents the total mass of living tissue. The other predictors are heart rate, which provides an indirect measure of the hemodynamic and metabolic status of the infant, and postnatal age, which has been shown to influence REE in the first few weeks of life.

# Thermoregulation

After delivery the relatively low ambient temperature and evaporation of the residual amniotic fluid from the skin further increase the heat loss from the newborn. Neonates are homeotherms. They are far more susceptible to changes in environmental temperature than are adults[28] because they have a small mass and relatively large surface area, they possess relatively little insulating tissue such as fat and hair, they are unable to make significant behavioral alterations such as increasing the central heating or putting on extra clothing, and they have limited energy reserves. The thermoneutral zone is of critical importance to infants[38] and is higher (32 to 34° centigrade for full-term appropriate-for-gestational age infants) than it is for adults.[55] There are a number of published tables giving the optimum environmental temperature for infants of different weights and ages.[55] Numerous studies have shown that the morbidity and mortality of infants nursed outside the thermoneutral zone, is significantly increased. There are however indications such as hypoxic ischemic encephalopathy in which therapeutic moderate hypothermia is used,[56] and the difference between iatrogenic hypothermia (potentially with rapid uncontrolled rewarming) and therapeutic controlled hypothermia (with slow controlled rewarming) should be emphasized.

## RESPONSE TO COLD

Heat is lost through radiation/conduction/convection (70%), evaporation (25%), raising the temperature of feedings (3%), and with the excreta (2%).[38] The response of the infant to cooling depends on the maturation of hypothalamic regulatory centers and the availability of substrates for thermogenesis.[38] The initial response, which is mediated through the sympathetic nervous system, is to reduce heat losses by

vasoconstriction[28] and to increase heat production by shivering and nonshivering thermogenesis. The most important site of nonshivering thermogenesis is the brown adipose tissue. This is well established by 22 weeks of gestation and makes up 90% of the total body fat by 29 weeks of gestation.[57] Other sites include the brain, liver, and kidneys. Studies have shown that the preferred fuels for nonshivering thermogenesis are free fatty acids.[58] The energy cost of thermoregulation in a cold environment is considerable. Even within the thermoneutral zone, thermoregulation can account for up to 8% of total energy expenditure.[59] The REE can double when full nonshivering thermogenesis is taking place.

Neonates undergoing major operations under general anesthesia frequently become hypothermic.[60,61] Compared with adults newborns experience greater difficulties in the maintenance of physiologic body temperature in the presence of a cold environmental challenge.[62] Hypothermia may increase the incidence of postoperative complications such as acidosis, impaired immune function, and delayed wound healing.[63] Newborns are not able to respond to cold exposure by shivering but have a highly specialized tissue, brown fat, capable of generating heat without the presence of shivering (nonshivering thermogenesis). As environmental temperature decreases, an increased blood flow to brown fat stores is observed and heat is produced in brown fat mitochondria. During an operation the neonate is exposed not only to a cool environment but also to a wide variety of anesthetic and paralytic agents that may have detrimental effects on heat production (energy expenditure) and core temperature.[64,65] Nonshivering thermogenesis is inhibited by anesthetic agents in experimental animals.[62,66] Albanese and associates[62] have shown that termination of general anesthesia during cold exposure causes a rapid and profound increase in nonshivering thermogenesis in rabbits. This may explain the sudden and rapid increase in energy expenditure observed in young infants at the end of an operation.[64,67]

It has long been known that brown adipose tissue is responsible for heat production, containing a protein (uncoupling protein 1) that dissipates the proton gradient formed across the mitochondrial inner membrane during substrate oxidation.[58] However it is only in recent years that a contribution of the proton leak to thermogenesis in liver has been postulated.[68] The magnitude of the proton leak may be a major determinant of metabolic rate.[69] Oxidative breakdown of nutrients releases energy, which is converted to usable chemical fuel (ATP) in the mitochondria of cells by oxidative phosphorylation. This is used to drive energy-consuming processes in the body. During oxidative phosphorylation, protons are pumped from the mitochondrial matrix to the intermembrane space. Proton pumping is directly proportional to the rate of oxygen consumption and generates and maintains a difference in electrochemical potential of protons across the inner membrane. Protons return to the matrix by one of two routes: the "phosphorylation pathway," which generates ATP, or by the "leak pathway," which is nonproductive and releases energy as heat. A significant proportion (20% to 30%) of oxygen consumed by resting hepatocytes in adult rats is used to drive the heat-producing proton leak.[70] This leak pathway in liver and other organs is a significant contributor to the reactions that compose the standard REE and therefore results in significant resting heat production.[71,72] The proton permeability of the inner mitochondrial membrane that is present in rat liver mitochondria is high in fetuses and is significantly reduced during early neonatal life and reaches the lowest maintained level in adults.[73] These authors suggest that this could provide a physiologic protective mechanism for thermal adaptation of newborn rats during the perinatal period before the establishment of brown adipose tissue thermogenesis.[73] It is conceivable that human newborns are "preprogrammed" with similar protective mechanisms that allow them to survive the stresses of birth (cold adaptation), surgery (cord division), and starvation (transient hypoglycemia).

## Carbohydrate, Fat, and Protein Metabolism of the Neonate

The profound physiologic changes that take place in the perinatal period are reflected by equally dramatic changes in nutrition and metabolism. The fetus exists within a thermostable environment in which nutrition is continually supplied "intravenously" and waste products are equally efficiently removed. At birth, this continual nutrient supply ceases abruptly, resulting in a brief period of starvation. At the end of this period of starvation, nutrition also changes from the placental supply of glucose to milk, which is high in fat and low in carbohydrate. In addition the kidney and lung of the neonate have to become much more active metabolically and the neonate must maintain its own body temperature by activating both metabolic and physiologic mechanisms of thermogenesis and heat conservation, as described previously. The successful adaptation of the neonate to extrauterine life requires carefully regulated changes in glucose and fat metabolism, together with the use of stored protein reserves, until adequate nutritional supply of protein or amino acids, or both, is established. Toward the end of the neonatal period nutrition again changes as the infant is weaned onto a diet that is higher in carbohydrate and lower in fat than the milk diet of the neonatal period. Hence a healthy neonate is in a state of metabolic flux, and these changes must be carefully regulated in order to maintain growth and brain development in this "critical epoch." It is now known that nutrition and growth during the neonatal period are important later determinants of cardiovascular disease[74] and neurodevelopment.[75] Additional physiologic stresses caused by prematurity, infection, gastrointestinal dysfunction, anesthesia, and surgical stress present a considerable challenge to the neonate to maintain metabolic homeostasis. Careful management of nutrition and metabolism by surgeons and physicians is necessary to avoid additional morbidity and mortality caused by malnutrition and the neurologic sequelae of hypoglycemia or hyperglycemia.[76] The long-term metabolic, neurologic, and cardiovascular sequelae of surgery, parenteral nutrition, or sepsis during the neonatal period are unknown, but given the importance of this period on subsequent development, nutritional management of the neonate undergoing surgery is also likely to play a role in adult health.

### NEONATAL GLUCOSE METABOLISM

Most of the energy supply (approximately 70% of total calories as carbohydrate, $<10\%$ as fat[24]) of the fetus comes from maternally supplied glucose. At birth the switch from a high-carbohydrate diet to a diet that is high in lipid and lower

in carbohydrate (approximately 40% of calories as carbohydrate, 50% as fat[24]) means that the neonate must not only adapt to a difference in timing and magnitude of carbohydrate supply but also must regulate its own level of glycemia by insulin/glucagons, gluconeogenesis, and the other mechanisms of glucose homeostasis. The brain can use only glucose or ketone bodies; it is not able to oxidize lipids directly, so maintenance of euglycemia during the neonatal period is particularly important for favorable neurologic outcomes. Despite the greater supply of fats as a fuel source in neonates than in adults, glucose turnover is greater in neonates (3 to 5 mg/kg/min) than in adults (2 to 3 mg kg/min) partly due to the relatively increased brain/body mass ratio. Premature infants have an even greater glucose turnover rate (5 to 6 mg/kg/min).[77] In the premature and term infant, 90% of glucose is used by the brain, whereas this decreases to about 40% in adults.[78] The term infant has two important means of glucose production to maintain euglycemia: glycogenolysis and gluconeogenesis. Glucose production in term neonates originates from glycogenolysis (approximately 40%) and gluconeogenesis from glycerol (20%), alanine and other amino acids (10%), and lactate (30%).[79]

### Glucagon/Insulin Axis in the Perinatal Period

Although the fetus is capable of synthesizing and releasing glucagon and insulin, the function of insulin during pregnancy is probably its promotion of anabolism and enhancing growth rather than regulating circulating glucose.[77] Glucagon is important for the induction of gluconeogenic enzymes during pregnancy, and the surge in glucagon at birth, which results from cord clamping, is probably responsible for the rapid postnatal increase in gluconeogenic capacity.[80] Islet cell function is relatively unresponsive for the first 2 weeks of neonatal life so that increases in insulin secretion and decreases in glucagon secretion are relatively slow in response to increased glucose concentration.[77] There is a similarly slow response to hypoglycemia in the neonate so that if a neonate starts to become hypoglycemic, it may be some time before insulin secretion is decreased and glucagon secretion is increased to stimulate gluconeogenesis. In addition insulin sensitivity is lower in end organs of neonates than in those of adults so that plasma insulin is less closely linked with blood glucose, whereas plasma glucagon is more closely linked to glycemia.[81,82] The maturation of the response to glucose is even slower in preterm infants than in term neonates.[83]

### Glycogen and Glycogenolysis in the Perinatal Period

During the third trimester of pregnancy, storage of maternal glucose as glycogen takes place. Most fetal storage is in the liver, although some glycogen is stored in fetal skeletal muscle, kidney, and intestine, and only to a small degree in brain. Hepatic and renal glycogen is mobilized at and immediately after birth to maintain circulating glucose concentration; however the hepatic glycogen stores are exhausted within 24 hours of birth, or even sooner in premature neonates (who have had an abbreviated or no third trimester), SGA neonates, or neonates who have experienced extensive perinatal stress and have therefore had early catecholamine-stimulated mobilization of hepatic glycogen. Other tissues such as heart, skeletal muscle, and lung can metabolize stored glycogen intracellularly but cannot mobilize it to the circulation because of a lack of the enzyme glucose-6-phosphatase. Mobilization and use of glycogen stores takes place in response to the perinatal surge in glucagon or catecholamine, or both.

### Gluconeogenesis in the Neonate

Key enzymes of gluconeogenesis are present in the fetus from early in gestation and increase throughout gestation and during the neonatal period. However in vivo fetal gluconeogenesis has not been demonstrated and it is not known whether cytosolic phosphoenolpyruvate carboxykinase (necessary for gluconeogenesis from amino acids or lactate) or glucose-6-phosphatase (necessary for gluconeogenesis from all substrates and for glucose export after glycogenolysis) is expressed adequately to support gluconeogenesis by fetal liver. Glucose-6-phosphatase expression is low in the fetus but increases in activity within a few days of birth in term neonates.[84] Studies measuring gluconeogenesis from glycerol in preterm infants have suggested that some gluconeogenesis from glycerol can occur[85] but can only partly compensate a decrease in exogenous glucose supply in preterm infants, probably because of limitation at the level of glucose-6-phosphatase.[86] Parenteral glycerol[87] supports enhanced rates of gluconeogenesis in preterm infants, whereas no increase in gluconeogenesis was observed by provision of mixed amino acids[88] or alanine[89] to preterm neonates, supporting the hypothesis that gluconeogenesis from amino acids or lactate is limited by lack of phosphoenolpyruvate carboxykinase activity in preterm infants. Parenteral lipids stimulate gluconeogenesis in preterm infants,[88] probably by providing both carbon substrate (glycerol) and fatty acids. Fatty acid oxidation is indispensable for gluconeogenesis; although fatty acid carbon cannot be used for glucose, fat oxidation provides both an energy source (ATP) to support gluconeogenesis and acetyl coenzyme A (acetyl-CoA) to activate pyruvate carboxylase. In experimental animals the increase in the glucagon/insulin ratio at birth stimulates maturation of the enzymes of gluconeogenesis, particularly phosphoenolpyruvate carboxykinase, although little is known about the induction of gluconeogenesis in human neonates. Gluconeogenesis is evident within 4 to 6 hours after birth in term neonates.[90,91]

### Neonatal Hypoglycemia

Blood glucose levels fall immediately after birth but rise either spontaneously from glycogenolysis/gluconeogenesis or as a result of feeding. This period of hypoglycemia is not considered of clinical significance, but the appearance of hypoglycemia subsequent to this should be avoided. However there is considerable controversy as to which blood glucose level should be considered the cutoff below which infants are considered hypoglycemic. It is also debated what the duration of hypoglycemia should be before preventive or investigational measures, or both, are instigated,[92] particularly as glucose concentrations fluctuate significantly during this period of massive metabolic, physiologic, and nutritional change. In addition the symptoms of neonatal hypoglycemia are nonspecific and may include the signs and symptoms shown in Table 6-5, many of which are subjective. Current recommendations for operational thresholds of circulating glucose levels are less than 45 mg/dL (2.5 mmol/L) for the term neonate with abnormal clinical signs, persistently less than 36 mg/dL (2.0 mmol/L) for the term neonate with risk factors for compromised metabolic adaptation, 47 mg/dL

(2.6 mmol/L) for preterm neonates (although data is limited), and maintenance of blood glucose greater than 45 mg/dL (2.5 mmol/L) at all times in parenterally fed infants because of the likelihood of increased insulin (and therefore suppressed lipolysis and ketogenesis) in these neonates.[93] Causes of hypoglycemia in the neonatal period are shown in Table 6-6. Glucose metabolism is particularly important for the brain during this critical growth period, and hypoglycemia less than 2.6 mmol/L has been found to be associated with short-term neurophysiologic changes[94] and poor neurodevelopmental outcome.[95,96] However in these studies it is difficult to reliably delineate hypoglycemia as a risk factor independent from those of comorbidities and causes of hypoglycemia—such as prematurity, congenital hyperinsulinism,[97] SGA status,[96] or a diabetic mother[98]—and there is uncertainty concerning the frequency, degree, and duration of hypoglycemia that may cause neurologic problems.[99] Recent advances in neonatal cerebral imaging modalities have suggested a wide spectrum of features that may result from neonatal hypoglycemia.[100] However there is remarkably little strong evidence regarding which blood glucose levels are the thresholds below which adverse neurodevelopmental sequelae are likely to result, and many normal healthy infants experience glucose levels below these thresholds without adverse effects.[101,102] It is likely that duration of hypoglycemia and other metabolic factors such as ketone body levels (see later) are important as determinants of outcome. Treatment of hypoglycemia in the neonate depends on the feeding route and whether risk factors have been identified. Frequent monitoring of blood glucose levels is necessary and treatment/investigation algorithms combine increased enteral feeds with intravenous administration of glucose if clinical signs of hypoglycemia are present.[92]

### Neonatal Hyperglycemia

Neonatal hyperglycemia can also occur and has been recognized as representing several distinct clinical entities. Diabetes mellitus can present in the neonatal period, although the condition is rare, representing approximately 1 in 400,000 to 1 in 500,000 live births.[103,104] Both permanent and transient neonatal diabetes occurs. Transient neonatal diabetes mellitus, which usually resolves within 3 to 6 months but may lead to the development of permanent diabetes in childhood or adolescence, represents about 50% of cases and permanent neonatal diabetes mellitus represents the other 50%. Transient neonatal diabetes mellitus is due to paternal imprinting[105,106] and one of the molecular causes of the permanent form has been elucidated.[107] However most hyperglycemia in neonates is self-limiting, resolves spontaneously, and has few features in common with diabetes. Its frequency appears to be increasing in parallel with increased survival of extremely low-birth-weight infants who are fed parenterally and receive corticosteroids. The etiology of neonatal hyperglycemia is not well understood, but possible causes[92] include inability to suppress gluconeogenesis in response to glucose infusion, excessive glucose infusion rates, end-organ insulin resistance, low plasma insulin levels in combination with high catecholamine levels (e.g., due to corticosteroid administration), infection, or response to pain or surgery (see later). The management of hyperglycemia in the neonate is to manage the cause, for example, treat infection or pain or decrease excessive glucose infusion rates. There is still controversy regarding insulin administration:[108] on the one hand insulin infusion allows maintenance of high glucose infusion rates (and may therefore increase weight gain), whereas on the other hand there are reports of adverse effects. Neither the acute nor the long-term sequelae of hyperglycemia in the neonate are well understood. Ketosis or metabolic acidosis does not occur as a result of hyperglycemia, but osmotic diuresis and glycosuria may lead to dehydration. Hyperglycemia has been found to be associated with increased mortality in premature infants.[109–111] Hyperglycemia has also been associated with increased morbidity and mortality in neonates with necrotizing enterocolitis.[112] However, except for a study linking hyperglycemia with white matter injury in premature infants,[109] evidence for a cerebral pathologic cause and adverse neurodevelopmental outcome as a result of neonatal hyperglycemia is scant, although there is a risk of increased

cerebral bleeds from osmotic shifts. There has been a great deal of interest in the tight control of blood glucose in patients in adult intensive care units after the study of Van Den Berghe and colleagues.[113] In very-low-birth-weight infants, insulin therapy to maintain normoglycemia was not found to improve outcomes,[114] whereas a recent study (including some neonates) in glucose control in a pediatric intensive care unit suggested that intensive insulin therapy improved short-term outcomes.[115] Hence it remains uncertain whether tight control of blood glucose concentration is beneficial in neonates or in specific subgroups of neonates.

## NEONATAL LIPID AND FAT METABOLISM

Fat is the main energy source of the neonate, providing 40% to 50% of calories in milk or formula. As discussed earlier, fat oxidation becomes a major fuel used within 3 hours after birth.[25,26] In addition fat is the main store of energy within the body. Although most chain lengths of fatty acids can be used for energy, fatty acids, in the form of phospholipids and other fat-derived lipids, are extremely important structural components of cell membranes, and the function of these membranes is critically dependent on the availability of the correct chain length and degree of unsaturation of fatty acids. Thus throughout the period of growth of the neonate, an array of different fatty acids, either supplied by the diet or metabolized by the body, is essential to support growth, particularly that of the brain, which is rich in complex lipids.

### Fatty Acid Oxidation and Ketogenesis in Neonates

Fatty acid beta oxidation is the major process by which fatty acids are oxidized, by sequential removal of two-carbon units from the acyl chain, providing a major source of ATP for heart and skeletal muscle. Hepatic beta oxidation serves a different role by providing ketone bodies (acetoacetate and β-hydroxybutyrate) to the peripheral circulation and supporting hepatic gluconeogenesis by providing ATP and acetyl-CoA to activate pyruvate carboxylase activity. In addition kidney,[116] small intestine,[117] white adipose tissue,[118] and brain astrocytes[119] may be ketogenic under some conditions. Ketone bodies are another significant fuel for extrahepatic organs, especially the brain, when blood glucose levels are low. Consequently, ketogenesis is extremely important to provide an alternative fuel for the brain when glucose levels may be fluctuating because of alterations in feeding pattern and adaptation of physiologic and metabolic homeostasis. For oxidation of the acyl groups of stored, ingested, or infused triacylglycerol to take place, nonesterified fatty acids must be released. This can take place distant from the site of use by the action of hormone-sensitive lipase (HSL) in the adipocyte or locally by the action of endothelial lipoprotein lipase (LPL).[120,121] Nonesterified fatty acids (NEFA) bound to albumin provide the main substrate that is taken up and oxidized by tissues. In addition intracellular triacylglycerol stores can also provide a significant source of acyl moieties for beta oxidation in the heart and skeletal muscle, again through the action of HSL. HSL and LPL are under control of the hormonal and nutritional milieu so that fatty acid oxidation is partly controlled by the supply of NEFA to the tissue.[122] In the immediate postnatal period the plasma levels of NEFA increase rapidly in response to the glucagon/catecholamine surge that stimulates lipolysis and the fall in insulin that occurs as a result of birth and cord division.[123,124] This lipolysis also results in the release of glycerol, which can be used as a gluconeogenic precursor (see previous discussion).[123,124] Ketone bodies are formed fairly soon after birth, [24,125–129] reaching 0.2 to 0.5 mmol/L in the first 1 postnatal day, and 0.7 to 1.0 mmol/L between 5 and 10 days,[125] although this may be impaired in premature or SGA infants.[126,128,130] During hypoglycemia, ketone body concentrations can raise to 1.5 to 5 mmol/L.[125] The enzymes of fatty acid oxidation and ketogenesis all increase in activity postnatally in experimental animals, accounting for this increase in capacity for fatty acid oxidation and ketogenesis,[24] although little is known about the induction of fatty acid oxidation enzymes in humans. Hydroxymethylglutaryl-CoA synthase is thought to be particularly important in the control of ketogenesis and is subject to short-term activation by glucagon, which may account for the rapid surge in ketogenesis at birth.[131]

### Ketone Body Use

Little is known about the ontogeny of the enzymes of ketone body use in human tissues. Heart, muscle, kidney, and brain are all capable of ketone body use and the enzymes required have been shown in human tissue.[132–134] In rats the activities of the ketone body use enzymes are very active in neonatal brain and decrease at weaning, whereas they are lower than adult levels in neonatal muscle and kidney, suggesting preferential use by the brain.[24]

### Neonatal Protein and Amino Acid Metabolism

In contrast to healthy adults who exist in a state of neutral nitrogen balance, infants need to be in positive nitrogen balance in order to achieve satisfactory growth and development. Infants are efficient at retaining nitrogen and can retain up to 80% of the metabolizable protein intake on both oral and intravenous diets. [34,135,136] Protein metabolism is dependent on both protein and energy intake. The influence of dietary protein is well established. An increased protein intake has been shown to enhance protein synthesis,[137,138] reduce endogenous protein breakdown,[139] and thus enhance net protein retention.[139,140] The influence of nonprotein energy intake on protein metabolism is more controversial. Protein retention can be enhanced by giving carbohydrate or fat,[141–146] which are thus said to be protein sparing. Although some studies have suggested that the protein-sparing effect of carbohydrate is greater than that of fat,[142,143,146] others have suggested that the protein-sparing effect of fat may be either equivalent to or greater than that of carbohydrate.[141,144,145] The addition of fat calories to the intravenous diet of newborns undergoing surgery reduces protein oxidation and protein contribution to the energy expenditure and increases protein retention.[144] In order to further investigate this positive effect on protein metabolism we studied the various components of whole protein metabolism by the combined technique of indirect calorimetry and stable isotope ($^{13}$C-leucine) tracer technique. Two groups of neonates receiving isonitrogenous and isocaloric total parenteral nutrition were studied: one group received a high-fat diet and the other a high-carbohydrate diet.[65] There was no significant difference between the two groups with regard to any of the components of whole-body protein metabolism: protein synthesis, protein breakdown, protein oxidation/excretion, and total protein flux. This study confirms previous observations that infants have high rates of protein turnover, synthesis, and breakdown, which may be

up to eight times greater than those reported in adults. In newborn infants receiving parenteral nutrition, synthesis and breakdown of endogenous body protein far exceed intake and oxidation of exogenous protein. Infants are avid retainers of nitrogen, and carbohydrate and fat have an equivalent effect on protein metabolism. This supports the use of intravenous fat in the intravenous diet of newborns undergoing surgery.

The protein requirements of newborns are between 2.5 and 3.0 g/kg/day. Amino acids, the building blocks of protein, can be widely interconverted so that several are described as dispensable (or nonessential). These are alanine, aspartate, asparagine, glutamate, and serine. Others are described as indispensable (or essential): histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. There are yet other amino acids (arginine, cysteine, glycine, glutamine, proline, and tyrosine) that are not usually essential but can become limiting during metabolic stress such as sepsis. Sulfur amino acids (i.e., cysteine, methionine) and tyrosine, in particular, are abundant in acute-phase proteins, so their supply becomes particularly important during acute-phase responses. Human milk provides amino acids in the form of protein and as free amino acids. However milk proteins are not just important for their nutritive value but also possess other important properties such as antiinfective activity (IgA, IgM, IgG, lactoferrin, lysozyme).[147] Platelet-activating factor acetylhydrolase, a minor component of human milk, has been suggested to be responsible for some of the protective effects of breast milk against necrotizing enterocolitis.[148] The amino acid glutamine is of particular interest in premature neonates and neonates undergoing surgery.

The nitrogen source of total parenteral nutrition is usually provided as a mixture of crystalline amino acids. The solutions commercially available contain the eight known essential amino acids plus histidine, which is known to be essential in children.[140] Complications like azotemia, hyperammonemia, and metabolic acidosis have been described in patients receiving high levels of intravenous amino acids.[149] These complications are rarely seen with amino acid intake of 2 to 3 g/kg/day.[150] In patients with severe malnutrition or with additional losses (i.e., in those who have undergone jejunostomy or ileostomy) the protein requirements are higher.[140] The ideal quantitative composition of amino acid solutions is still controversial. Cysteine, taurine, and tyrosine seem to be essential amino acids in newborns. However the addition of cysteine in the parenteral nutrition of neonates does not cause any difference in the growth rate and nitrogen retention.[136] The essentiality of these amino acids could be related to the synthesis of neurotransmitters, bile salts, and hormones. The consequences of failure to supply these amino acids may be poor long-term neurologic or gastrointestinal function.[151] The incidence of abnormalities of plasma aminograms during parenteral nutrition is low. There are no convincing data at the moment to support the selection of one crystalline amino acid solution over another in newborns. Glutamine is a nonessential amino acid that has many important biologic functions, such as being a preferential fuel for the immune system and the gut. Various authors have postulated that glutamine may become "conditionally essential" during sepsis and that addition of glutamine to parenteral feedings of premature neonates or those undergoing surgery may help to preserve mucosal structure, prevent bacterial translocation, and hence reduce the number of infections and the time before full enteral feeding can be established.

# Metabolic Response to Stress

The body has developed a system of responses to deal with various noxious stimuli that threaten survival. In some respects these responses are stereotypical and lead to the so-called stress response. Stress can be defined as "factors that cause disequilibrium to an organism and therefore threaten homeostasis."[152] Initiators of the stress response in newborns include operative trauma and sepsis. In this section we discuss the response to operative trauma. The physiologic changes due to sepsis are discussed in another chapter.

## OPERATIVE TRAUMA

The stress response that follows operative procedures is initiated and coordinated by several messengers and affects whole body systems. The insult of operative trauma can be considered a form of "controlled" injury.

After surgery there are alterations in metabolic, inflammatory, endocrine, and immune system responses. These responses have evolved to enhance survival to trauma and infection in the absence of iatrogenic intervention. They limit patient activity in the area of injury to prevent secondary damage and start the healing process through the inflammatory signals produced. Changes in metabolism increase the availability of substrates needed by regenerating and healing tissue. The immune stimulation allows for the swift eradication of any causal or secondary opportunistic microbial invasion, whereas the subsequent immune paresis may allow for a dampening of this immune stimulation to allow for healing to ensue.

In contrast to adults the energy requirement of infants and children undergoing major operations seems to be modified minimally by the operative trauma per se. In adults trauma or surgery causes a brief "ebb" period of a depressed metabolic rate followed by a "flow phase" characterized by an increase in oxygen consumption to support the massive exchanges of substrate between organs (Fig. 6-9).[153] In newborns major abdominal surgery causes a moderate (15%) and immediate (peak at 4 hours) elevation of oxygen consumption and REE and a rapid return to baseline 12 to 24 hours postoperatively (see Fig. 6-9).[64] There is no further increase in energy expenditure in the first 5 to 7 days after an operation.[64,154] The timing of these changes corresponds with the postoperative increase in catecholamine levels described by Anand and associates.[155] The maximum endocrine and biochemical changes are observed immediately after the operation and gradually return to normal over the next 24 hours. It is of interest that infants who have a major operation after the second day of life have a significantly greater increase in REE than infants who undergo surgery within the first 48 hours of life. A possible explanation for this may be the secretion of endogenous opioids by the newborn. It has been suggested that nociceptive stimuli during the operation are responsible for the endocrine and metabolic stress response and that these stimuli may be inhibited by opioids.[155,156] This is supported by studies showing that moderate doses of opioids blunt the endocrine and metabolic responses to operative stress in infancy.[155,156] The levels of endogenous opioids in the cord blood of newborn infants are five times higher than plasma levels in resting adults.[157] Thus, it is possible that

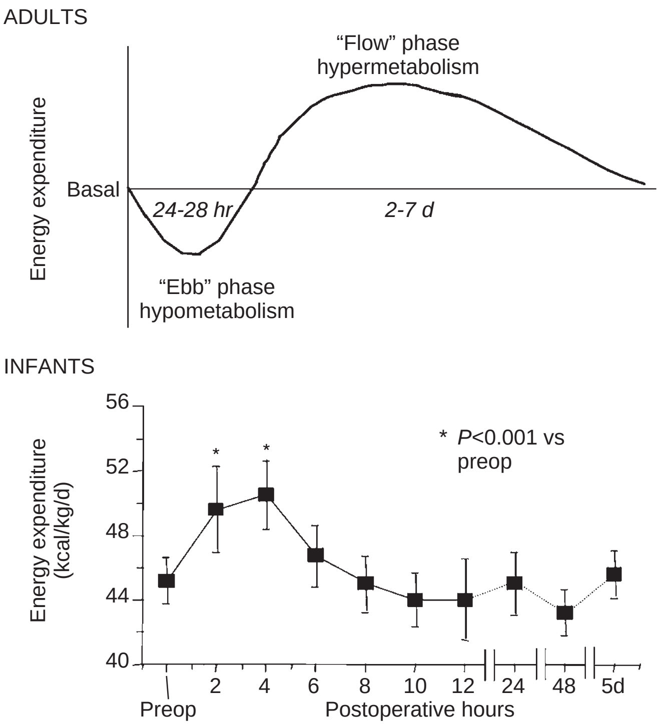

**FIGURE 6-9** Postoperative variations in energy expenditure in adults and neonates undergoing major operations. Data for infants are expressed as mean ± SEM. (Adapted from Jones MO, Pierro A, Hammond P, et al: The metabolic response to operative stress in infants. J Pediatr Surg 1993;28:1258-1262; and Pierro A: J Pediatr Surg 2002;37:811-822.)

the reduced metabolic stress response observed in neonates less than 48 hours old is related to higher circulating levels of endogenous opioids. This may constitute a protective mechanism blunting the response to stress in the perinatal period. Chwals and colleagues[158] demonstrated that the postoperative increase in energy expenditure can result from severe underlying acute illness, which frequently necessitates surgery (i.e., sepsis or intense inflammation). REE is directly proportional to growth rate in healthy infants, and growth is retarded during acute metabolic stress. These authors suggest that energy is used for growth recovery after the resolution of the acute injury response in neonates undergoing surgery. The authors indicate that serial measurement of postoperative REE can be used to stratify injury severity and may be an effective parameter to monitor the return of normal growth metabolism in neonates undergoing surgery.

Operative trauma initiates a constellation of inflammatory pathways that regulate a whole-body response to operative stress, which is similar to that seen after injury. The responses can be initiated and controlled by both chemical/hormonal signals and afferent nervous signals. Some of the chemical signals responsible for the responses originate in the operative wound in response to cellular injury.

## Cytokines

One of the key chemical messenger systems in the control and the coordination of the response to injury are cytokines. Cytokines are a group of low-molecular-weight polypeptides or glycoproteins, which act to regulate the local and systemic immune function and modulation of the inflammatory response. They are active at very low concentrations, found usually at the picogram level, and their production is usually transient. Cytokines bring about their action by altering gene expression in target cells. They act in a paracrine and autocrine manner at concentrations in the picomolar to nanomolar range, but can have systemic effects if there is spill over into the circulation.

Cytokines generally have a wide range of actions in the body. Cytokines are not usually stored intracellularly and must therefore be synthesized de novo and released into the tissues on appropriate stimulation and gene transcription. One of the crucial controllers of cytokine gene regulation is nuclear factor kappa B (NFκB),[159,160] a protein transcription factor that enhances the transaction of a variety of cytokine genes. Lymphocytes are activated at the site of injury. The first cells to be recruited to the site of inflammation are monocytes and neutrophils, where they produce cytokines in the first few hours after the onset of a surgical or traumatic wound.[161] These cytokines are chemoattractant to other white cells.

Cytokines are divided into proinflammatory and antiinflammatory types on the basis of whether they stimulate the immune system or decrease or dampen the immune response. Although most cytokines have a clear proinflammatory or antiinflammatory response, a few have dual properties. Some cytokines may exhibit a proinflammatory action in a particular cell or certain conditions but an antiinflammatory response in a different cell or under different conditions.[162] The presence of antiinflammatory cytokines is of importance in abating the immune response to prevent excessive tissue destruction and death. The presence of naturally occurring inhibitors helps abate the otherwise catastrophic positive feedback loop that could lead to widespread tissue destruction from excessive inflammation. The cytokines that are commonly released after trauma include the proinflammatory interleukins (ILs) IL-1 and IL-6 and tumor necrosis factor-α (TNF-α) and the antiinflammatory IL-1ra and IL-10.

Both proinflammatory and antiinflammatory cytokines are produced in response to operative stress. The actual cytokine cascade is heterogeneous and is determined by various factors, which include the type and magnitude of the operation. The cytokine cascade in response to operations in adults has been well characterized.[163] There have been limited studies in neonates. Cytokines bond to specific membrane receptors of target organs. Their actions in the acute stress response include (1) changes in gene expression and proliferation, thereby affecting wound healing and immunocompetence; (2) release of counterregulatory hormones; and (3) facilitation of cell-to-cell communication.[164] Substrate use is also affected by cytokine release. Glucose transport is increased by TNF, hepatic gluconeogenesis is stimulated by IL-1, and hepatic lipogenesis is stimulated by IL-1, IL-6, and TNF. IL-1 and TNF also appear to promote muscle proteolysis. In neonates IL-6 increases maximally 12 hours after major surgery and the increase is proportional to the degree of operative trauma,[165] indicating that this cytokine is a marker of stress response in neonates. IL-1 and TNF may have a synergistic effect in producing the metabolic manifestations seen after injury and infection.[153] However systemic cytokine release cannot account for all the metabolic changes seen after injury because cytokines are not consistently found in the bloodstream of injured patients and systemic cytokine administration does not produce all the metabolic effects observed in injured adult individuals.

Other mediators of the response to tissue injury include *histamine*, a well-known chemical mediator in acute inflammation that causes vascular dilatation and the immediate transient phase of increased vascular permeability; *5-hydroxytryptamine (serotonin)*, a potent vasoconstrictor; *lysosomal compounds* released from activated neutrophils, monocytes, and macrophages; *lymphokines,* chemicals involved in the inflammatory cascade with vasoactive or chemotactic properties; the *complement system*, and the *kinin system*. These mediators cause vasodilation, increased vascular permeability, and emigration and stimulation of white blood cells. The postoperative changes that occur also affect the immune system. There is a period of immune stimulation that is often followed by a period of immune paresis. There is a proinflammatory response that is balanced by an antiinflammatory response. The balance often determines and predicts the development of complications and outcome in terms of morbidity and mortality.

Other responses may be initiated by peripheral and central nervous system stimulation. Peripheral efferent from pain receptors, for instance, can feed back to the central nervous system and produce some of the clinical signs of inflammation and the responses seen after operative stress. Indeed blockage of this afferent stimulus is associated with dampening of the stress response.[155] Fentanyl and morphine are commonly used in pediatric anesthesia for pain relief. Studies in preterm infants and neonates have shown that fentanyl blunts the metabolic response to operative stress.[155,156,166]

### Endocrine Response

Various studies have characterized the endocrine response to surgery in infants and children.[167–169] These studies have revealed that the response lasts between 24 and 48 hours postoperatively. The response differs in some respects to that of adults, which usually lasts longer.[170,171] Compared with values seen after an overnight fast, there is an increase in insulin levels in the early postoperative period. However this increase in insulin levels is not proportional to the increase in glucose. There is a change in the insulin/glucose ratio in the postoperative period,[167,172] which lasts more than 24 hours postoperatively. Anand and colleagues[167] found that neonates exhibited an initial decrease in the insulin/glucose ratio in the immediate postoperative period that was restored by 6 hours. Ward-Platt and associates[172] found an instantaneous and continuous rise in the ratio in older infants and children.

Cortisol is significantly elevated and remains elevated for the first 24 hours postoperatively and is accompanied by a rise in catecholamines.[173,174] Both the hormones have antiinsulin effects. The rise in cortisol and catecholamines partially drives the postoperative hyperglycemic response and may be responsible for the relative insulin insensitivity in the postoperative period. Anand and colleagues found a very significant correlation between glucose and adrenaline levels in neonates at the end of abdominal surgery.[167] There is an increase in lactate levels in the postoperative period in both adults and infants/children.[156,175,176] The increase in lactate in the postoperative period is related to the alteration in glucose metabolism[167] and more acutely the presence of tissue hypoperfusion related to surgery.[176] The increase in lactate may represent a means of discriminating the magnitude of operative stress. Altogether the changes in hormone levels are related to the magnitude of the operative stress and have been shown in some but not all procedures to be lessened by laparoscopic surgery.

### Effect of Surgery on Glucose Metabolism in Neonates

Surgery in adults is well known to cause hyperglycemia, and a hyperglycemia response to surgery has also been well documented in neonates,[155,156,166,167,177–181] with the degree of hyperglycemia being negatively correlated with age.[181] In contrast to adults, however, in whom blood glucose concentration may remain high for several days postoperatively, the rise in glucose levels in neonates is short-lived, lasting only up to 12 hours. In an elegant study, Anand and Aynsley-Green showed a strong correlation between the degree of surgical stress and the increase in glucose levels.[168] In the same study stress scores were also strongly positively correlated with plasma levels of adrenalin, noradrenalin, glucagon, insulin, and less strongly with cortisol.[168] The hyperglycemic response to surgery is probably multifactorial, including increased glycogenolysis and gluconeogenesis in response to increases in plasma catecholamine and subsequently glucagon. In addition the insulin response to hyperglycemia may be inappropriately low, especially in preterm neonates undergoing surgery,[167] and tissues may become relatively refractory to insulin. Support for the hypothesis that these effects are driven by catecholamine release are provided by Anand's group, who in a series of studies showed that blunting of the catecholamine response to surgery by modulation of the anesthetic regimen led to a blunting of the hyperglycemic/endocrine response to surgery.[155,156,166] The timing of the adrenaline, noradrenaline, and glucose response to neonatal surgery is shown in Figure 6-10.

Carbohydrate conversion to fat (lipogenesis) occurs when glucose intake exceeds metabolic needs. The risks associated with this process are twofold: accumulation of the newly synthesized fat in the liver[182] and aggravation of respiratory acidosis resulting from increased carbon dioxide production, particularly in patients with compromised pulmonary function.[183] Jones and coworkers[184] have shown that there is a negative linear relationship between glucose intake (grams per kilogram per day) and fat use (oxidation and conversion to fat) expressed in grams per kilogram per day ($y = 4.547 - 0.254x$; $r = -0.937$; $P = <0001$) in infants undergoing surgery who receive parenteral nutrition. From this equation it was calculated that "net fat synthesis from glucose" exceeds "net fat oxidation" when the glucose intake is greater than 18 g/kg/day. Jones and colleagues[184] also found a significant relationship between glucose intake and carbon dioxide production (milliliters per kilogram per minute) ($y = 3.849 + 0.183x$; $r = 0.825$; $P = <0001$). The slope of this relationship was steeper when glucose intake exceeded 18 g/kg/day ($y = 2.62 + 0.244x$; $r = 0.746$; $P = <05$) than when glucose intake was less than 18 g/kg/day ($y = 5.30 + 0.069x$; $r = 0.264$; $P = .461$). Thus the conversion of glucose to fat results in a significantly increased production of carbon dioxide. Glucose intake exceeding 18 g/kg/day is also associated with a significant increase in respiratory rate and plasma triglyceride levels. In summary:

1. Glucose intake is the principal determinant of carbohydrate and fat use.
2. The maximal oxidative capacity for glucose in infants undergoing surgery is 18 g/kg/day, which is equivalent to the energy expenditure of the infant.

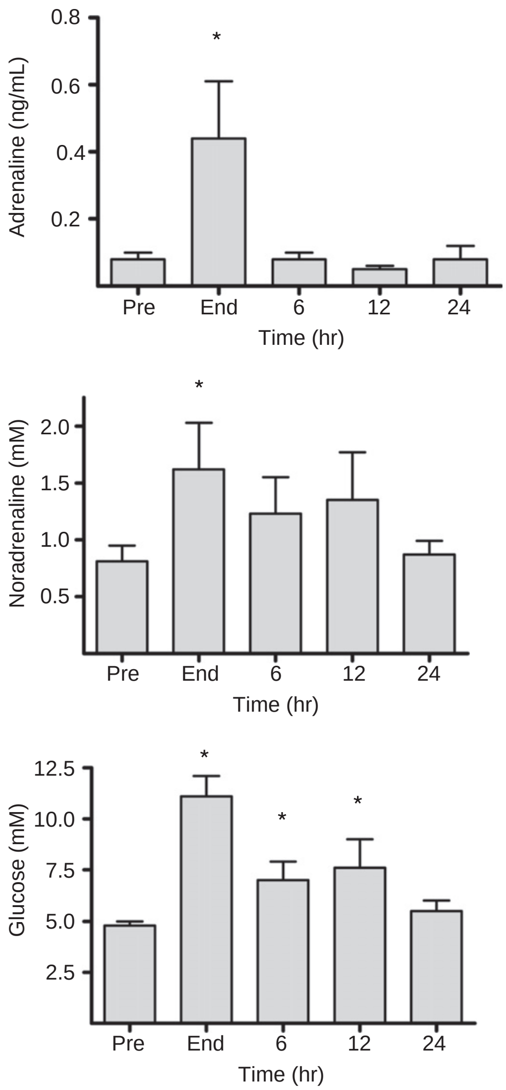

**FIGURE 6-10** Response of adrenaline, noradrenaline, and glucose to surgery in neonates. (Data from Anand KJS, Brown MJ, Causon RC, et al: Can the human neonate mount an endocrine and metabolic response to surgery? J Pediatr Surg 1985;20:41-48.)

3. If glucose is given in excess of maximal oxidative capacity: (a) net fat oxidation ceases; (b) net fat synthesis begins; (c) the thermogenic effect of glucose increases and the efficiency with which glucose is metabolized decreases; (d) carbon dioxide production and respiratory rate increase; (e) plasma triglyceride levels increase.

It is advisable therefore in stable newborns undergoing surgery and requiring parenteral nutrition not to exceed 18 g/kg/day of intravenous glucose intake.[184,185]

### Effect of Surgery on Fat Metabolism in Neonates

Surgery in neonates causes an increase in NEFA and ketone body levels,[156,166,167,180] which can be decreased by modulating the catecholamine release,[156,166] suggesting that catecholamine stimulation of lipolysis is responsible for this increase. Pierro and colleagues have studied intravenous fat use by performing an "Intralipid use test."[185] This consisted of infusing for 4 hours Intralipid 10% in isocaloric and isovolemic amounts to the previously given mixture of glucose and amino acids. Gas exchange was measured by indirect calorimetry to calculate the patient's oxygen consumption and carbon dioxide production, and net fat use. The study showed that (1) infants undergoing surgery adapt rapidly (within 2 hours) to the intravenous infusion of fat; (2) more than 80% of the exogenous fat can be oxidized; and (3) carbon dioxide production is reduced during fat infusion as a consequence of the cessation of carbohydrate conversion to fat.[185] This study did not measure the rate of fat use during a mixed intravenous diet including carbohydrate, amino acids, and fat. More recent studies on stable newborns undergoing surgery receiving fixed amounts of carbohydrate and amino acids and variable amounts of intravenous long-chain triglycerides (LCTs) fat emulsion have shown that at a carbohydrate intake of 15 g/kg/day (56.3 kcal/kg/day) the proportion of energy metabolism derived from fat oxidation does not exceed 20% even with a fat intake as high as 6 g/kg/day. At a carbohydrate intake of 10 g/kg/day this proportion can be as high as 50%.[186] This study seems to indicate that during parenteral nutrition in neonates undergoing surgery the majority of the intravenous fat infused is not oxidized but deposited. Net fat oxidation seems to be significantly influenced by the carbohydrate intake and by the REE of the neonate. When the intake of glucose calories exceeds the REE of the infant, net fat oxidation is minimal regardless of fat intake.[186] In order to use intravenous fat as an energy source (i.e., oxidation to carbon dioxide and water), it is therefore necessary to maintain carbohydrate intake at less than basal energy requirements.

Commonly used fat emulsions for parenteral nutrition in pediatrics are based on LCTs. The rate of intravenous fat oxidation during total parenteral nutrition can theoretically be enhanced by the addition of L-carnitine or medium-chain triglycerides (MCTS), or both, to the intravenous diet. Important differences have been observed between MCTS and LCTS with respect to physical and metabolic properties. MCTs are cleared from the bloodstream at a faster rate and are oxidized more completely for energy production than are LCTs. Therefore they seem to serve as a preferential energy source for the body. We have investigated the effects of MCTs on intravenous fat use during total parenteral nutrition in stable newborns undergoing surgery.[187] Two groups of neonates undergoing surgery and receiving total parenteral nutrition were studied: one group received LCT-based (100% LCTs) fat emulsion and the other group received an isocaloric amount of MCT-based (50% MCTs + 50% LCTs) fat emulsion. In newborns receiving carbohydrate calories in excess of measured REE (56 kcal/kg/day), net fat oxidation was not enhanced by the administration of MCT-based fat emulsion. Conversely in infants receiving carbohydrate calories less than REE (41 kcal/kg/day), the administration of MCT fat emulsion increased net fat oxidation from 0.6 ± 0.2 to 1.7 ± 0.2 g/kg/day. The administration of MCT-based fat emulsion did not increase the metabolic rate of the infants. Fats that are not used can become the substrates for free-lipid peroxidation and free-radical production. Peroxidation has been specifically linked with lipids in parenteral nutrition[188,189] and has been shown to be dependent on the amount of carbohydrate given: If net fat oxidation is not taking place because carbohydrate intake is high, more lipid is present to be peroxidized.[190]

### Effect of Surgery on Protein and Amino Acid Metabolism in Neonates

Major operative stress in adults results in a negative nitrogen balance due to muscle protein catabolism. The neonate is already in a more precarious position regarding nitrogen balance, so if major protein catabolism were to take place in the neonate who undergoes surgery, growth and other important functions would be impaired. Nitrogen losses are increased after surgery in neonates,[191–194] and muscle protein breakdown has also been demonstrated by increased 3-methylhistidine excretion in these neonates.[155,166] However these changes are relatively short-lived and can be overcome by provision of additional dietary nitrogen or calories, or both. Powis and associates[195] investigated protein metabolism kinetics in infants and young children who had undergone major operations. Patients were studied for 4 hours preoperatively and for the first 6 hours after surgery. There were no significant differences in the rates of whole-body protein flux, protein synthesis, amino acid oxidation, and protein degradation between the preoperative and postoperative times, indicating that infants and children do not increase their whole-body protein turnover after major operations. It is possible that infants and children are able to convert energy expended on growth to energy directed to wound repair and healing, thereby avoiding the overall increase in energy expenditure and catabolism seen in the adult.[195] However little is known about the components of protein turnover in neonates who have surgery. The only available study, in six neonates with necrotizing enterocolitis, showed no differences in protein turnover between acute and recovery phases of the disease.[196]

CHAPTER 7

# Respiratory Physiology and Care

Jay M. Wilson and John W. DiFiore

"The body is but a pair of pincers set over a bellows and a stewpan and the whole fixed upon stilts."[1] This chapter discusses the bellows. In doing so we examine normal lung development, pulmonary physiology, devices (invasive and noninvasive) for patient monitoring, and devices designed to provide ventilatory support. Finally we discuss how to apply this information to the management of infants and children with respiratory failure in the modern intensive care unit.

The primary function of the respiratory system is the continuous absorption of oxygen and the excretion of carbon dioxide. This is achieved by bringing into close proximity massive amounts of air and blood while simultaneously humidifying inspired gas and filtering out contaminants. Ordinarily this process requires a minimal amount of work, but stressful conditions and disease can ultimately overwhelm the system. Since a reasonable understanding of the normal anatomy and physiology of the respiratory system is essential to the understanding and management of pulmonary diseases, we briefly review it here.

## Lung Development

Lung development is divided into five phases: embryonic, pseudoglandular, canalicular, saccular, and alveolar. The boundaries between these phases are not sharp; they blend into one another with considerable overlap at any given time between areas within the lung, and they vary from person to person.[2]

### EMBRYONIC PHASE

The human fetal lung originates in the 3-week-old embryo as a ventral diverticulum that arises from the caudal end of the laryngotracheal groove of the foregut.[3] This diverticulum grows caudally to form the primitive trachea. By 4 weeks the end of the diverticulum divides, forming the two primary lung buds. The lung buds develop lobar buds, which correspond to the mature lung lobes (three on the right side and two on the left side). By the sixth week of gestation the lobar buds have further subdivided to form the bronchopulmonary segments. During this time the vascular components of the respiratory system also begin their development. The pulmonary arteries form as a branch off the sixth aortic arch and the pulmonary veins emerge from the developing heart.

The primitive lung bud is lined by an epithelium derived from endoderm; it differentiates into both the respiratory epithelium that lines the airways[4] and the specialized epithelium that lines the alveoli and permits gas exchange.[5] The lung bud grows into a mass of mesodermal cells from which blood vessels, smooth muscle, cartilage, and other connective tissues that form the framework of the lung will differentiate.[6] Ectoderm contributes to the innervation of the lung (Fig. 7-1, *A*).[7]

### PSEUDOGLANDULAR PHASE

From the seventh to sixteenth weeks of gestation, conducting airways and the associated pulmonary vasculature are formed by repeated dichotomous branching, resulting in 16 to 25 generations of primitive airways.[3] During this phase the lung has a distinctly glandular appearance (hence the term *pseudoglandular*) created by small epithelium-lined tubules surrounded by abundant mesenchyma (Fig. 7-1, *B*).[6] By the sixteenth week of gestation all the bronchial airways have been formed.[8–10] After this time further growth occurs only by elongation and widening of existing airways and not by further branching. During this period the respiratory epithelium begins to differentiate, cilia appear in proximal airways, and cartilage begins to develop from the surrounding mesoderm to support airway structures. The amount of cartilage supporting the airway decreases, moving distally from the trachea as smooth muscle cells increase. Alterations in the development of smooth muscle, cartilage, and vascular structures are responsible for many pulmonary disorders.

### CANALICULAR PHASE

The canalicular phase takes place from the sixteenth to twenty-fourth weeks of gestation. During this time the basic structure of the gas-exchanging portion of the lung is formed and vascularized.

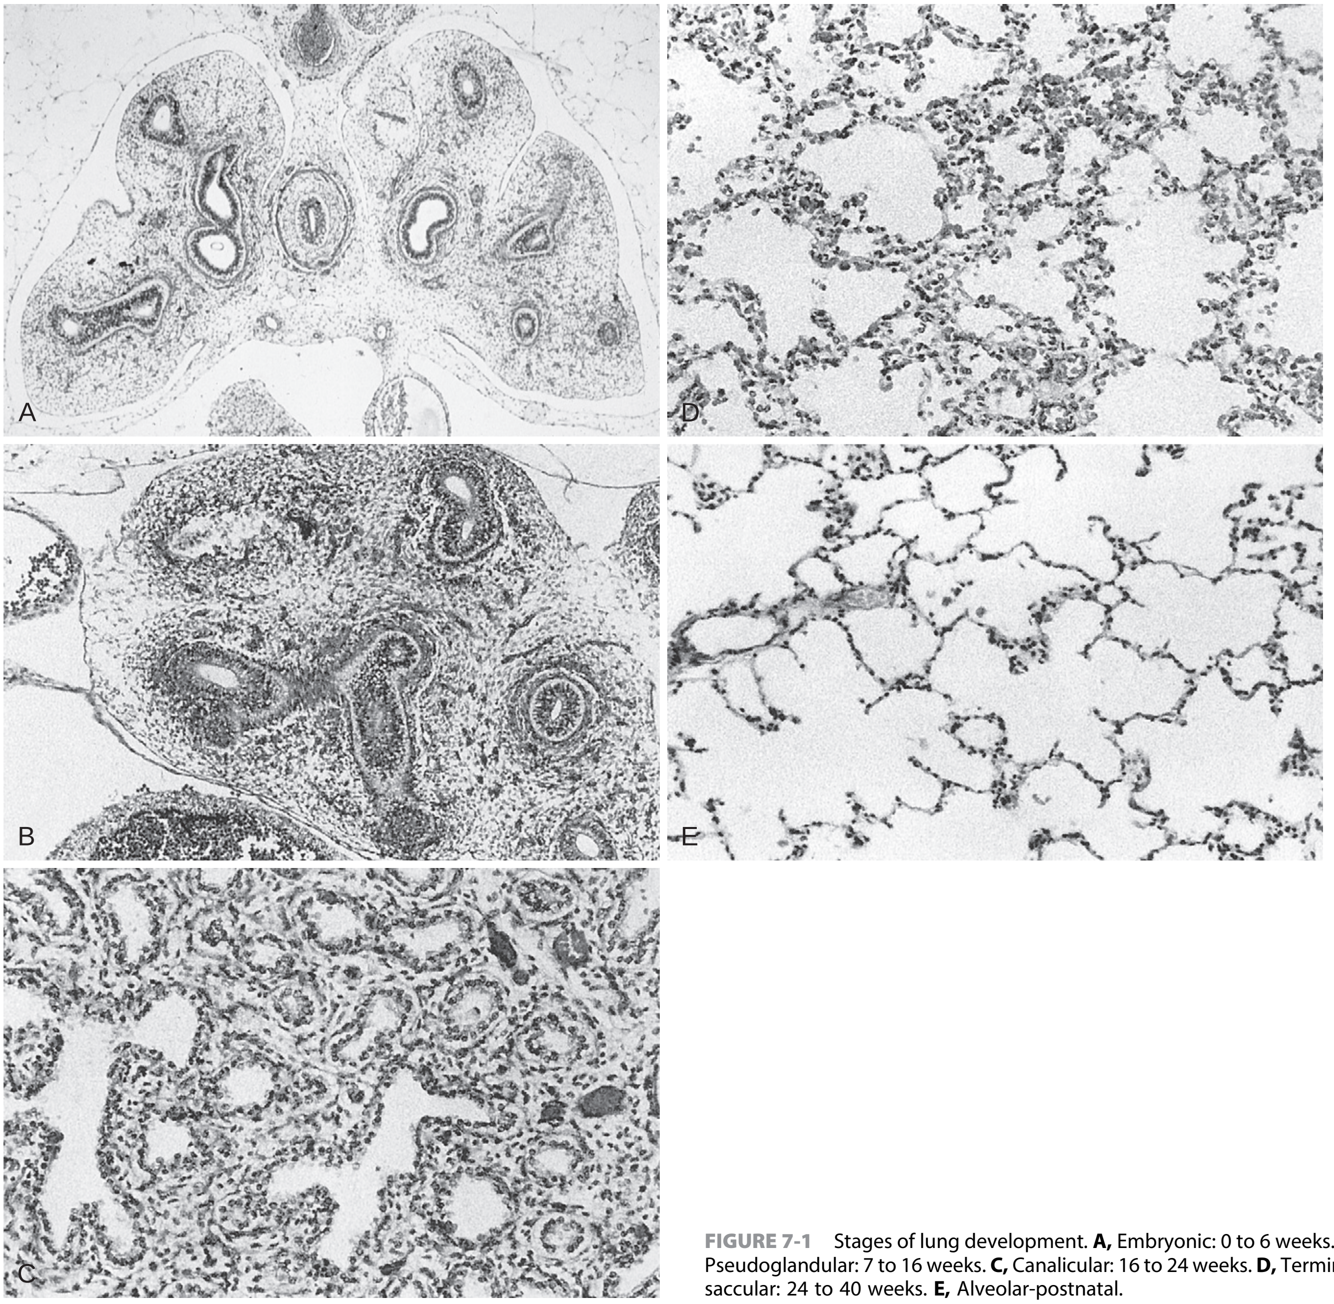

**FIGURE 7-1** Stages of lung development. **A,** Embryonic: 0 to 6 weeks. **B,** Pseudoglandular: 7 to 16 weeks. **C,** Canalicular: 16 to 24 weeks. **D,** Terminal saccular: 24 to 40 weeks. **E,** Alveolar-postnatal.

Early in the canalicular period the lungs have a simple airspace configuration. Potential gas-exchanging structures are smooth-walled blind-ending channels that are lined by cuboidal epithelium and supported by abundant loose interstitium and scattered small blood vessels. As the canalicular period progresses interstitial tissue decreases, capillary growth increases, and these "channels" assume a more complex irregular pattern (Fig. 7-1, *C*).

At approximately 20 weeks' gestation differentiation of the primitive epithelial cells begins. The first morphologic evidence of this phase of differentiation is the growth of capillaries beneath the epithelial cells that line the primitive gas-exchanging channels. In one population of overlying epithelial cells, capillary ingrowth results in thinning of the cytoplasm, narrowing of the air-blood interface, and differentiation into type I pneumocytes—the cells ultimately responsible for gas exchange. In other overlying epithelial cells, the lamellar bodies that are associated with surfactant synthesis begin to appear; these bodies identify the type II cells that will ultimately produce surfactant. Although some investigators have concluded that the progenitor of type I cells is an undifferentiated epithelial cell, a more convincing body of evidence suggests that type I cells develop from differentiated type II cells.[11–15] By the end of the canalicular period, structural development of the lung has progressed to the point that gas exchange is possible.

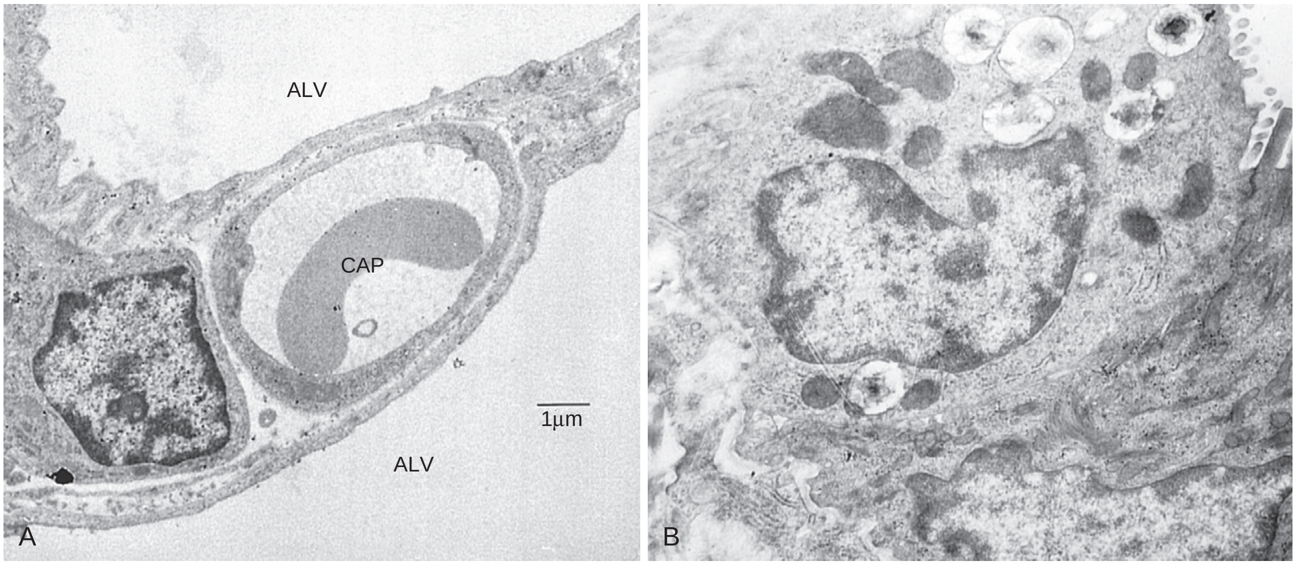

**FIGURE 7-2** **A,** Electrophotomicrograph of a type I pneumocyte. Note the thin alveolar-arterial interface. **B,** Electrophotomicrograph of a type II pneumocyte. Note the lamellar bodies filled with surfactant. ALV, alveolar; CAP, capillary.

## TERMINAL SACCULAR PHASE

The terminal saccular phase of lung development takes place from 24 weeks' gestation until term and is associated with remarkable changes in the appearance of the lung. Interstitial tissue becomes less prominent and airspace walls demonstrate marked thinning. Tissue projections into the distal airspace regions divide the distal airspaces into saccules, where capillaries are generally exposed to only one respiratory surface (Fig. 7-1, *D*). Later in the mature alveolus, each capillary is simultaneously exposed to at least two alveoli.[16]

The cells that line the terminal saccules of the human fetal lung at this stage of development are recognizable type I and type II pneumocytes. Morphologically they are indistinguishable from the corresponding cells described in neonatal or adult human lung tissue. However the surfactant produced by the early fetal lung differs biochemically from that produced later in gestation. Although no apparent morphologic differences in the lamellar bodies exists, immature lungs produce surfactant that is rich in phosphatidylinositol, whereas the surfactant produced by lungs late in gestation is rich in phosphatidylglycerol.[17]

## ALVEOLAR PHASE

An alveolus is defined as an open outpouching of an alveolar duct lined almost exclusively by the thin processes of type I pneumocytes. Its interstitial capillaries are simultaneously exposed to at least two alveoli, and because the nuclei of all cells are located away from the gas-exchange surface, the barrier to gas exchange is usually only a few nanometers thick.[18] The barrier between the gas in the alveoli and the blood in the capillaries is composed of three layers: the thin processes of the type I cells, a basement membrane that appears to be common to the endothelial and alveolar cells, and the thin extensions of the endothelial cells (Fig. 7-2, A). The type I cell is responsible for gas exchange and the type II cell synthesizes and secretes surfactant.

At birth the lung has no mature alveoli but instead contains approximately 20 million primitive terminal sacs.[19–22] These sacs are lined by mature alveolar epithelium; they resemble large shallow cups.[9,19–22] At approximately 5 weeks after birth, these 20 million primitive terminal sacs begin to develop into the 300 million alveoli that will be present by 8 years of age, with the fastest multiplication occurring before 4 years of age (Fig. 7-1, *E*).[21–23] After age 8 years, increases in lung volume result from increases in alveolar size but not number.[21]

## ARTERIAL GROWTH

The pattern of growth of pulmonary arteries differs depending on the location of the artery relative to the acinus. The preacinar region refers to the conducting airways and includes the trachea, major bronchi, and bronchial branches to the level of the terminal bronchiolus. The acinus refers to the functional respiratory unit of the lung and includes structures that are distal to the terminal bronchiolus (specifically the respiratory bronchioli, alveolar ducts, and alveoli). In the preacinar region the pulmonary artery gives off a branch to accompany each airway branch—a "conventional" artery that ultimately provides terminal branches to the acini. Many additional branches arise from the conventional arteries and pass directly into adjacent respiratory tissue to supply the peribronchial parenchyma; these are called *supernumerary* arteries.[8,24]

Mirroring the branching of bronchial airways, the development of all preacinar conventional and supernumerary arteries is complete by 16 weeks' gestation.[24,25] Subsequent changes in the preacinar arteries involve only size not number. In the intra-acinar region terminal branches of the conventional pulmonary arterioles supply the capillary bed. Concurrent with alveolar development these small vessels of the lung

multiply rapidly after birth to keep pace with alveolar multiplication.

In adults complete muscularization of pulmonary arteries is found throughout the acinus, even in the walls of alveoli immediately under the pleura. In the fetus, however, complete muscularization of the arteries occurs only proximal to or at the level of the terminal bronchioli. Consequently only partially muscular or nonmuscular arteries are found within the acinus itself. New alveoli appear during early childhood simultaneously with the accompanying intra-acinar arteries. However muscularization of these arteries is a slow process.[9]

### MEDIATORS OF FETAL LUNG DEVELOPMENT

Although a complete discussion of the genetics of lung development is beyond the scope of this chapter, some of the basic pathways are becoming better understood and are thus worthy of mention. Early lung bud development and airway branching involves the genes *GATA*6, HNF-3, *FGF*-10, *SHH*, and TGF-b. Alveolar development involves *platelet-derived growth factor, tropoelastin,* and glucocorticoids. Pulmonary vascular development involves *TGF-b*, *VEGF-A*, *FOX*, and *integrin*.[26] So far not enough is known about the genetics of lung development for it to be exploited clinically, but that day is probably not far off.

The distribution of fetal lung fluid has been exploited clinically. There is a large body of evidence supporting the role of lung liquid in normal and experimental fetal lung growth. Fetal lung fluid is a combination of plasma ultrafiltrate from the fetal pulmonary circulation, components of pulmonary surfactant, and other fluids from pulmonary epithelial cells. This fluid is produced constantly to keep the fetal lung inflated and at slightly positive pressure, which is essential to stimulate normal lung development. Naturally occurring airway occlusions in humans have resulted in large fluid-filled lungs that histologically have either normal or slightly distended alveoli.[27–31] In other instances intrauterine airway occlusion results in large lungs despite the presence of other anatomic abnormalities, such as Potter syndrome or congenital diaphragmatic hernia, that would normally lead to pulmonary hypoplasia.[32–34]

Experimental studies of normal fetal lambs have confirmed that retention of lung liquid leads to pulmonary hyperplasia, whereas drainage of liquid leads to hypoplasia. Fetal tracheal occlusion has also been shown to prevent pulmonary hypoplasia associated with fetal diaphragmatic hernia.[35–38] Since these initial studies, multiple experimental animal models of fetal tracheal occlusion have shown dramatic increases in lung growth. Subsequently several clinical trials of tracheal occlusion in association with congenital diaphragmatic hernia have shown some progress in alleviating the associated pulmonary hypoplasia, but preterm labor has continued to limit its application.[39,40] Postnatal intrapulmonary distention with perfluorocarbon liquid has also been shown to accelerate neonatal lung growth, but randomized clinical trials have been thwarted by regulatory issues.[26]

Although increased intrapulmonary pressure has been cited as the primary stimulus for lung growth in tracheal occlusion models, it is likely only a trigger for more complex downstream regulatory changes. Tracheal occlusion has been associated with increased expression or production of multiple growth factors, including keratinocyte growth factor, vascular endothelial growth factor, transforming growth factor-β2, insulin-like growth factor I, and many others, all of which may participate in a complex regulatory pathway for lung development enhanced by tracheal occlusion.[41–44]

## Pulmonary Physiology

Shortly before birth epithelial cells cease production of lung fluid and begin to actively absorb it back into the fetal circulation. This process is facilitated by active sodium transport and is stimulated by thyroid hormone, glucocorticoids, and epinephrine.

At birth as the lung expands with the first few breaths, pulmonary arterial $P_{O_2}$ increases and $P_{CO_2}$ decreases. This results in pulmonary vasodilation, lowered pulmonary vascular resistance, and constriction of the ductus arteriosus. The loss of maternal prostaglandins further stimulates ductus arteriosus closure. Cessation of umbilical blood flow results in closure of the ductus venosus and a rise in the systemic vascular resistance, which in turn results in an increase in left-sided heart pressures above the pressure in the right side of the heart, resulting in closure of the foramen ovale. With this final right-to-left shunt closure, the transition from fetal to postnatal circulation is complete. Failure of any of these events can lead to persistence or recurrence of fetal circulation and respiratory failure.

The process of breathing is complex and involves contraction of the inspiratory muscles to generate negative pressure in the trachea to bring fresh air into the lungs. In the lungs the process of oxygen uptake and carbon dioxide elimination occurs by means of diffusion across the ultrathin alveolar capillary membrane. This process is critical not only to fuel the cells of the body with oxygen for metabolism but also to maintain appropriate acid-base status by careful regulation of carbon dioxide. Dysfunction in any part of this process can lead to respiratory failure and the need for mechanical ventilatory support.

### LUNG VOLUMES

To understand the process of respiration, it is necessary to understand the terminology associated with the assessment of pulmonary function. The total volume of the lung is divided into subcomponents, defined as follows (Fig. 7-3):

- Functional residual capacity (FRC): The volume of gas in the lung that is present at the end of a normal expiration when airflow is zero and alveolar pressure equals ambient pressure
- Expiratory reserve volume: The additional gas that can be exhaled beyond FRC to reach residual volume
- Residual volume: The minimum lung volume possible; this is the gas that remains in the lung after all exhalable gas has been removed
- Total lung capacity: The total volume present in the lung
- Inspiratory capacity: The difference in inhaled volume between FRC and total lung capacity
- Vital capacity: The amount of gas inhaled from FRC to total lung capacity

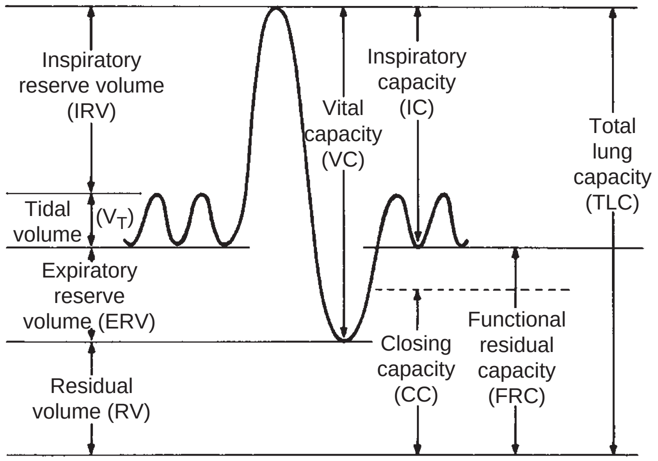

**FIGURE 7-3** Functional components of lung volume.

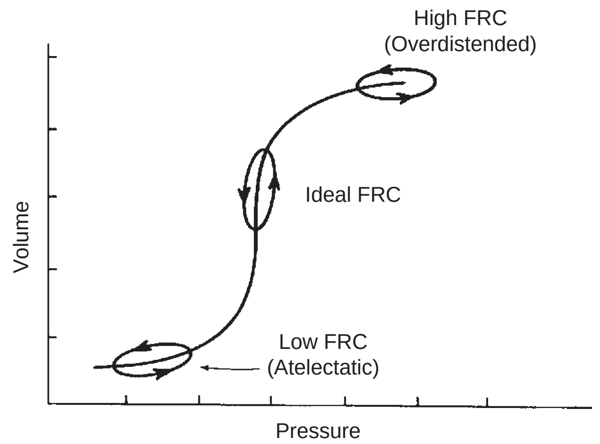

**FIGURE 7-4** Static compliance curve with superimposed dynamic flow-volume loops for high, low, and ideal functional residual capacities (FRCs).

- Inspiratory reserve volume: The amount of gas inhaled from peak normal inspiratory volume to total lung capacity
- Tidal volume: The volume of a normal inspiration

Tidal volume, vital capacity, inspiratory capacity, inspiratory reserve volume, and expiratory reserve volume can be measured directly by spirometry. Conversely total lung volume, FRC, and residual volume cannot be measured by spirometry, and one of the following techniques must be used: (1) the nitrogen washout test, in which the nitrogen eliminated from the lungs while breathing pure oxygen is measured; (2) the helium dilution test, which measures the equilibration of helium into the lung; or (3) total-body plethysmography, which measures changes in body volume and pressure to calculate FRC using Boyle's law.[45]

## CLOSING CAPACITY

Inspiratory pressure within the airway decreases as gas travels in a distal direction. Eventually the intraluminal pressure stenting the airway open equals the surrounding parenchymal pressure; this is called the *equal pressure point*.[46] Downstream of the equal pressure point, intraluminal pressure drops to less than surrounding parenchymal pressure, and airway closure occurs leading to unventilated alveoli and a physiologic shunt. In normal lungs little or no unventilated area exists at FRC. However any reduction in FRC (which frequently occurs in diseased lungs) will cause more areas of the lung to reach closing volume and become atelectatic and increase the shunt.[47] Conversely an increase in FRC (achieved by positive-pressure ventilation) may open some areas that were closed, thereby reducing the physiologic shunt.

## PULMONARY COMPLIANCE

Pulmonary compliance is defined as the change in lung volume per unit change in pressure.[48] Dynamic compliance is the volume change divided by the peak inspiratory transthoracic pressure. Static compliance is the volume change divided by the plateau inspiratory pressure.[49] With the initiation of an inspiratory breath the transthoracic pressure gradient increases to a peak value. This increase is a function of elastic resistance of the lung and chest wall as well as airway resistance. The pressure then falls to a plateau level as the gas redistributes in alveoli. Consequently dynamic compliance is always lower than static compliance. Figure 7-4 demonstrates a standard static compliance curve.[50] Ventilation normally occurs in the steep portion of the curve, whereas large changes in volume occur in response to small changes in pressure. However at low and high volumes, large changes in pressure result in minimal changes in volume. In diseased lungs in which compliance has dropped into the flat portion of the curve, the goal of mechanical ventilation is to return it to the steep portion. Excessive pressure applied by the ventilator results in ventilation at the top of the curve where the process once again becomes inefficient.[51]

Changes in lung volume and pleural pressure during a normal breathing cycle, which reflect the elastic and flow-resistant properties of the lung, are displayed as a pressure-volume loop in Figure 7-5. The slope of the line that connects the end-expiratory and end-inspiratory points in the figure provides a measure of the dynamic compliance of the lung. The area that falls between this line and the curved lines to the right and left represents the additional work required to overcome flow resistance during inspiration and expiration, respectively.

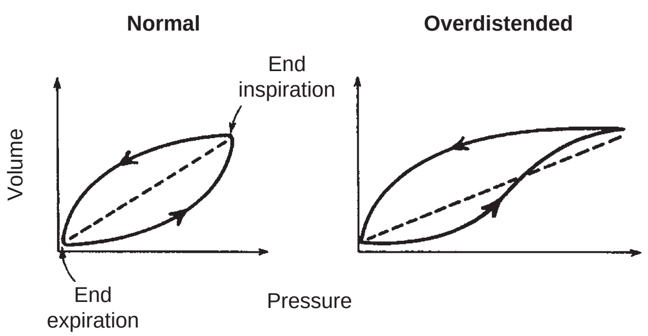

**FIGURE 7-5** Dynamic pressure-volume loop demonstrating an idealized ventilatory cycle and overdistention during positive-pressure ventilation.

## AIRWAY RESISTANCE

Resistance to gas flow is a function of the physical property of the gas (molecules interact with one another and with airway walls) as well as the length of the tube through which the gas travels. Most important, resistance is a function of the internal diameter of the tube. Because the airways in small children are narrow, a slight change in diameter secondary to airway swelling can result in a dramatic increase in resistance. Because airways are smaller at the base of the lung, resistance is greater there than in the apical region.[52] In addition the velocity of flow affects resistance because below critical velocity gas flow is laminar. However above critical velocity there is turbulent flow and resistance increases.

## TIME CONSTANTS

The time constant is a product of the compliance and resistance of the lung and calculates how quickly exhalation can occur. Consequently increases in compliance or resistance of individual alveolar units or areas of the lung increase the time constant. One time constant is defined as the time required to complete 63% of tidal volume expiration (two, three, and four time constants = 87%, 95%, and 99%, respectively).[53] Because the resistance of the airways leading to individual alveoli varies depending on alveolar location, and because the compliance of individual alveoli also varies, the measured time constant is actually an average of many different time constants throughout the lung. The importance of understanding time constants becomes apparent when assisted mechanical ventilation is contemplated. In a lung with high compliance or high resistance the time constant is prolonged. Mechanical ventilator settings would consequently need to be adjusted to allow for near-complete expiration (three time constants, or 95% expiration) to avoid breath stacking and overdistention. Conversely in lungs with low compliance or low resistance, the time constant is less; under these circumstances an increase in minute ventilation should be accomplished with increases in respiratory rate rather than increases in tidal volume. Because of low compliance, tidal volume would be more likely to lead to high pressure and barotrauma.

## PULMONARY CIRCULATION

Mixed venous blood from the systemic circulation collects in the right atrium, passes into the right ventricle, and then travels into the pulmonary capillary bed where gas exchange occurs. Blood subsequently drains into the left atrium where it is pumped into the left ventricle and ultimately into the systemic circulation. Desaturated blood that originates from systemic sources through the bronchial and pleural circulation represents 1% to 3% of the total volume of blood that exits the left atrium. In pathologic situations this anatomic right-to-left shunting can approach 10%.[54] In addition under any circumstance in which pressure in the right atrium exceeds that of the left atrium, the foramen ovale (which is anatomically patent in all neonates and in 20% to 30% of older children) becomes another major area for extrapulmonary right-to-left shunting.

Because blood is a fluid and is affected by gravity, in an upright individual blood pressure and thus blood flow in the pulmonary capillary bed are lowest at the apex of the lung and greatest at the base. Under normal circumstances pulmonary artery pressure is adequate to deliver some blood to the apex of the lung; however in pathologic situations such as hemorrhage or shock, blood flow to the apex can fall to zero, resulting in an area that is ventilated but not perfused; such areas are referred to as dead space. The lung can be divided into four regions designated progressively in a caudal direction from apex to base. In zone 1 (the apex) the alveolar pressure exceeds pulmonary artery pressure and little or no flow occurs. In zone 2 the arterial pressure exceeds alveolar pressure, but alveolar pressure exceeds venous pressure. In this region flow is determined by arterial-alveolar pressure differences. In zone 3 the pulmonary venous pressure exceeds alveolar pressure and flow is determined by the arterial-venous pressure differences. In zone 4 (the base) pulmonary interstitial pressure exceeds both pulmonary venous and alveolar pressure and flow in this region is determined by arterial interstitial pressure differences.[55]

Because oxygen is a pulmonary vasodilator, hypoxemia is a potent stimulus for vasoconstriction in the pulmonary vascular bed. In addition because acidosis is a pulmonary vasoconstrictor and alkalosis is a vasodilator, the partial pressure of carbon dioxide ($P_{CO_2}$) indirectly affects the capillary bed because of its effect on pH.

## PULMONARY GAS EXCHANGE

### Diffusion

Oxygen and carbon dioxide pass between the alveolus and the pulmonary capillary bed by passive diffusion from higher to lower concentration.[56] Because diffusion in a gaseous environment is a function of molecular weight, oxygen diffuses more rapidly through air than carbon dioxide does. However because diffusion across the capillary alveolar membrane involves a shift from the gaseous phase to the liquid phase, solubility of the gas in liquid becomes rate limiting, so carbon dioxide (being far more soluble than oxygen) diffuses 20 times more rapidly.[57]

Diffusion is driven not only by differences in solubility but also by differences in partial pressure of the gases across the capillary alveolar membrane. Gas exchange is consequently most rapid at the beginning of the capillary where the differences in the partial pressure of oxygen ($P_{O_2}$) and $P_{CO_2}$ between the alveoli and the capillaries are greatest; gas exchange is virtually complete one third of the way across the pulmonary capillary bed.[58] Consequently in normal individuals the principal limiting factor for oxygen uptake at rest or during exercise is pulmonary blood flow.[59] Although the rate of diffusion is not rate limiting in the healthy state, when the alveolar capillary membrane is thickened, diffusion may become sufficiently impaired to prevent complete saturation of available hemoglobin. Carbon monoxide, which has diffusion characteristics similar to those of oxygen, is used to measure diffusion capacity.

### Dead Space

Minute ventilation, which is defined as the total volume of air inspired each minute, is calculated as the product of the tidal volume and the respiratory rate. However the entire volume of gas does not participate in gas exchange; the portion of each tidal

breath that ventilates only the oropharynx, larynx, trachea, and major conducting bronchi (the anatomic dead space) does not participate in gas exchange.[60] In addition to the anatomic dead space, a certain volume of gas ventilates unperfused alveoli and consequently does not participate in gas exchange. This is known as alveolar dead space and is minimal in the absence of disease. The combination of anatomic and alveolar dead space, known as physiologic dead space, is equal to approximately one third of the normal tidal volume; dead space that exceeds this amount is considered pathologic.[61]

### Ventilation-Perfusion Matching

For optimal gas exchange, the ventilation (V) and perfusion (Q) to a given segment of the lung should be matched.[62] The V/Q ratios of different lung units are not identical,[58] but the averaged ratio of alveolar ventilation/blood flow in the lung is approximately 0.8. At the apex of the lung the V/Q ratio is higher; at the base of the lung the ratio is lower. Under normal circumstances V/Q mismatching is minimal and inconsequential. However in disease states mismatching can contribute significantly to the impairment of gas exchange. When blood flows through regions of the lung with no ventilation, a right-to-left shunt that can significantly decrease the arterial oxygen saturation is created.

### Oxygen Transport

Oxygen is transported through the bloodstream in one of two ways. It may be transported in aqueous solution in the plasma or in chemical combination within hemoglobin in erythrocytes. The amount of oxygen transported in solution is negligible. Thus most oxygen is carried bound to hemoglobin in erythrocytes. At full saturation, 1 g of hemoglobin is capable of carrying 1.34 mL of oxygen. However the actual amount of oxygen carried by hemoglobin varies and is defined by a sigmoid-shaped curve referred to as the oxyhemoglobin dissociation curve (Fig. 7-6). Under normal circumstances hemoglobin is 100% saturated with oxygen; however the sigmoid shape of this curve ensures that the oxygen carrying capacity of hemoglobin remains relatively high, even at a $P_{O_2}$ as low as 60. As a result mild pulmonary disorders do not interfere with oxygen delivery. At the same time the steep area of the dissociation curve ensures that a large quantity of oxygen can be unloaded into the peripheral tissues as $P_{O_2}$ drops. The oxyhemoglobin dissociation curve can be shifted to the left or right by changes in the affinity of hemoglobin for oxygen. A shift to the left results in a higher affinity of hemoglobin for oxygen and is caused by alkalosis,[63] hypothermia, decreased erythrocyte 2,3-diphosphoglycerate[64] (which often occurs in old banked blood),[65] or fetal hemoglobin.[66] In this situation, at a given $P_{O_2}$, the hemoglobin is more saturated than normal and tissue perfusion should therefore be increased to deliver the same amount of oxygen for metabolic needs. A shift to the right is the result of a lowered affinity of hemoglobin for oxygen and is caused by acidosis,[63] hyperthermia, and an increased red blood cell 2,3-diphosphoglycerate content.[64] This rightward shift results in hemoglobin that is less saturated at a given $P_{O_2}$ thereby allowing the unloading of more oxygen at lower rates of flow to the peripheral tissues.

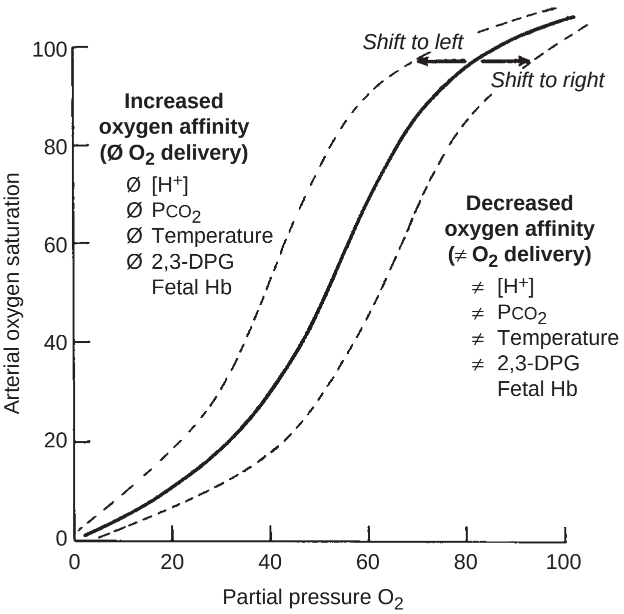

**FIGURE 7-6** Oxyhemoglobin dissociation curve. DPG, diphosphoglycerate; Hb, hemoglobin.

### Carbon Dioxide Equilibrium and Acid-Base Regulation

Because carbon dioxide is produced as an end product of metabolism, its rate of production is a function of metabolic rate. Under normal circumstances the amount of carbon dioxide produced is slightly less than the amount of oxygen consumed. This is defined by the respiratory quotient (R):

$$R = \frac{\text{Rate of } CO_2 \text{ output}}{\text{Rate of } O_2 \text{ uptake}}$$

Under normal circumstances, the respiratory quotient is 0.8, but it can vary from 1.0 to 0.7, depending on whether carbohydrate or fat is used as the principal source of nutrition. The lungs are primarily responsible for the elimination of carbon dioxide, and the rate of elimination depends on pulmonary blood flow and alveolar ventilation. Carbon dioxide is carried in the bloodstream in several forms. In aqueous solution it exists in a state of equilibrium as dissolved carbon dioxide and carbonic acid ($CO_2 + H_2O \rightleftharpoons H_2CO_3$). This equation normally is shifted markedly to the left. In erythrocytes, however, the enzyme carbonic anhydrase catalyzes the reaction, which shifts the equation to the right.[67,68] The ability of carbonic acid to dissociate and reassociate ($H_2C_3 \rightleftharpoons H^+ + HCO_5$) is an important factor in buffering plasma to maintain a physiologic pH. The relationship is defined using the Henderson-Hasselbalch equation. A small amount of carbon dioxide is also carried combined with hemoglobin in the form of carbaminohemoglobins.[67]

## Monitoring

Because the condition of acutely ill infants and children can deteriorate rapidly, continuous surveillance of their physiologic status is necessary to provide ideal care. Many options for physiologic monitoring are available to the clinician in the modern intensive care unit; the most useful are discussed in this section.

## NONINVASIVE MONITORING

### Pulse Oximetry

Pulse oximetry provides continuous noninvasive monitoring of hemoglobin saturation. The principle of pulse oximetry is based on spectrophotometry and relies on the fact that oxygenated and deoxygenated hemoglobin transmits light at different frequencies. Oxygenated hemoglobin selectively absorbs infrared light (940 nm) and transmits red light (660 nm), whereas deoxyhemoglobin absorbs red light and transmits infrared light. The pulse oximeter probe contains two light-emitting diodes that pass light at the wavelengths noted through a perfused area of tissue to a photodetector on the other side. The photodiode compares the amounts of infrared, red, and ambient light that reach it to calculate the oxygen saturation in arterial blood ($SaO_2$).[69,70]

The advantages of pulse oximetry are that it is noninvasive and has a rapid response time, making changes in clinical status immediately apparent. Disadvantages of oximetry are that it is insensitive to large changes in arterial $PO_2$ at the upper end of the oxygenated hemoglobin dissociation curve. In addition at an oxygen saturation less than 70%, the true $SaO_2$ is significantly underestimated by most oximeters. When $SaO_2$ measurements are routinely less than 85%, determination of its correlation with actual partial pressure of oxygen in arterial blood ($PaO_2$) through the use of indwelling arterial catheters is necessary. Errors can also occur when other forms of hemoglobin exist.[71] The presence of carboxyhemoglobin and methemoglobin results in falsely elevated $SaO_2$ readings.[65] Conversely certain dyes such as methylene blue result in a marked decrease in measured $SaO_2$.[72] The presence of fetal hemoglobin, which has an absorption spectrum similar to that of adult hemoglobin, has no impact on the accuracy of $SaO_2$ measurements. Physical factors—including poor peripheral perfusion, abnormally thick or edematous tissue at the site of sensor placement, the presence of nail polish, and excessive ambient light—also lead to inaccurate readings.[73–75]

### Capnometry

Capnometry is a noninvasive method that measures the end-tidal partial pressure of carbon dioxide in the expired gas.[76] As with pulse oximetry capnometry is based on the principle that carbon dioxide absorbs infrared light. Exhaled gas passes through a sampling chamber that has an infrared light source on one side and a photodetector on the other side. Based on the amount of infrared light that reaches the photodetector, the amount of carbon dioxide present in the gas can be calculated. Depending on the equipment, data can be reported as the maximum concentration of carbon dioxide (end-tidal carbon dioxide) or it can provide a display of the entire exhaled carbon dioxide waveform; this display is known as a capnogram.[77]

Two categories of carbon dioxide monitors exist: mainstream monitors and sidestream monitors.[78] Mainstream monitors, in which the sampling cell is connected to the airway between the ventilator and the endotracheal tube, respond faster to changes in carbon dioxide but must be heated to prevent water condensation. These chambers are consequently heavy and hot and must be supported to avoid contact with the patient. Sidestream monitors draw a continuous sample of gas from the respiratory circuit into the measuring cell. This system is lightweight and can theoretically be used in nonintubated patients[79]; however because of the longer transit time to the sampling chamber, this unit is slow in responding to changes in carbon dioxide.

Because the carbon dioxide that is measured in expired gases is a product of metabolic rate, pulmonary circulation, and alveolar ventilation, these variables must all be considered when interpreting changes in end-tidal carbon dioxide measurements.

### Transcutaneous Measurement of Gas Tension

Measurement of $PO_2$ and $PCO_2$ at the skin surface is possible by means of transcutaneous monitoring.[80] The principle of this device is based on the fact that $PO_2$ and $PCO_2$ approximate arterial values in areas where blood flow exceeds the metabolic requirements of the tissue. To increase blood flow the devices used to measure transcutaneous $PO_2$ and $PCO_2$ contain a sampling electrode and a warming device to increase local blood flow.[81] The advantage of transcutaneous monitoring is that it may reduce the number of (but not eliminate the need for) arterial blood gas determinations required in a sick individual. One limitation of the device is that the measured transcutaneous $PO_2$ and $PCO_2$ are not equal to arterial blood gas tensions and can frequently be 5 to 10 mm Hg higher or lower than the arterial counterpart. Changes in peripheral perfusion caused by shock or vasopressors can make these values even more inaccurate.[82] Another disadvantage is that burns or blisters may occur at the electrode site because of the warming component. This requires frequent changing of the monitoring site, at which time recalibration is necessary.

## INVASIVE MONITORING

### Mixed Venous Oxygen Monitoring

Measurement of mixed venous oxygen saturation ($SvO_2$) may be the single most useful measurement in determining critical impairment in oxygen delivery to the tissues (usually interpreted as an $SvO_2$ <60%). Because the $SvO_2$ is a function of arterial saturation, cardiac output, and hemoglobin concentration, any deviation in these values is detected in the $SvO_2$.

Although a lowered $SvO_2$ does not identify the cause of the impairment, it provides several hints to solving the problem. Increasing the fractional concentration of oxygen in inspired gas ($FIO_2$) to elevate $SaO_2$, using pressors or volume expansion to increase the cardiac output, or increasing the hemoglobin concentration with transfusions can all be used to correct a critically low $SvO_2$. The $SvO_2$ can be monitored by intermittent measurement of blood withdrawn from a pulmonary artery catheter or by continuous monitoring using a pulmonary artery catheter equipped with a fiberoptic bundle.[83]

### Arterial Catheterization

Indwelling arterial catheterization provides access for continuous monitoring of arterial blood pressure and intermittent arterial blood gas sampling. This method is indicated for patients who require frequent blood gas sampling or who are hemodynamically unstable.

In children the most common locations for arterial catheter placement are the radial, posterior tibial, or dorsalis pedis arteries. When placing a radial artery catheter, it is imperative to ascertain the patency of the ulnar artery by assessing blood

flow to the hand and fingers while the radial artery is compressed (Allen test).[84] Otherwise ischemic necrosis of the hand may occur.[85] In newborn infants the umbilicus provides two additional arteries for access. The catheter tip is generally placed at one of two positions. The high position (T6 through T8) places the tip below the ductus arteriosus but above the major abdominal tributaries. The low position (L3 through L4) places the catheter tip between the renal arteries and inferior mesenteric arteries. These positions have the advantage of minimizing the potential complications of thrombus or embolus into the tributary vessels.

The advantage of direct arterial catheterization is that it provides the most accurate continuous measurement of blood pressure as well as the most accurate assessment of $Pa_{O_2}$ and $Pa_{CO_2}$. The disadvantage is that the technique is invasive and therefore involves a risk of infection,[2,86] embolization,[87] and thrombosis[88]; this risk increases with time.[89] Another complication is the potential for anemia because the presence of indwelling arterial lines has been associated with excessive blood testing.[90] Consequently daily assessment of the necessity of direct arterial monitoring is essential and catheters should be removed as soon as the patient can be managed without them.

In infants the right radial artery is unique in that it provides peripheral arterial access to preductal blood (i.e., blood ejected from the left ventricle before being mixed in the aorta with blood from a patent ductus arteriosus). When pulmonary hypertension exists (e.g., congenital diaphragmatic hernia), significant differences in preductal and postductal arterial saturation may occur and monitoring of both sites is often useful in guiding therapy.

### Pulmonary Artery Catheterization

The pulmonary artery catheter enables the direct measurement of right atrial pressure, right ventricular end-diastolic pressure, pulmonary artery pressure, and $Sv_{O_2}$.[91–96] In addition calculation of cardiac output and left ventricular filling pressures can be calculated indirectly. Complications include cardiac arrhythmias in up to 50% of critically ill patients, conduction defects (6%), pulmonary infarction (<1%), pulmonary artery rupture (0.2%), catheter knotting, balloon rupture (5%), and infection.[97–102] Because of these safety concerns and the evolution of less invasive methods such as echocardiography, use of pulmonary artery catheters in noncardiac pediatric patients is now rare.

# Mechanical Ventilators

A basic knowledge of mechanical ventilators is important for pediatric surgeons because many surgical procedures result in transient respiratory failure, and respiratory failure is the most frequent diagnosis requiring admission to neonatal and pediatric intensive care units.[103] The goals of mechanical ventilation are to achieve adequate excretion of carbon dioxide by maintaining alveolar ventilation, maintain adequate arterial oxygenation, expand areas of atelectasis by increasing lung volume, and reduce the mechanical work of breathing. While achieving these goals, mechanical ventilation must also avoid inflicting further injury from barotrauma or oxygen toxicity, or both.[104]

The first-generation ventilator developed by O'Dwyer in 1968 was powered by a foot pump and was not significantly improved on until 1970, when Siemens introduced the 900A. Since then ventilators have evolved from simple devices delivering bulk volumes of air based on cycling pressure and time to more advanced devices. Microprocessor-driven models provide new functions such as pressure support ventilation (PSV), mandatory minute ventilation, airway pressure release ventilation, and more recently proportional assist ventilation and volume-assured PSV.

## CYCLING MECHANISMS

### Mechanical Breath Phases

All ventilators deliver mechanical breaths that cycle through four distinct phases: inspiration, cycling, expiration, and triggering. Inspiration is the point at which expiratory valves close and fresh gas is introduced under pressure into the lungs. Cycling is the point at which inspiration changes to expiration and can occur in response to elapsed time, delivered volume, or pressure met. At this point inflow of gas stops and expiratory valves open to allow passive release of gas from the lungs. Triggering is the changeover from expiration to inspiration and can occur in response to elapsed time (control mode) or in response to a patient-initiated event (assist mode), such as changes in airway pressure or gas flow. Most of the recent refinements in ventilator design are aimed at decreasing the mechanical lag time between patient effort and ventilator response, thereby increasing patient comfort and reducing the work of breathing.[105,106]

## VENTILATOR TYPES

Ventilators can be broadly classified into two groups: volume controlled and pressure controlled, based on the specific parameter by which the ventilator cycles are controlled.

### Pressure-Controlled Ventilation

Pressure-controlled ventilation uses pressure as the main parameter to define inspiration. With pressure control the inspiratory phase ceases when a preset peak inspiratory pressure (PIP) is reached. Some ventilators, known as time-cycled ventilators, use a preset inspiratory time to determine inspiration but are pressure limited and thus classified as pressure ventilators. A variation of this, intermittent positive pressure ventilation using a time-cycled pressure limited continuous-flow ventilator, is currently the most common form of ventilation used in infants. The major advantage of pressure ventilation is that it allows careful control of PIP and mean airway pressure thereby avoiding barotrauma. The disadvantage is that tidal volume is a function of not only the difference between PIP and PEEP but also the inspiratory time and compliance. Consequently as lung compliance changes during the course of an illness, tidal volumes may change dramatically. Therefore use of pressure-cycled ventilators requires careful attention to the tidal volume being delivered at a given setting to avoid underventilation as compliance worsens or overdistention and barotrauma as compliance improves (see Fig. 7-5).

### Volume-Controlled Ventilation

Volume-controlled ventilation uses a preset tidal volume to define inspiration. The major advantage of this type of ventilator is that a consistent tidal volume is delivered. However in reality, what is actually controlled is the volume of gas injected into the ventilator circuit not the volume of gas delivered into the patient's lungs. Humidification, compression of gas, distention of the compliant circuit, and the variable leak around an uncuffed endotracheal tube contribute to inaccurate control of delivered tidal volume. Frequently as the pathologic process progresses, adjustments in tidal volume and rate are necessary to maintain the desired minute ventilation and avoid high pressures and barotrauma. To avoid dangerously high PIPs most volume-cycled ventilators have a pressure-limit valve that prematurely interrupts inspiration when the preset limit is reached. Because this can lead to significant alveolar hyperventilation, a pressure-limit alarm sounds to alert the clinician that this is occurring. Volume-cycled ventilation is more commonly used in older children but can be used in infants.[104]

## MODES OF VENTILATION

Modes of mechanical ventilation are classified on the basis of three factors: How is each breath initiated? How is gas flow controlled during breath delivery? How it is the breath ended? The mode indicates how the ventilator interfaces with the patient's own breathing efforts. Most pressure- and volume-cycled ventilators are capable of providing several modes, which vary from total control of ventilation to simple maintenance of PEEP without ventilatory assistance.

### Control Mode

Total control is used when it is necessary to maintain complete control of the patient's ventilation.[79] Because the mechanisms for patient-triggered assist modes are disabled, it is generally necessary to paralyze and sedate the patient to eliminate asynchrony with the ventilator. The control mode is generally used when extremes of ventilation are necessary, such as very high minute ventilation requiring rapid respiratory rates.

### Assist-Control Mode

Assist-control mode is similar to the control mode in that the variables of volume pressure and inspiratory time are preset. However the patient is allowed to override the preset respiratory rate with patient-triggered breaths, which are then completely supported by the ventilator. In the assist-control mode, each breath, whether the patient or the ventilator triggers it, is fully supported by the ventilator. This method may be advantageous if the goal is to reduce the work of breathing or disadvantageous in situations such as weaning, when exercise of the patient's respiratory muscles is desirable.[91] Another disadvantage is that in small infants with high respiratory rates, hyperventilation and asynchrony with the ventilator are common.

### Intermittent Mandatory Ventilation

Intermittent mandatory ventilation (IMV) differs from the control and assist-control methods in that the ventilator controls are preset for mandatory inflations, but spontaneous unsupported ventilation is also allowed. The advantage of this method is that it allows exercise of the respiratory muscles. IMV is also an excellent weaning technique, and in infants with high respiratory rates it can avoid the hyperventilation seen with control modes. One disadvantage is the potential for asynchrony with the ventilator because a machine-driven inspiration may be stacked on top of a patient's spontaneous exhalation. This increases the work of breathing and may result in hypoventilation or even pneumothorax.[107]

### Synchronized Intermittent Mandatory Ventilation

Synchronized IMV allows the mandatory ventilator-delivered breaths to be synchronized with the patient's spontaneous efforts. The obvious advantage of this mode is synchronization of breaths, which should reduce the work of breathing.[108] However spontaneous breaths in excess of the set rate are not supported, which results in uneven tidal volumes and a higher work of breathing during weaning. Other disadvantages relate to the sensitivity of the synchronizing mechanisms because a spontaneous inspiratory effort (usually identified by a change in airway pressure) that is not immediately responded to with a synchronous breath can actually increase the work of breathing.[91]

### Pressure Support Ventilation

Pressure support ventilation (PSV) is a spontaneous mode of ventilation in which each breath is initiated by the patient but is supported by constant pressure inflation. This method has been shown to increase the efficiency of inspiration and decrease the work of breathing.[109,110] Like IMV, PSV is useful for weaning patients from mechanical ventilation. Unlike IMV, in which weaning involves decreasing the number of mandatory breaths with maintenance of inspiratory pressures, PSV involves steady decreases in the level of pressure support because the rate is controlled by the patient.

### Continuous Positive Airway Pressure and Positive End-Expiratory Pressure

With continuous positive airway pressure (CPAP), a predetermined positive airway pressure is administered to the patient throughout the respiratory cycle.[111] The patient however is responsible for generating the tidal volume. This method increases the FRC and usually improves oxygenation by preventing atelectasis.[112] However this technique can increase the work of breathing.

Positive end-expiratory pressure (PEEP) provides continuous positive pressure throughout the ventilatory cycle, which can prevent atelectasis, increase FRC, and improve oxygenation. PEEP is commonly administered in the range of 2 to 10 cm/$H_2O$ in neonates and 5 to 20 cm/$H_2O$ in older children, although most ventilators can provide PEEP at significantly higher levels.

### Inverse Ratio Ventilation

With inverse ratio ventilation, the inspiratory/expiratory time ratio is greater than 1 as opposed to the typical ratio of 1:2 to 1:5. It has been advocated for use in severe acute respiratory distress syndrome (ARDS) or acute lung injury to improve oxygenation while minimizing volutrauma or barotrauma.[1] This is because inverse ratio ventilation allows for increases in mean airway pressure without increases in tidal volume or PIP. Its use remains controversial; several small studies support its use but others report higher complication rates than

with more conventional modes of ventilation.[113–117] However it should be considered when traditional modes of ventilation have failed to reverse hypoxemia despite high airway pressures.[118]

### High-Frequency Ventilation

High-frequency ventilation (HFV) is defined as mechanical ventilation that uses a tidal volume less than or equal to dead space delivered at superphysiologic rates (>150 breaths per minute).[119] The potential advantages of HFV include smaller volume and pressure changes during the respiratory cycle, gas exchange at significantly lower pressures, and less depression of endogenous surfactant production. A large body of animal data suggests that ventilator-induced lung injury results from changes in pulmonary volume rather than from changes in pressure.[120] Large cyclic volume changes during conventional ventilation have been shown to disrupt the alveolar capillary interface, resulting in increased microvascular permeability and pulmonary interstitial edema.[121] This combination of fluid and protein in the interstitial and alveolar spaces results in surfactant inhibition, further reducing lung compliance. Conversely it has been shown that maintaining high lung volume with minimal changes in alveolar pressure or volume does not result in significant pulmonary injury.[122]

Several techniques of HFV exist. High-frequency positive-pressure ventilation is a modification of conventional pressure-limited ventilators, providing rates up to 150 breaths per minute.[123] High-frequency flow interrupters deliver high-pressure, short-duration breaths, with passive expiration.[40] High-frequency jet ventilators deliver short jet breaths at the distal end of the endotracheal tube; expiration is passive.[124] High-frequency oscillatory ventilation (HFOV) uses extremely small tidal volumes delivered at very high rates.[125,126] Unlike the other forms of HFV, the expiratory phase of oscillating ventilators is active.

The mechanism of gas exchange is poorly understood in HFV. With a tidal volume less than dead space volume, alveolar ventilation should equal zero, and the technique should not work. However the probable mechanisms are bulk axial flow, interregional gas mixing (pendelluft), and molecular diffusion.

Oxygenation is improved by recruiting or maintaining lung volume. Unlike conventional ventilation, which requires elevated peak pressure, mean lung volumes can be maintained with ventilation occurring around a relatively fixed intrapulmonary pressure.[127] Elimination of carbon dioxide is much more sensitive to changes in tidal volume than changes in rate.[128] Consequently when a lower $P_{CO_2}$ is desired, it can be accomplished by reducing breathing frequency because the benefit of the increased volume output per stroke exceeds the detriment of decreasing the rate.

Currently there are two strategies for applying HFV. The high-volume strategy is designed for patients with atelectasis-prone lungs. The mean airway pressure is steadily increased in small increments while oxygenation is monitored. Risks of this approach include using inadequate pressure, thereby worsening atelectasis, or using excessive pressure, leading to injury and air leak.[129] The low-volume strategy is for patients with pneumothorax or air trapping.[130] A higher $F_{IO_2}$ is frequently necessary with this strategy, and a higher $Pa_{CO_2}$ (50 to 60 mm Hg) is frequently tolerated.

The initial clinical experience with HFOV (the most widely used HFV at present) was in premature infants with hyaline membrane disease.[131] That initial study did not show a particular benefit of HFV over conventional ventilation, but its methods have been criticized and its conclusions have not been corroborated by subsequent studies. Later studies of HFOV in neonates demonstrated a significant reduction in the incidence of chronic lung disease,[126] improvement in oxygenation, and reduction in the incidence of air-leak syndrome.[125] Several other studies have shown HFOV to be a reasonable alternative to extracorporeal membrane oxygenation (ECMO) for infants who meet ECMO criteria.[132,133]

Clinical data in older children are sparse; however, a series from Children's Hospital in Boston demonstrated that HFOV has some efficacy as a rescue therapy for pediatric patients who meet ECMO criteria.[134] In this study the high-volume strategy was used to rapidly attain and maintain optimal lung volume. A multicenter prospective randomized trial has since been completed, comparing HFOV with conventional mechanical ventilation in pediatric patients with diffuse alveolar disease or air-leak syndrome.[135] Those data showed that HFOV offered rapid and sustained improvements in oxygenation, and despite the use of higher mean airway pressures, a lower incidence of barotrauma was seen with HFOV than with conventional mechanical ventilation. However a 2009 Cochrane database analysis reported that although early observational studies and randomized studies did not show benefit of HFOV, important other changes in the practice of medicine including surfactant and inhaled nitric oxide (INO) might affect that and therefore recommended new prospective randomized controlled trials.

### Extreme Modes of Gas Exchange

***Extracorporeal Life Support*** Extracorporeal life support (ECLS) sits at the extreme end of the gas exchange spectrum. It supports or temporarily replaces the function of the heart or the lungs, or both, with an extracorporeal mechanical device. Further details and indications for its use are discussed in Chapter 8.

***Intravascular Oxygenation*** Intravascular oxygenation involves an intracorporeal gas exchange device inserted into the inferior vena cava that functions similarly to the ECLS circuit. Space constraints in the inferior vena cava limit its use to a supportive role. This is discussed in greater detail in Chapter 8.

***Extracorporeal Carbon Dioxide Removal*** Extracorporeal removal of carbon dioxide is similar to that in ECLS, but it is used when carbon dioxide elimination is the principal problem. This is discussed further in Chapter 8.

***Liquid Ventilation*** Although the ability to provide gas exchange by means of a liquid medium was first demonstrated in the laboratory almost 30 years ago, liquid ventilation did not become a reality until 1990 when the first clinical evaluations were performed in moribund premature newborn infants with respiratory distress syndrome.[136] That study was the first to demonstrate that gas exchange could be supported clinically using a liquid medium. Since then additional clinical studies have been performed to assess the safety and efficacy of liquid ventilation in adults and children.[137–140]

To date the clinical trials of liquid ventilation have used perfluorocarbons as the liquid vehicle. Perfluorocarbons are clear, colorless, odorless fluids that have low surface tension and carry a large amount of oxygen and carbon dioxide. There are currently two methods of liquid ventilation: total liquid ventilation (TLV) and partial liquid ventilation (PLV). In TLV the lungs are completely filled with perfluorocarbon to FRC. Subsequently tidal volumes of additional perfluorocarbon are administered using a device similar to the ECMO circuit. The tidal volume of perfluorocarbon must pass through an external membrane oxygenator (where gas exchange occurs) before reentering the lungs. Because of the complexity of this process, to date TLV has been performed only in laboratory investigations. PLV in contrast is quite easy to perform and very similar to standard mechanical ventilation. In PLV the lungs are filled with the perfluorocarbon liquid to FRC. Tidal volume however is provided by a standard ventilator that uses gas.[138,141] The mixing of the liquid and the gas in the conducting airways of the lung allows the transfer of gases between the two mediums. Because of its ease of use, PLV has been used exclusively for all clinical trials to date.

The mechanism by which liquid ventilation improves gas exchange is probably a combination of a direct surfactant effect of the perfluorocarbon, resulting from its low surface tension, and a lavage effect that removes exudates in the peripheral airways. These two effects result in recruitment of atelectatic lung regions and better ventilation-perfusion matching.

After the initial clinical evaluation of perfluorocarbon liquid in newborns with respiratory distress, several other uncontrolled clinical studies were done in adults and children; these studies generally demonstrated improvement in pulmonary function with liquid ventilation.[137–139]

The only prospective randomized controlled trial of PLV in children was stopped prematurely; at the termination of the study the 28-day mortality rate was not significantly different between the control group and the PLV group.[142]

# Investigational Adjuncts to Mechanical Ventilation

## PRONE POSITIONING

Placing patients with ARDS in the prone position is purported to improve oxygenation by redistributing gravity-dependent blood flow into nonatelectatic areas of nondependent lung by placing them in a dependent position. Several small series have demonstrated at least transient improvements in oxygenation,[39] whereas another failed to show significant improvements in ventilator-free days or survival. In addition this latter study noted significant complications with this technique.[143] Most recently a Cochrane database review determined that compared with the supine position, the prone position improved oxygenation, including desaturation episodes, when used for short periods or when patients were stable and in the process of weaning.[144] The value of this adjunct continues to be investigated.

## INHALED NITRIC OXIDE

Nitric oxide is a potent short-acting pulmonary vasodilator that has been in clinical trial since the early 2000s. In neonates with primary pulmonary hypertension, it has been shown to improve oxygenation and decrease the use of ECLS. However despite a transient improvement in oxygenation, it has failed to improve ventilator weaning or survival in three large trials of patients with ARDS.[145,146]

In 2010 a Cochrane database report determined that there was insufficient evidence to support the use of INO in any category of ARDS in either adult or pediatric patients.[147] Despite these findings INO continues to be used widely in the pediatric and neonatal intensive care unit.

### Pharmacologic Adjuncts in Acute Respiratory Distress Syndrome

Several pharmacologic adjuncts have been proposed for patients with ARDS, including prostaglandin E, acetylcysteine, high-dose corticosteroids, surfactant, and a variety of antioxidants. Unfortunately despite encouraging results from several small series, a recent meta-analysis of all published trials demonstrated no effect on early mortality and a greater number of adverse events in the active therapy arm in the prostaglandin, surfactant, and steroid trials.[148] Consequently none of these agents can be routinely recommended as adjunctive measures in the treatment of respiratory failure or ARDS at this time. Investigation continues.

# Management of Respiratory Failure

The management of respiratory failure and infants and children is the subject of entire textbooks. Presented here will be the briefest of overviews. Respiratory failure is defined as inadequate oxygenation leading to hypoxemia or inadequate ventilation leading to hypercarbia. The first step in treating respiratory failure is to establish an adequate airway. Usually this is accomplished using an endotracheal tube, which can be placed either orally or nasally. However recent interest in noninvasive methods of respiratory support such as continuous positive airway pressure and bilevel positive airway pressure (BiPAP) occasionally allow mild respiratory distress or failure to be treated without intubation. If appropriate these methods can be evaluated first. The approximate internal diameter of the endotracheal tube can be estimated in children older than 2 years using the following formula:

$$\frac{16 + \text{age of child}}{4}$$

Traditionally in children older than 8 years, uncuffed tubes are often used, in which case there should be an air leak present when positive pressure between 20 and 30 cm $H_2O$ is achieved. If properly cared for, these uncuffed tubes can be left in place for several weeks without fear of tracheal injury. Recently however softer cuffed tubes have become available and are used almost exclusively even in neonates in some units.

The goal of mechanical ventilation is to restore alveolar ventilation and oxygenation toward normal without causing injury from barotrauma or oxygen toxicity. In general this correlates to maintaining $Pa_{O_2}$ between 50 and 80 mm Hg, $Pa_{CO_2}$ between 40 and 60 mm Hg, pH between 7.35 and 7.45, and mixed venous oxygen saturation at less than 70%.

Initial ventilator settings on pressure-cycled ventilators should be $FiO_2$ = 100%, rate = 20 to 30 breaths per minute, PIP = 20 to 30 mm Hg, PEEP = 3 to 5 mm Hg, and inspiratory-expiratory ratio = 1:2. The aim is to provide an initial tidal volume of 6 to 8 mL/kg. PEEP should be used in cases of diffuse lung injury to support oxygenation. Support should be started at 2.0 cm $H_2O$ and adjusted in increments of 1 to 2 cm $H_2O$. PEEP greater than 10.0 cm $H_2O$ in infants and 15.0 cm $H_2O$ in older children is rarely indicated. Sedation often enhances the response to mechanical support by allowing better synchrony between patient and machine. After the patient has been stabilized for a brief period, the ventilatory management must be individualized depending on the underlying physiologic condition.

## MANIPULATING THE VENTILATOR SETTINGS

Various parameters can be preset on most ventilators, including the respiratory rate, PIP, PEEP, inspiratory time, and gas flow rate. When adjusting these parameters it is necessary to consider the pathologic condition present in the lung. Infants with primary pulmonary hypertension have very compliant lungs that are easily overdistended. In these patients adequate minute ventilation may be achieved with low PIP and PEEP, a short inspiratory time, and a moderate respiratory rate. Conversely a child with ARDS has noncompliant lungs and may require a relatively high PIP and PEEP, a short inspiratory time, and a high respiratory rate to achieve adequate alveolar ventilation. Obstructive disorders such as meconium aspiration syndrome and asthma have a longer time constant and require ventilation at a slower rate. After determining the initial settings, however, the patient's response must be evaluated and adjustments must be made to stay abreast of dynamic changes in pulmonary compliance and resistance that occur over time.

## ADJUSTING THE PARTIAL PRESSURE OF CARBON DIOXIDE

The $PaCO_2$ is directly related to alveolar ventilation and consequently to minute ventilation (tidal volume × respiratory rate). An increase in minute ventilation can be achieved by adjusting either tidal volume or more frequently respiratory rate. However at high rates or in lungs with prolonged time constants, increases in respiratory rate can lead to breath stacking, overdistention, reduced alveolar ventilation, and a subsequent rise in $PCO_2$.

## ADJUSTING THE PARTIAL PRESSURE OF OXYGEN

In most conditions requiring mechanical ventilation, patchy atelectasis, caused by a drop in FRC toward closing capacity, results in a significant intrapulmonary shunt that is relatively insensitive to increases in $FiO_2$. Recruitment of the atelectatic areas by increasing the mean airway pressure is far more likely to be effective in increasing $PaO_2$. This can be achieved by increasing PIP, PEEP, or the inspiratory-expiratory ratio. High PIP has been shown to cause barotrauma, most likely as a result of overdistention of the more compliant (i.e., healthier) portions of the lung.[50] Consequently increases in PIP should be used sparingly. An increased PEEP is generally preferable to an increased PIP because the PEEP can recruit collapsed alveoli (by increasing FRC) thereby decreasing the intrapulmonary shunt without significant risk of barotrauma. However if a pressure-cycled ventilator is used, increases in PEEP without changes in PIP will result in a lower tidal volume and require adjustments in respiratory rate to maintain minute ventilation. Monitoring compliance also ensures that breaths are provided at the most compliant part of the ventilation curve.

## WEANING

Weaning is the process during which mechanical ventilation is slowly withdrawn, allowing the patient to assume an increasing amount of the work of breathing. The specific technique of weaning depends on which form of ventilation is being used. Weaning from mechanical ventilation should be attempted only when the patient is hemodynamically stable on acceptable ventilator settings and is able to spontaneously maintain an acceptable $PaCO_2$. In general this translates into an $FiO_2$ less than 0.4, PIP less than 30, PEEP less than 5, and ventilator-assisted breaths less than 15 per minute. The child should also have adequate nutrition and a ratio of dead space gas/tidal volume of less than 0.6 (normal = 0.3).

Weaning from IMV support involves a gradual decrease in the frequency of ventilator-delivered breaths. The rate of weaning depends on the patient's clinical condition and response. Monitoring the patient's spontaneous respiratory efforts and blood gas parameters can assist in this process. In older patients the IMV rate can be reduced to as low as 2 to 4 breaths per minute before the patient is extubated. Because of higher airway resistance in the smaller endotracheal tubes used in younger patients, extubation is generally attempted when the rate is reduced to 8 to 10 breaths per minute.

Weaning from PSV involves a slow decrease in the level of pressure support while monitoring the quality and quantity of the patient's spontaneous respiratory effort. In general this type of ventilation is withdrawn by reducing the pressure in increments of 1 to 2 cm $H_2O$.

## WEANING FAILURE

Despite multiple indicators that predict successful weaning, 10% of patients will fail extubation. In most cases this failure is due to excessive respiratory load. This is manifested clinically as the development of rapid shallow breathing, worsening of lung mechanics, and increase in respiratory muscle load.[149,150] Factors that contribute to this are increased ratio of dead space gas/tidal volume, which accompanies the onset of rapid, shallow breathing; excessive carbon dioxide production caused by increased work of breathing; and, sometimes, excessive carbohydrate calories. Respiratory muscle fatigue due to increased respiratory load can cause prolonged (>24 hours) impairment in diaphragmatic and respiratory muscle function.[151] Consequently time must be allowed for recovery before attempting to wean again. Metabolic abnormalities such as acute respiratory acidosis decrease the contractility and endurance of the diaphragm.[152] Imbalances in phosphate, calcium, potassium, and magnesium also impair respiratory muscle function[153–155] as does

hypothyroidism.[156] Correction of these variables toward normal ensures that the patient's best effort is being evaluated.

## Complications of Mechanical Ventilation

Barotrauma is the principal complication of mechanical ventilation. It is caused by overdistention of alveoli by inappropriately high PIP or PEEP or excessive tidal volumes. The consequences of barotrauma include pneumothorax, pneumomediastinum, and pulmonary interstitial emphysema.[157] In addition, because barotrauma seems to be more closely related to volume changes than to pressure changes, the incidence and severity of barotrauma can potentially be lowered by the use of lower tidal volumes (5 to 7 mL/kg) and by accepting a lower pH and a higher $P_{CO_2}$—a ventilatory technique known as permissive hypercapnea.[158]

Oxygen toxicity is another complication of mechanical ventilation. The mechanism of injury is purported to be damage to the capillary endothelium, as well as type I and type II pneumocytes, from oxygen free radicals.[159] Every attempt should be made to maintain the $F_{IO_2}$ at less than 0.6 by adjusting mean airway pressure to improve intrapulmonary shunting and by accepting marginal levels of $P_{O_2}$ (50 to 60 mm Hg) as long as $S_{VO_2}$ remains adequate.

Bronchopulmonary dysplasia is a progressive chronic condition that may occur in 15% of infants who require mechanical ventilation. It is unclear whether the cause of this dysplasia is related to barotrauma or oxygen toxicity, or both. Consequently bronchopulmonary dysplasia can best be avoided by paying careful attention to providing adequate ventilatory support at the lowest possible pressures and oxygen concentration.

These complications are all a direct consequence of positive-pressure inflation of an organ designed to function in a negative-pressure environment. Consequently it is unlikely that any current or future variation of positive-pressure ventilation will ever be completely safe.

Other common complications not directly related to the mechanics of ventilation itself include nosocomial pneumonia acquired because of the ubiquitous nature of pathogens in the intensive care unit and breach of upper airway defenses by the endotracheal tube. Deep vein thrombosis and pulmonary emboli are not uncommon in older pediatric patients, and these patients should receive prophylaxis. Laryngeal trauma during intubation, tracheal stenosis caused by ill-fitting tubes and prolonged intubation, and sinusitis principally associated with nasal intubation round out the list of the more common complications. Most can be avoided or treated by careful attention to detail.

# CHAPTER 8

# Extracorporeal Life Support for Cardiopulmonary Failure

Ronald B. Hirschl and Robert H. Bartlett

Extracorporeal life support (ECLS) or extracorporeal membrane oxygenation (ECMO) denotes the use of prolonged extracorporeal cardiopulmonary bypass, usually through extrathoracic cannulation, in patients with acute reversible cardiac or respiratory failure who are unresponsive to conventional medical or pharmacologic management.[1,2] It is important to recognize that ECLS is not a therapeutic intervention; it simply provides cardiopulmonary support so that the patient is spared the deleterious effects of high airway pressure, high oxygen fraction in inspired air ($FiO_2$), vasoactive drugs, and perfusion impairment while reversible pathophysiologic processes are allowed to resolve either spontaneously or by medical or surgical intervention. The technology of ECLS is similar for all applications, but the indications, management, and results are best considered separately for adults, children, and neonates with either respiratory or cardiac failure. This chapter is limited to neonates and children with respiratory or cardiac failure.

In 1989 the active ECLS centers formed the Extracorporeal Life Support Organization (ELSO), which standardized many aspects of ECLS. ELSO maintains a registry of all cases treated by the member centers. Much of the information provided here is based on reports from the ELSO Registry.[3] As of January 2011 the ELSO Registry database reported 44,824 adult, pediatric, and newborn patients with cardiorespiratory failure who were supported with ECLS, with an overall 62% survival rate.[3,4]

## Background

ECLS was first successfully applied in a newborn with respiratory failure in 1975.[5] By 1982 it had been used in 45 premature and full-term newborns with respiratory failure, demonstrating a survival of 55% and short-term normal growth and development in 80% of the survivors.[5–7] Three prospective, randomized trials compared the effectiveness of ECLS with that of conventional mechanical ventilation in full-term newborns with severe respiratory insufficiency. In 1985 our group used an adaptive design known as "play-the-winner," which weighted randomization toward the successful and away from the unsuccessful intervention.[8] The randomization scheme resulted in 11 patients who received ECLS and survived and 1 control patient who died. Although statistically significant in view of the 80% to 90% predicted mortality among the enrolled patients, this study was highly controversial and was not well accepted by the medical community. In 1989 O'Rourke and colleagues[9] conducted a randomized trial using a similar adaptive design. Survival in the control group was 6 of 10 patients (60%) and in the ECLS group 28 of 29 (97%) patients survived. A traditional randomized prospective study was performed in the United Kingdom that demonstrated a significant difference in survival between full-term newborns managed with ECLS (72%) and those managed by conventional means (41%).[10] Based on these studies ECLS is considered to be indicated in neonatal respiratory failure whenever the risk of mortality is high.[11] As of the beginning of 2011, 24,344 newborns had been managed with ECLS with a 75% survival rate.[3,12] Interestingly, the rate of use of ECLS in neonates has markedly decreased over the past two decades as newer ventilatory strategies have been developed and applied.

Timmons and associates[13] conducted a multicenter data collection study of pediatric respiratory failure in 1991. The only treatment variable that correlated with improved outcome was ECLS. This large database was further evaluated by Green and colleagues.[14] They did a matched-pair study of patients who were managed with ECLS (74% survival) compared with those managed by conventional means (53% survival). As of January 2011 there were 4771 cases of respiratory failure in children more than 30 days old in the registry, with an overall survival of 56%.

ECLS has been used successfully for pediatric cardiac failure since 1972. Intraoperative or postoperative cardiac failure is the most common indication, although preoperative use of ECLS is effective as a bridge to surgical palliation or anatomic repair.[15] In the past ECLS was the only mechanical support system available to support cardiac failure in children, but now ventricular assist devices such as the Berlin Heart (Berlin Heart AG, Berlin, Germany) are available, increasing in use, and may be associated with enhanced outcome.[16–18] The ELSO Registry documents 9453 cases of cardiac failure in newborns and children with an overall survival of 44%.

## Indications

ECLS is indicated for acute severe respiratory or cardiac failure when recovery can be expected within 2 to 4 weeks. Severe cardiac or respiratory failure can be defined as any acute failure in which the mortality risk is greater than 50%; survival ranges from 50% to 90% in different categories of patients. In some cases the risk is easy to identify (e.g., cardiac arrest or inability to be removed from cardiopulmonary bypass in the operating room). In other cases it is more difficult to quantitate (e.g., a neonate with borderline oxygenation receiving 80% oxygen on moderate ventilatory settings with nitric oxide). Some scoring systems have been devised in these categories of patients to try to define high mortality risk:

1. Mortality risk in neonatal respiratory failure can be measured by an oxygen index (OI) that is based on arterial oxygenation ($PaO_2$) and mean airway pressure (MAP) despite and after all appropriate treatment. It is computed according to the following formula:

$$OI = (MAP \times FiO_2 \times 100)/PaO_2$$

2. In the early ECLS studies an OI greater than 40 in three of five postductal arterial blood gas measurements (each drawn 30 to 60 minutes apart) was predictive of a mortality rate greater than 80%.[19,20] A randomized controlled study performed by our group suggested that "early" initiation of ECLS based on an OI greater than 25, which is predictive of a 50% mortality rate, is associated with a trend toward higher mental developmental scores and a lower incidence of morbidity at 1 year of age when compared with a control group of patients in whom ECLS was initiated at an OI greater than 40.[21] We currently consider institution of ECLS when a series of postductal arterial blood gas measurements demonstrates an OI greater than 25, with mandatory application of ECLS when the OI is greater than 40.
3. Criteria for high mortality risk among older children with respiratory failure are based on the OI or alveolar-arterial oxygen ($PAO_2 - PaO_2$) gradient. Rivera and associates[22] suggest that a ventilation index (respiratory rate $\times$ $PaCO_2$ $\times$ peak inspiratory pressure/1000) greater than 40 and an OI greater than 40 are associated with a mortality rate of 77%, and a combination of peak inspiratory pressure of 40 cm $H_2O$ or greater and an $AaDO_2$ greater than 580 mm Hg are associated with a mortality of 81%. We consider $PAO_2 - PaO_2$ greater than 600 on $FiO_2$ 1.0—despite and after optimal treatment—an indication of high mortality risk in children.
4. Criteria for the initiation of ECLS in pediatric patients with cardiac failure include clinical signs of decreased peripheral perfusion, including oliguria (urine output <0.5 mL/kg per hour), metabolic acidosis, and hypotension despite the administration of inotropic agents and volume resuscitation.[23,24] ECLS is applied in pediatric cardiac patients in the setting of cardiogenic shock (20%), cardiac arrest (20%), and acute deterioration (10%); an additional 20% of patients are placed on ECLS directly in the operating room because of an inability to be weaned from heart-lung bypass.

Current relative contraindications for ECLS are as follows:

1. Prematurity. The lower limit for newborns is 1.5 kg and 30 weeks' gestational age because of a higher incidence of intracranial bleeding in smaller, younger infants.[25,26]
2. Pre-ECMO intracranial hemorrhage higher than grade 2.[27]
3. Prolonged mechanical ventilation. Mechanical ventilation for longer than 7 days in newborn and pediatric patients has been considered a contraindication to ECLS because of the high incidence of bronchopulmonary dysplasia and irreversible fibroproliferative pulmonary disease. However reviews of the ELSO Registry data suggest that the survival rate remains at approximately 50% to 60% after 14 days of pre-ECLS mechanical ventilation in neonatal and pediatric patients with respiratory failure.[28] We currently consider ECLS in any patient who has received mechanical ventilation for up to 14 days, keeping in mind that morbidity and mortality increase with time on the ventilator.
4. Cardiac arrest that requires cardiopulmonary resuscitation in the pre-ECLS period. This has been considered a contraindication to the institution of extracorporeal support. However survival rates of up to 60% have been observed among neonates who suffer cardiac arrest before or during cannulation.[12,29] Of those who survive at least 60% have a reasonable neurologic outcome. Similar survival rates (64%) without long-term sequelae were noted among pediatric patients with cardiac failure who endured cardiac arrest for 65 ± 9 minutes before the institution of ECLS.[30] Based on these data many centers now consider patients who sustain pre-ECLS cardiac arrest to be candidates for extracorporeal support.
5. Congenital diaphragmatic hernia (CDH) with severe pulmonary hypoplasia. Although CDH with severe pulmonary hypoplasia was originally a contraindication to ECLS,[31,32] it was subsequently demonstrated that a number of patients who met this exclusion criteria survived. Thus most centers now consider any patient with CDH a candidate for ECLS.[33–35] Other centers suggest that failure to generate a best preductal $PaO_2$ greater than 100 mm Hg and a $PaCO_2$ less than 50 mm Hg accurately identifies nonsalvageable newborns with CDH who should be excluded from ECLS.
6. Profound neurologic impairment, multiple congenital anomalies, or other conditions not compatible with meaningful life.

Additional relative contraindications for older children include the following:

1. Multiorgan system failure: In general organ system failure other than cardiac, pulmonary, and renal failure, which can be effectively supported with ECLS, are considered contraindications.
2. Major burns: Although thermal injury was previously considered a contraindication, ECLS has been applied in pediatric burn patients (mean of 46% of total body surface area burned), with survival in three of five patients.[36,37]
3. Immunodeficiency: Conditions associated with compromise of the immune system in the past have been considered contraindications to ECLS. Data from the ELSO Registry suggest however that survival is 31% with ECLS in pediatric patients with a diagnosis associated with immunocompromise although specific diagnoses such as bone marrow transplantation carry a poor outcome.[38]
4. Active bleeding.
5. An incurable disease process.

## Methods of Extracorporeal Support

The goal of ECLS is to perfuse warmed arterialized blood into the patient.[1] To achieve this goal the extracorporeal blood flow is used most commonly in venoarterial (VA) mode for cardiac support and venovenous (VV) mode for respiratory support. VA mode provides complete support, but there are significant disadvantages: (1) a major artery must be cannulated and at least temporarily sacrificed, (2) the risk of dissemination of particulate or gaseous emboli into the systemic circulation is substantial, (3) pulmonary perfusion may be markedly reduced, (4) left ventricular output may be compromised owing to the presence of increased ECLS circuit-induced afterload resistance, and (5) the coronary arteries are perfused predominantly by the relatively hypoxic left ventricular blood.[37] VV access, either by two vessels or by a single vessel through a double-lumen catheter, supports gas exchange without the disadvantages of VA support. VV or double-lumen VV ECLS is now the preferred method for patients of all age groups who do not require cardiac support (Fig. 8-1).[39] Data from the ELSO Registry and a nonrandomized multicenter study suggest that bypass performed with the double-lumen VV configuration may increase the survival rate and reduce the incidence of intracranial hemorrhage in neonates.[40] However a matched-pairs analysis that corrected for pre-ECLS severity of cardiopulmonary dysfunction revealed no difference in either parameter between patients undergoing bypass with a double-lumen VV or a VA configuration.[32] Femoral and jugular cannulation is used for most children, although recent availability of the Avalon double-lumen cannulas (Avalon Laboratories, LLC, Rancho Dominguez, Calif.) from 13 to 31 French has broadened the use of double-lumen VV ECLS.

Arteriovenous support, typically through cannulation of the femoral artery and vein, is being applied for arteriovenous carbon dioxide removal (AVCO2R). This technique has been shown to be reduce $Pa{CO_2}$ and ventilatory requirements in adults with acute respiratory distress syndrome (ARDS) and children with asthma.[41,42]

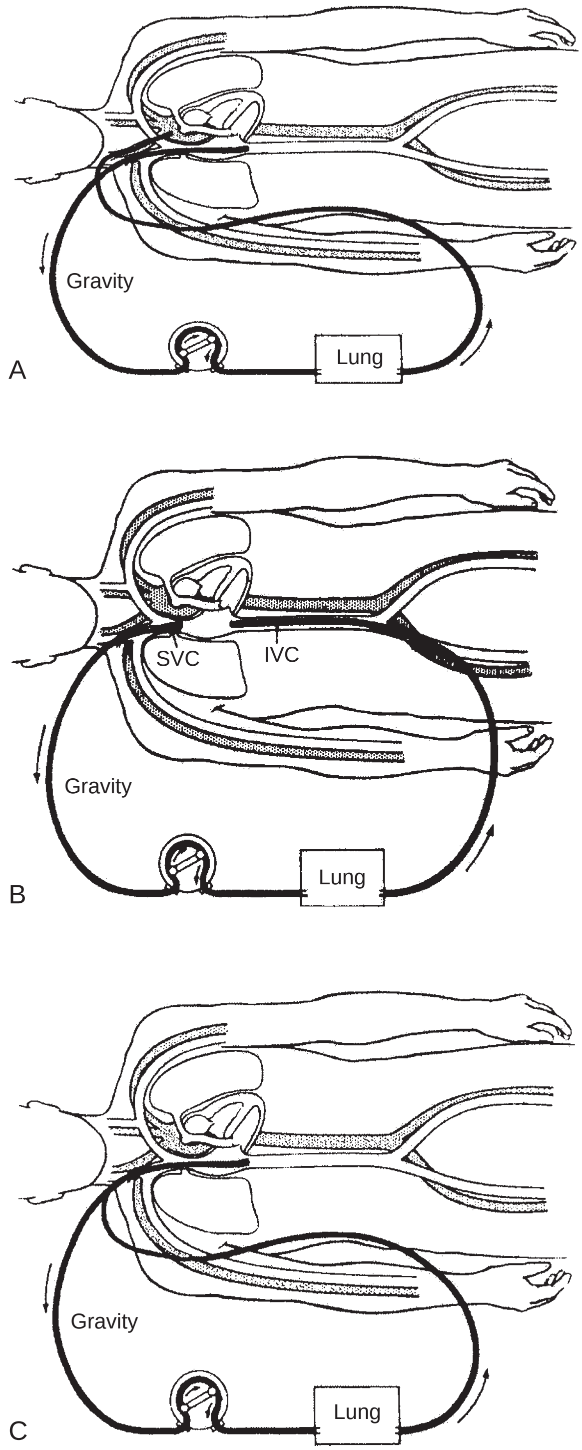

**FIGURE 8-1** Three most common extracorporeal bypass configurations. **A,** Venoarterial configuration with drainage from the internal jugular vein and reinfusion into the carotid artery. **B,** Venovenous configuration with drainage from the internal jugular vein and reinfusion into the femoral vein. **C,** Venovenous configuration with a double-lumen cannula placed into the internal jugular vein. IVC, inferior vena cava; SVC, superior vena cava.

## Extracorporeal Life Support Circuit

The ECLS circuit comprises a pump, a membrane lung, and a heat exchanger (Fig. 8-2), as well as other devices associated with safety and monitoring functions. A full description of the technology, including device function and malfunction, is published in the ELSO's textbook.[43] Right atrial blood is drained by gravity siphon by a cannula placed through the right internal jugular or right femoral vein. Roller pumps are the most common perfusion devices used and require continuous servoregulation and monitoring to prevent the application of high levels of negative pressure to the drainage circuit and high levels of positive pressure, with a risk of circuit disruption, to the infusion limb of the circuit if occlusion occurs.[44] Application of high negative pressures to the drainage circuit (e.g., with a centrifugal pump) results in hemolysis, damage to the endothelium of the right atrium or vena cava, and cavitation as air is drawn out of solution.

The artificial lung most commonly used is the Kolobow spiral coil (Medtronic, Minneapolis, Minn.) solid silicone

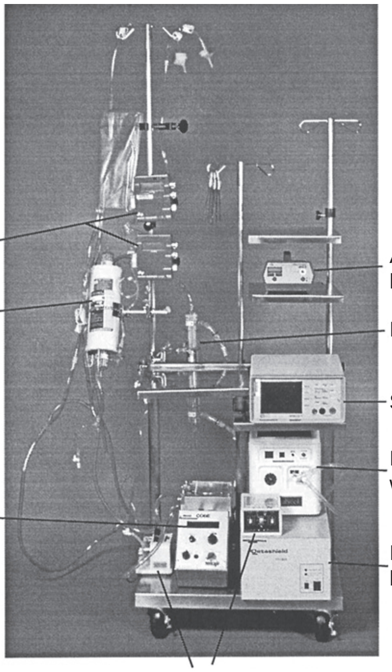

**FIGURE 8-2** Extracorporeal life support circuit. The essential components include the roller pump, the membrane lung, and the heat exchanger. The remainder of the devices shown perform monitoring and safety functions.

rubber membrane lung.[45] The size of the various ECLS components required as a function of patient weight is shown in Table 8-1. Hollow-fiber artificial lungs made of microporous materials are highly efficient with regard to gas exchange, have low resistance to blood flow, and are easy to prime. The disadvantage of the microporous membrane is the increased rate of condensation of water in the gas phase and the frequent need for replacement owing to the development of plasma leak.[46] Phospholipid adsorption onto the blood surface of the hollow fiber at the site of 5-μm pores is the mechanism by which the plasma leak occurs.[46] Artificial lungs with hollow fibers that do not have pores resolve this problem and are preferred for ECLS. These devices have been used in Europe and Japan but are not available in the United States. Plasma leak is retarded in artificial lungs that use polymethylpentene fibers; such artificial lungs are being used more frequently in the United States and other parts of the world.[44]

The volume of the neonatal circuit is approximately 400 to 500 mL, which is one to two times the newborn blood volume. The circuit must therefore be primed carefully to perfuse the neonate at the onset of bypass with blood containing the appropriate pH, hematocrit, calcium, clotting factors, and electrolytes and at the appropriate temperature. However, as shown in Table 8-1, ECLS may be instituted in patients weighing more than 35 kg without the addition of blood to the priming solution.

## Patient Management

Patient management is described in detail in the ELSO textbook.[43] The size of the venous cannula is the factor that determines the blood flow rate and therefore the level of extracorporeal support. The largest possible venous access cannula should be used; it should be of sufficient size to provide adequate blood flow (∼100 mL/kg per minute) with the assistance of 100-cm $H_2O$ gravity siphon pressure. The flow-pressure characteristics of a given cannula are determined by a number of geometric factors, including length, internal diameter, and side hole placement. The M number provides a standardized means for describing the flow-pressure relationships in a variety of vascular access devices.[47,48]

The first choice for venous access is the internal jugular vein because it is large and provides easy access to the right atrium through a short cannula. The femoral vein is the second choice for venous drainage access during ECLS and the first choice for drainage during VV support. In children younger than 5 years, the femoral vein is too small to function as the primary drainage site, and VV access is used in a jugular-to-femoral fashion or using a double-lumen VV cannula in young children. A proximal venous drainage cannula can be placed in the proximal internal jugular vein to enhance venous

drainage to the extracorporeal circuit.[49] One study demonstrated a reduction in intracranial hemorrhage after initiation of the use of such a cannula when compared with historical controls.[50] An ELSO Registry study however failed to demonstrate an effect on intracranial hemorrhage or survival during routine use of a proximal venous drainage cannula. (F. L. Fazzalari, R. B. Hirschl, T. Delosh, R. H. Bartlett, oral communication, 1994).

The size of the reinfusion cannula is less critical than that of the venous drainage cannula, although it must be large enough to tolerate the predicted blood flow rate at levels of total support without generating a pressure greater than 350 mm Hg proximal to the membrane lung. When only respiratory support is required, the reinfusion cannula may be placed into the femoral vein to provide VV support. Rich and associates[52] demonstrated advantages in terms of reduced blood recirculation and overall oxygenation when the femoral cannula was used for drainage and the internal jugular cannula was used for reinfusion. When cardiovascular support is required, the first choice for placement of a cannula into the arterial circulation is the carotid artery in all age groups because it provides easy access to the aortic arch. Few complications have been associated with carotid artery cannulation and ligation in newborns and children.[53,54] The second choice for arterial access is the femoral artery. Distal perfusion of the lower extremity arterial circulation may be required when the femoral artery is cannulated and may be achieved through antegrade perfusion of the common femoral artery or retrograde perfusion of the posterior tibial artery.[55] However arch perfusion and oxygenation, and therefore heart and brain circulation, are poorly achieved with femoral artery reinfusion. This may be overcome and carotid artery cannulation-ligation avoided using the technique of venoarterial-venous (VAV) ECLS in which a drainage cannula is placed into the femoral vein and reinfusion cannulas into the femoral artery and internal jugular vein. Reinfusion into the femoral artery is limited to that required to maintain blood pressure, thus allowing a substantial portion of arterialized blood to reinfuse through the internal jugular vein, providing oxygenation of the blood perfusing the aortic arch.

The cannulation procedure is usually performed by direct cutdown using local anesthesia (Fig. 8-3). The tips of the arterial and venous cannulas (see Table 8-1 for sizes) are optimally located at the opening of the right brachiocephalic artery and the inferior aspect of the right atrium, respectively. The double-lumen VV cannula must be placed so that the tip is in the midright atrium, with the reinfusion ports oriented toward the tricuspid valve to minimize recirculation of reinfused blood. Percutaneous access to the internal jugular and femoral veins is the routine and preferred approach to cannulation in adults and children older than 3 years. Sequentially larger dilators are placed over a wire, and a Seldinger technique allows final access of the cannula itself into these large veins. A 12 or 15 French double-lumen VV cannula is amenable to percutaneous introduction into the internal jugular vein in neonates. The Avalon cannula can be placed by a percutaneous approach in patients of all ages. This cannula has distal and proximal drainage ports with a midcannula reinfusion lumen. As such the cannula design is intended for placement of the distal tip into the inferior vena cava with the reinfusion lumen opening positioned at the level of the tricuspid valve.

The cannulas are connected to the ECLS circuit and cardiopulmonary bypass is initiated. Flow is increased over the ensuing 10 to 15 minutes to levels of approximately 100 mL/kg. Once a patient is receiving extracorporeal support there is typically rapid cardiopulmonary stabilization. All paralyzing agents, vasoactive drugs, and other infusions are discontinued during VA support; some pressor or inotropic support may be necessary when VV bypass is used.[39] Ventilator settings are adjusted to minimal levels (peak inspiratory pressure <25 and $F_{IO_2}$ <0.4) to allow the lung to rest and any air leaks secondary to barotrauma to seal.[1] Application of positive end-expiratory pressure in the range of 12 to 14 cm $H_2O$ during the course on extracorporeal support has been demonstrated to decrease the duration of ECLS from 132 ± 55 hours to 97 ± 36 hours.[56] Because only partial bypass is used, oxygenation and carbon dioxide elimination are determined by a combination of native pulmonary function and extracorporeal flow. The mixed venous oxygen saturation ($S_{VO_2}$) is conveniently monitored by a fiberoptic Oximetrix catheter placed in the venous limb of the circuit, which allows one to determine the adequacy of oxygen delivery in relation to oxygen consumption, especially during VA ECLS. Pump flow is adjusted to maintain oxygen delivery so that the $S_{VO_2}$ is greater than 70% during VA support and, because of the effects of reinfusion into the venous system, greater than 85% during VV support. The $Pa_{CO_2}$ is inversely proportional to the flow rate of gas ventilating the membrane lung.

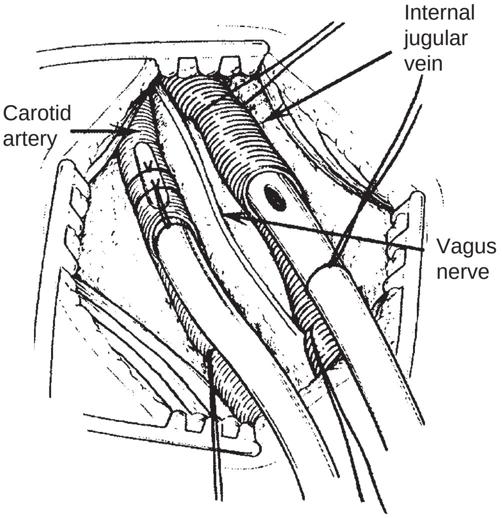

**FIGURE 8-3** Cannulation for venoarterial extracorporeal support. The transverse right supraclavicular incision is shown. In neonates the cannulas are placed 2.5 cm into the artery and 6.0 cm into the vein. They are secured using two circumferential 2-0 silk ligatures with a small piece of plastic vessel loop placed underneath to protect the vessels from injury during decannulation. One of the ends of the marking ligature is tied to the most distal circumferential suture for extra security.

## Cannulation for Cardiac Support

Deterioration in myocardial function is observed in approximately 7% of neonates after initiation of ECLS.[57–59] This "myocardial stun" usually occurs in patients with exaggerated levels of hypoxia, with more frequent episodes of cardiac arrest, and who required more frequent epinephrine pressor

support before ECLS. It typically resolves over the first 24 to 48 hours after initiation of ECLS.

If the left ventricle does not eject (no arterial pulse contour), the left ventricle and atrium will distend and cause pulmonary edema. If this occurs balloon or blade atrial septostomy may be required to decompress the left oximetry and allow the resolution of pulmonary edema and eventual improvement in cardiac function.[60]

Heparin is titrated to prevent thrombus formation throughout the course of ECLS. The level of anticoagulation is monitored hourly by the whole-blood activated clotting time (ACT).[1,2] The ACT is maintained at 50% to 60% above normal (180–220 seconds for the Hemochron device [ITC, Edison, NJ]).[61] Transfusion of red blood cells to maintain the hematocrit at greater than 45% and fresh frozen plasma to maintain the fibrinogen levels at greater than 200 mg/dL are frequently required. Platelets are transfused to maintain the platelet count at greater than 100,000/mm$^3$, although the decrease in platelet function and count associated with extracorporeal support appears to be only transiently corrected by platelet administration.[62] Stallion and colleagues[63] suggested that maintaining the platelet count at greater than 200,000/mm$^3$ appears to be associated with a decrease in bleeding complications. We continue to maintain the platelet count at greater than 100,000/mm$^3$, except in patients who are at high risk for or have ongoing hemorrhage, in which case the platelet count is maintained at greater than 150,000/mm$^3$.

Diuresis or hemofiltration is titrated to normal “dry” weight. Renal function may be transiently impaired during ECLS; therefore use of a hemofilter placed in the circuit to supplement urine output may be necessary in some patients.[64,65] Routine use of a hemofilter may reduce time on ECLS and mechanical ventilation.[66] Renal insufficiency that develops before or during ECLS can also be easily managed by a hemofilter or continuous renal replacement therapy placed in the extracorporeal circuit as necessary.[67] Nutrition remains a high priority in a critically ill patient requiring ECLS.

Most operative procedures performed during ECLS are carried out in the intensive care unit, although as comfort with ECMO transport increases, travel to the operating or cardiac catheterization suite is becoming more routine.[68] Either isoflurane gas anesthesia administered through the oxygenator of the ECLS circuit or intravenous anesthesia with fentanyl or sufentanil and vecuronium may be used. Nagaraj and associates[69] described 44 procedures performed in 37 neonates receiving ECLS. These procedures consisted of recannulation or repositioning of cannulas (14), tube thoracostomy (11), cardiac surgery (6), cardiac catheterization (4), repair of CDH (5), and thoracotomy (4). Hemorrhagic complications, which occurred in 46% to 55% of patients, were associated with a higher mortality. Therefore one should strongly consider whether the procedure is necessary (e.g., placement of thoracostomy tubes for small pneumothoraces) or whether the operation can be delayed until ECLS is discontinued. During procedures performed while the patient is receiving ECLS, electrocautery should be used generously, the ACT reduced to a maximum of 160 to 180 seconds, and the platelet count maintained at greater than 150,000/mm$^3$. One should also consider perioperative administration of aminocaproic acid (Amicar).[70]

Repair of CDH can be done before, during, or after ECLS. Practice changed when we realized that pulmonary dysfunction is caused by hypoplasia and vasospasm and not the hernia. Connors and colleagues[71] first described the repair of CDH in six newborns at a mean of 25 hours after initiation of ECLS, with four survivors. Lally and coworkers[72] reported a 43% survival rate among 42 newborns undergoing diaphragmatic hernia repair while receiving extracorporeal support. Vazquez and Cheu[73] reported that up to 48% of patients with CDH who require ECLS undergo repair while receiving extracorporeal support. Other studies suggest that operative repair in a newborn with CDH can be performed after discontinuation of ECLS, continued resolution of pulmonary hypertension, and ventilator weaning. Based on data from the ELSO Registry, Vazquez and Cheu[73] demonstrated that surgical hemorrhage requiring transfusion occurred in 38% of CDH repaired while the patient was receiving ECLS versus 18% and 6% of those repaired before and after, respectively. Wilson and coworkers[70,74] observed a reduction in blood loss and transfusion requirement in a group of 22 patients receiving ECLS in whom repair was performed electively before decannulation. In these patients the ACT was maintained at the 180- to 200-second level, and aminocaproic acid was administered continuously for 72 hours postoperatively or until decannulation in all patients. Reexploration for hemorrhage was not required.[75] Bryner and associates[75] suggested that survival is enhanced when repair is performed following discontinuation of ECLS. In general our current practice is to repair the hernia after weaning the patient from ECLS, although there is a trend across the United States toward early repair while the patient is receiving ECLS.

When pulmonary function improves, ECLS flow is decreased, leading to a “trial off” (without ECLS). During VV bypass, the gas phase of the membrane lung can simply be capped indefinitely so that the patient remains on extracorporeal blood flow but without the artificial lung’s contribution to gas exchange. Patients receiving VA bypass are tested by clamping the lines (no flow). Such trials are performed on a daily basis when cardiopulmonary physiology suggests improvement with optimal pressor support and are frequently accompanied by echocardiographic evaluation in patients with cardiopulmonary compromise.

Once it has been determined that ECLS can be discontinued, the cannulation site incisions are opened and the right carotid artery or internal jugular vein, or both, are ligated. The carotid artery can be repaired after a course of VA extracorporeal support, although there is no proven benefit and there is the potential risk of distal embolism, late stenosis or thrombosis, and development of atherosclerosis.[14,49,76,77] The internal jugular vein can be repaired as well, especially in patients with congenital heart disease who will require future percutaneous access.[78] A central line or Broviac catheter may be placed into the vein during decannulation with a surprisingly low risk of infection.[79] Percutaneously placed cannulas can simply be removed and pressure applied without concern about the patient’s anticoagulation status. The femoral artery, if used, is repaired and the femoral vein is ligated.

The duration of ECLS (mean ± standard deviation) is 170 ± 126 hours for neonates with respiratory failure, 260 ± 224 hours for children with respiratory failure, and 151 ± 140 hours for patients with heart failure. Reasons to discontinue extracorporeal support other than when indicated by improvement of cardiopulmonary function include the presence of irreversible brain damage, other lethal organ failure, and uncontrollable bleeding. Neonates with CDH or pneumonia

and pediatric patients with cardiac or pulmonary failure may require substantially longer periods on ECLS before resolution of the cardiopulmonary process is observed. On occasion a second course of ECLS is required and results in survival rates of 44% in children.[80]

## Complications

In general the complications associated with ECLS fall into one of three major categories: (1) bleeding associated with heparinization, (2) technical failure, and (3) neurologic sequelae, a majority of which are secondary to the hypoxia and hemodynamic instability that occur before the onset of extracorporeal support.

The average number of patient complications per ECLS case is 2.1.[81] Because of systemic heparinization, bleeding complications are the most common and devastating.[82] Intracranial hemorrhage occurs in approximately 13% of neonates, 5% of pediatric patients, and 4% of cardiac patients. It is the most frequent cause of death in newborns managed with ECLS.[83] Because of the associated heparinization, intracranial hemorrhage may be unusual in terms of both extent and location.[84,85] The mechanism by which it occurs in newborns receiving ECLS is multifactorial. In addition to heparin administration, platelet function and number are decreased for up to 48 hours after discontinuation of ECLS, as are coagulation factor levels.[86] Wilson and colleagues[77] noted a reduction in the incidence of intracranial hemorrhage, compared with historical controls, among a cohort of 42 newborns considered to be at high risk for bleeding complications who received 100 mg/kg of aminocaproic acid just before or after cannulation, followed by a continuous infusion of 30 mg/kg per hour until decannulation. The incidence of intracranial hemorrhage is clearly increased in patients who are premature, especially those less than 37 weeks' gestational age. Although carotid ligation and institution of ECLS in normal animals do not affect carotid artery or cerebral blood flow, initiation of ECLS in the setting of hypoxia results in augmentation of carotid artery and cerebral blood flow and loss of cerebral autoregulation.[87] In addition, decreases in $Pa{CO_2}$ result in marked decreases in cerebral blood flow.[88] Therefore carotid artery and internal jugular vein ligation along with rapid institution of ECLS in the setting of hypoxia or hypercarbia may result in alterations in cerebral blood flow and cerebral autoregulation, with the potential induction of intracranial hemorrhage in a patient who has undergone anticoagulation.

Bleeding at extracranial sites is observed in 21% of neonatal patients, 44% of pediatric respiratory patients, and 40% of neonatal and pediatric cardiac patients. These sites of bleeding include gastrointestinal hemorrhage (2% to 5%), cannulation site bleeding (up to 6%), bleeding at another surgical site (neonatal respiratory patients, 6%; pediatric respiratory patients, 24%, neonatal and pediatric cardiac patients, 28%), and a miscellaneous group of bleeding sites, including pericardial, intrathoracic, and retroperitoneal (7% to 15%). Bleeding during ECLS is managed by maintaining the platelet count at greater than 150,000/mm$^3$ and decreasing the ACT to a maximum of 160 to 180 seconds. Occasionally discontinuation of heparin or, if tolerated, temporary discontinuation of bypass with normalization of the coagulation status may be necessary to achieve resolution of the bleeding.[89] If hemorrhage persists, aggressive surgical intervention is indicated. Administration of recombinant factor seven may be effective when nonsurgical bleeding is present, although thrombotic complications, including development of ECLS circuit or systemic arterial clots, is a concern.[90–94] We have found that intra-abdominal or intrathoracic packing with planned daily reexploration allows control of hemorrhage in most situations. Only in extreme circumstances should permanent discontinuation of bypass be considered in a patient with persistent cardiopulmonary failure. Heparin-induced thrombocytopenia occurs occasionally and argatroban or lepirudin may be used to provide systemic anticoagulation.[95,96]

Neurologic injury induced either before or after the onset of ECLS is a constant concern. Many neonates must endure the insult of hypoxia or ischemia before the institution of bypass and it has been suggested that ligation of the carotid artery in the minutes before the onset of ECLS, at a time when hypoxemia and hemodynamic instability are maximized, results in a further decrease in cerebral tissue oxygenation, which in turn might exacerbate the neurologic injury.[97] However Streletz and colleagues[98] noted no increase in the electroencephalographic abnormalities present before and during ECLS among 145 neonates. In addition Walsh-Sukys and associates[99] in a prospective evaluation of 26 neonates managed with conventional mechanical ventilation and 43 neonates managed with ECLS, noted a similar 25% rate of neurodevelopmental impairment in both groups at 8 to 20 months of age. The incidence of any neurodevelopmental impairment at 1 year of age was 28% among survivors of both groups in the United Kingdom neonatal randomized study.[10]

Seizures have been noted in 10% to 13% of patients undergoing ECLS.[100] The presence of seizures in newborns during ECLS portends a poor prognosis: 50% to 65% with electrographic seizures during ECLS either died or were developmentally delayed at 1 to 2 years of age.

Hemolysis (serum hemoglobin >100 mg/dL) occurs in 6% to 12% of patients. This complication is likely due to red blood cell trauma during extracorporeal support, which is often related to clot formation within the circuit or overocclusion of the roller pump. Centrifugal pumps have been associated in the past with development of hemolysis over time, likely caused by heat generation.[101] Newer generation magnetically levitated centrifugal pumps, which are magnetically suspended and therefore associated with minimal friction, can be used without major concerns about hemolysis generation. Hyperbilirubinemia is noted in 8% of patients and renal insufficiency in 10%. Pneumothorax (occurring in 4% to 14%) and pericardial tamponade are life-threatening intrathoracic complications that manifest with increasing $Pa{O_2}$ and decreasing peripheral perfusion and $Sv{O_2}$, followed by decreasing ECLS flow and progressive deterioration. Initial emergent placement of a pleural or pericardial drainage catheter, followed by thoracotomy for definitive treatment of a pericardial tamponade, may be lifesaving.

Technical complications occurred in 15% of the neonatal and pediatric cases reported to the ELSO Registry.[102] The average number of mechanical complications per ECLS case was 0.71.[102] The most notable technical complications include the presence of thrombus in the circuit (26%), cannula problems (10%), oxygenator failure (9%), pump malfunction

(2%%), and presence of air in the circuit (4%). The effect of technical complications on survival was not substantial, although there was a significant decrease among neonatal patients, from 84% without technical complications to 80% with them.

## Results and Follow-Up

A total of 44,824 cases have been reported to the ELSO Registry since 1975.[3,103] Of these, there have been 24,344 cases of neonatal respiratory failure, 4771 cases of pediatric respiratory failure, and 4232 cases of newborn cardiac failure, and 5221 of pediatric cardiac failure. The number and diagnosis of neonatal respiratory failure survivors are given in Table 8-2. Overall survival is 75%, with the best survival noted among neonatal patients with the diagnoses of meconium aspiration syndrome (94% survival), respiratory distress syndrome (84%), and persistent pulmonary hypertension of the newborn (78%). Patients with CDH continue to have the poorest survival among those who receive ECLS, likely because of the "irreversible" pulmonary hypoplasia associated with that condition. In fact the survival rate in patients with CDH who require ECLS has fallen from a high of 71% in 1987 to the current rate of 51%. The total number of neonatal respiratory ECLS cases peaked in 1992 with 1516 cases. There was a trend downward in the total number of neonatal cases to a low of 707 in 2009 owing to improved results with neonatal respiratory management, including the use of nitric oxide and high-frequency oscillatory ventilation.[3]

The experience with pediatric patients with respiratory failure who were managed with ECLS at the University of Michigan is shown in Table 8-3 and demonstrates an overall survival rate of 75% since 1982.[3,104] Patients in the younger age groups demonstrate greater survival rates, including 100% survival in infants younger than 1 year of age. The ELSO Registry demonstrates that pediatric respiratory cases are accumulating at a rate of 200 to 300 per year, with an overall survival rate of 56% (Table 8-4).[3] One of the most frequent diagnoses is viral pneumonia, which is dominated by respiratory syncytial virus, an entity associated with 49% to 58% survival.[23,105]

ARDS, acute respiratory distress syndrome.

Other studies from individual centers also suggest that the survival rate of pediatric patients with respiratory failure managed with ECLS is 41% to 53%.[74,106] An approximately 50% survival rate is noted in pediatric patients with multiorgan system failure and in those with overwhelming septic shock who are managed with ECLS.[107] Green and colleagues,[108] analyzing data from the ELSO Registry, demonstrated that the survival rate in pediatric patients with respiratory failure who receive ECLS for longer than 2 weeks was similar to the survival rate of patients supported for shorter periods. However judgment must be used regarding the reversible nature of the respiratory dysfunction, the presence of associated organ system failure, and the development of complications associated with ECLS in determining whether continuation is warranted after prolonged periods on ECLS.

The ELSO Registry results for cardiac support cases are summarized in Table 8-5.[3] The number of pediatric cardiac cases reported to the registry is increasing steadily and currently is approximately 600 to 750 cases each year, the vast majority of which are pediatric cardiac surgical cases.[3]

| Other | 1273 | 602 | 47 |
| Total | 9849 | 4294 | 44 |

The overall survival is 41%. Almost all patients are managed with VA bypass. The survival rate has been thought to be poor (0% to 25%) in patients with an anomaly that consists of a single ventricle, but Allan and colleagues[109,110] demonstrated a survival to discharge of 48% in patients with shunted single-ventricle physiology and 81% in patients who underwent cannulation for hypoxemia as opposed to hypotension-cardiovascular collapse. Although Ziomek and coworkers[111] demonstrated a 47% survival among 17 patients in whom ECLS was initiated in the operating room, other studies suggest a poor outcome when ECLS is initiated in the operating room, at a point more than 50 hours after operation, or when continued for more than 6 to 9 days.[111] Data from numerous centers demonstrate a survival rate ranging from 46% to 53%,[112,113] with Klein and colleagues[114] observing a survival rate of 61% among 39 infants and children. The cause of death was lack of improvement in cardiovascular function in 37% of patients and major central nervous system damage in 15%, suggesting that earlier intervention with ECLS could improve outcome.[113] In a large series from Children's Hospital of Philadelphia, ECLS was used for 3.4% of children undergoing cardiac operations; the overall survival was 39%.[115] Survival among patients in whom ECLS was a bridge to heart transplantation was 40% to 60%.[116] Using ECLS in pediatric patients with cardiac failure following cardiac transplantation is associated with a long-term survival of 46%.[117]

ECLS has been effective in other clinical situations such as blunt trauma in children and adults, with survival rates of approximately 65%.[118,119] ECLS has also been successfully applied to patients with tracheal anomalies requiring repair, those with alveolar proteinosis who require pulmonary lavage, and those with pulmonary hypoplasia due to in utero renal insufficiency, asthma, sickle cell disease, and pulmonary failure after lung transplantation.[120–127] ECLS has been successfully applied to the management of pediatric and adult patients with H1N1 pneumonia.[128] Another application of ECLS has been in the form of extracorporeal cardiopulmonary resuscitation in pediatric patients with cardiogenic shock, post-traumatic hypotension, hypothermia, arrhythmias, and cardiac arrest, with the ELSO Registry and the literature overall demonstrating an approximately 40% survival.[129–131] Patients with mediastinal malignancies and airway compromise may be stabilized on ECLS during operative biopsy in order to avoid the risk of cardiopulmonary collapse associated with general anesthesia.[132] Those with hypothermia due to cold water drowning or winter mishaps may also be successfully warmed using this technology.[133,134] Donation after cardiac death is a new approach in which patients in whom support is being withdrawn or those with irreversible cardiac arrest are placed on ECMO support after death is declared thus allowing organ support until harvest can be performed.[135] This management strategy has the promise of enhancing available organs for transplantation.

Multiple studies have involved the long-term follow-up of newborn and pediatric patients after a course of ECLS. Most documented normal neurologic function in 70% to 80% of patients, although at least two studies document that approximately 50% of school-aged patients undergoing ECMO have abnormalities on careful neurologic assessment.[136–141] Such studies demonstrate that neurologic morbidity is no different in ECLS-managed newborns than in those managed by conventional mechanical ventilation. Pulmonary function tests at 8 years of age after neonatal courses on ECMO document measurable pulmonary sequelae in approximately half of the patients, with newborns with CDH being most affected.[142]

Patients with CDH who are managed with ECLS demonstrate a high incidence of morbidity, including gastroesophageal reflux in up to 81%, the need for tube feeding in up to 69%, the development of chronic pulmonary disease in up to 62%, the development of extra-axial fluid collections or enlarged ventricles in 30%, and growth delay in 40% to 50%.[143–145] These problems tend to resolve with time. The neurodevelopmental outcome among newborns with CDH was not dissimilar to that of other ECLS-treated children. Although most patients with cardiac and pediatric respiratory failure demonstrate few sequelae at follow-up, long-term studies in these groups have been less complete.

Four studies have evaluated the relative cost of treating newborn patients with ECLS compared with more conventional means.[20] Pearson and Short[146] found that the average daily charge for neonates receiving ECLS was twice that for patients receiving conventional mechanical ventilation, but the mean hospital stay was decreased by 50% in the ECLS group. Hospital charges were 43% lower in the ECLS group compared with the conventionally treated group when only the survivors were considered. The most recent randomized controlled trial comparing the outcome and costs of ECLS and standard management in newborn respiratory failure revealed average total costs of £73,979 or the ECLS group when compared with £33,435 or those managed by conventional means (UK prices, 2005).[147]

Maintaining a patient on extracorporeal support for days or weeks requires a prepared, organized, well-trained, and highly skilled team of physicians, respiratory therapists, nurses, and ECLS technicians. It is not a technique to be undertaken in a haphazard fashion on the spur of the moment without prior preparation and organization. The current recommendations by the American Academy of Pediatrics Committee on the Fetus and Newborn suggest that neonatal ECLS centers be established only at recognized level III regional centers with appropriate educational programs, ongoing research activity, and infant follow-up programs.[148]

## Future of Extracorporeal Life Support

Although current devices allow safe and effective prolonged extracorporeal support, the future of ECLS depends on improvements in component technology, accompanied by circuit simplification and autoregulation. Safe nonocclusive pumps; leak-free low-resistance artificial lungs; circuit coatings that obviate the need for systemic anticoagulation, and simplified percutaneous single-cannulation systems are now either available or on the horizon. Once a compact servoregulated device is developed with the ability to provide extracorporeal support without anticoagulation, ECLS will be a simple technique rather than a complex labor-intensive intervention.[149] At that point the indications for extracorporeal support will broaden as the technique is applied to a wider population of patients with less severe cardiopulmonary insufficiency.

One of the major benefits of the ECLS experience may be the ability to explore the pathophysiology of cardiac and respiratory failure. Improved understanding of pulmonary and cardiac organ failure may lead to new preventive measures and improved treatment modalities that eventually eliminate the need for ECLS in patients with cardiorespiratory failure.

CHAPTER 9

# Neonatal Cardiovascular Physiology and Care

Albert P. Rocchini

To appropriately manage the cardiovascular needs of your patient, it is important to understand normal cardiovascular physiology. This chapter summarizes normal fetal and neonatal cardiovascular physiology and describes principles that are necessary for the medical management of common cardiovascular problems in neonates.

## Cardiovascular Physiology

Regardless of age, the major variables that affect cardiovascular function are preload (end-diastolic volume), heart rate, arterial pressure (afterload), and contractility (inotropic state of the heart).[1–3] At all ages, increasing myocardial muscle length, heart rate, and other factors that alter the inotropic state of the heart have a positive effect on cardiac function, whereas increasing afterload has a negative effect. However, in the intact animal or human, it is almost impossible to change one of these factors without also affecting another. The net physiologic response is the combined effect of the intervention. For example, in an isolated muscle preparation, increasing rate of stimulation of the muscle will always result in an increase in the force of contraction.[2] However, in animals and children, pacing the heart at a faster rate will cause a decrease in stroke volume and no change or even a slight decrease in cardiac output. These opposite effects result from the difficulty in controlling the interaction of venous return, end-diastolic volume, inotropic state, heart rate, and afterload.

In addition, the subject's age can affect cardiovascular function. For example, in the fetus, increases in systemic afterload have a much greater effect on fetal right ventricular function (decreasing it) than left ventricular function, whereas, in the infant, increases in systemic afterload have a much greater effect on left ventricular function (decreasing it) than on right ventricular function.[4] The following sections focus individually on heart rate, preload, afterload, and contractility in the fetus and neonate.

### HEART RATE

Changes in heart rate have the same effect on ventricular output in both the immature and the adult heart.[5] Increases in heart rate induced by atrial pacing also can result in a decrease of ventricular performance. Stroke volume falls with an increase in heart rate, a consequence of decreasing end-diastolic filling time and end-diastolic volume; however, because the decrease in stroke volume is usually proportional to the increase in heart rate, the net effect is either no change or a slight fall in cardiac output. In comparison with the adult, the fetus and neonatal infant have a relatively high resting heart rate. Because of the high basal heart rate, a neonate's cardiac output can rarely be increased by increasing heart rate. Similarly, in the neonate or fetus, decreases in heart rate to near adult levels, 60 beats/minute, are usually associated with marked decreases in cardiac output. Unlike pacing, a spontaneous increase in heart rate is usually associated with an increase in cardiac output. A spontaneous heart rate change differs from a similar change in heart rate resulting from atrial pacing, because the underlying stimuli that cause the spontaneous rate change also will affect inotropy, venous return, and/or afterload. For example, an increase in venous return that maintains end-diastolic volume, despite a rate-induced shortening of diastolic filling, can result in an increase in stroke volume. Similarly, if the stimulus to increase heart rate is associated with an increase in contractility, even though venous return may not increase, the increase in heart rate will still result in an increase in cardiac output. Exceptions to the positive effect of a spontaneous increase in heart rate on cardiac output can usually be explained by an increase in arterial pressure.[3] The negative effect of afterload on ventricular function results in a fall in stroke volume and cardiac output.

### PRELOAD

At all ages, ventricular output depends on end-diastolic volume. An increase in stroke volume or cardiac output occurs when end-diastolic volume is increased (the Frank-Starling relation).[1,6] This relation depends on both the number of cross-bridge attachments that can be made at a given sarcomere length, and the sarcomere length depends on myofilament sensitivity to calcium.[7] Although this relationship exists in

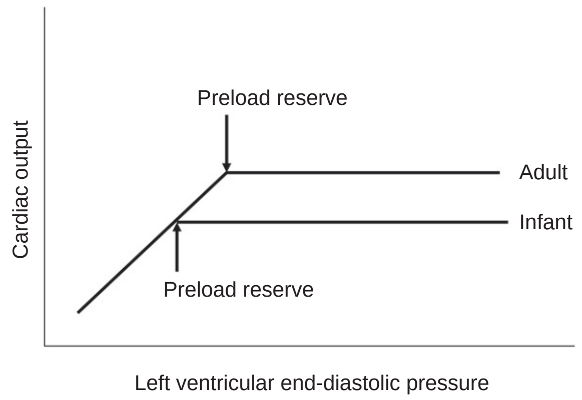

**FIGURE 9-1** The Frank-Starling relation between cardiac output and left ventricular end-diastolic pressure. The point at which further increases in end-diastolic volume result in no further increase in cardiac output is referred to as preload reserve *(arrow)*. Since the neonatal myocardium is stiffer and less compliant, the preload reserve occurs at lower pressure than in the mature adult heart.

both the newborn and the adult, the magnitude of the relationship is frequently diminished in the newborn. It is well known that when left ventricular end-diastolic pressure is high, only small increments in end-diastolic volume and stroke volume follow from a further increase in filling pressure. As can be seen in Figure 9-1, the end-diastolic pressure at which further increases result in little change in cardiac output is called preload reserve. In the newborn, because the myocardium is immature and has greater stiffness (reduced compliance), the preload reserve occurs at a lower pressure than in the adult.[8]

### AFTERLOAD

The cardiovascular function of both the immature and adult heart is negatively affected by an increase in afterload.[3,9,10] There is a maturational difference in the effect of afterload on myocardial function. The immature ventricle cannot eject against arterial pressures well-tolerated by the adult heart. This quantitative difference in response to afterload results from the weaker contraction of the immature myocardium (corrected for muscle cross-sectional area) and the thinner ventricular wall of the immature heart. Afterload also has a quantitatively different effect on right and left ventricular function. In both the neonate and the adult, increases in arterial pressure have a much greater negative effect on stroke volume of the right ventricle than that of the left. In the fetus and neonate with a widely patent ductus arteriosus, this difference is a consequence of the relatively larger right ventricular stroke volume, end-diastolic volume, and free wall curvature in the presence of similar right and left ventricular free wall thicknesses.[10] Because of Laplace's law, systolic wall stress of the right ventricle is greater than that of the left ventricle in the face of similar arterial pressures. This increase in right ventricular systolic wall stress causes the right ventricular ejection to be more negatively affected by an increase in arterial pressure.

### CONTRACTILITY

An intervention that does not alter preload or afterload yet increases the force of contraction or increases cardiac output is said to have a positive inotropic effect. This positive effect usually arises from either an increase in the sensitivity of the myofilaments to calcium or an increase in the cytosolic calcium transient. The immature heart responds to positive inotropic agents with an increase in left ventricular output; however, in comparison with the adult heart, this response is reduced. In cardiac muscle, the movement of calcium through the dihydropyridine-sensitive calcium channel is essential for calcium-induced calcium release from the sarcoplasmic reticulum.[11–15] Calcium-induced calcium release amplifies the effect of the calcium current on cytosolic calcium concentration.[15,16] In the absence of calcium-induced calcium release, trans-sarcolemmal calcium flow results in a contraction whose peak force is only a fraction of that achieved in the presence of the amplification system. Both the dihydropyridine-sensitive calcium channels and the sarcoplasmic reticulum calcium release channels (ryanodine receptors) are necessary for calcium-induced calcium release. Compared with the adult, the immature heart has a greater dependence on extracellular calcium, since it has reduced calcium-induced calcium release. The reduced dependence of the adult myocardium on extracellular calcium results from maturation of the sarcoplasmic reticulum. Both absolute and relative sarcoplasmic reticulum volume increases with age as does sarcoplasmic reticulum calcium release. For example, ryanodine has little effect on the force of contraction of the newborn myocardium. The immaturity of the sarcoplasmic reticulum and the greater dependence of the newborn heart on extracellular calcium concentrations are two explanations for why calcium channel blockers, such as verapamil, are poorly tolerated in the newborn.

## Fetal Circulation

In addition to understanding how preload, afterload, heart rate, and contractility effect neonatal cardiovascular function, it is important to understand how birth affects the cardiovascular system. The fetal circulation differs from the adult circulation in a number of ways. The adult circulation is characterized as blood flow in series, that is, blood returns to the heart from the venous system to the right atrium and ventricle and is then injected into the lungs for oxygenation. Oxygenated blood then returns through the pulmonary veins to the left atrium and ventricle and is then ejected into the arterial system. The right ventricle works against the low afterload of the pulmonary circulation, whereas the left ventricle works against the high afterload of the systemic circulation. In the fetus, oxygenation and carbon dioxide elimination take place in the placenta. Oxygenated blood flows to the fetus through the umbilical veins, which connect to the inferior vena cava through the ductus venous.[17–19] The oxygenated umbilical blood flow mixes with the poorly oxygenated portal blood from the gastrointestinal tract. Because of the eustachian valve in the right atrium, the higher saturated umbilical venous blood preferentially streams across the foramen ovale into the left atrium,[20,21] whereas the lower saturated blood from the distal inferior vena cava and from the superior vena cava enters the tricuspid valve and is directed to the right ventricle. Although there are preferential patterns of flow, some of the blood from the placenta does enter the tricuspid valve, and some of the blood from the distal inferior vena cava and

superior vena cava enters the foramen ovale. Both right and left ventricles pump to the systemic circulation. The right ventricular output is directed through the ductus arteriosus to the descending thoracic aorta, and the left ventricular output is directed although the aortic valve to the ascending aorta. Because of the preferential streaming of umbilical venous return, most oxygenated blood goes to the left ventricle and is distributed to the heart and cerebral circulations, whereas the lower oxygenated blood goes to the right ventricle and is distributed to the pulmonary arteries, abdominal organs, and placental arteries.[19]

Because of this unique fetal circulation, many types of congenital heart disease that are not compatible with life after birth are well tolerated in utero. For example, infants with hypoplastic or atretic left or right ventricular outflow tracts develop normally in utero, whereas after birth these lesions are fatal unless surgery is performed. With birth there is a rapid transformation from the fetal circulation to the adult circulation. This transformation involves elimination of the umbilical–placental circulation, establishment of an adequate pulmonary circulation, and separation of the left and right sides of the heart by closure of the ductus arteriosis and foramen ovale. Figure 9-2 depicts the fetal, immediate postbirth, and a few days postbirth hemodynamics.[22] Persistence of the fetal circulation after birth means that adequate pulmonary circulation is not achieved and fetal channels have not been closed. For example, infants with congenital diaphragmatic hernia have persistence of the fetal circulation because of high pulmonary resistance resulting from poor oxygenation and persistent patency of the foramen ovale and ductus arteriosus.

# Neonatal Management of Common Cardiovascular Problems

## CONGESTIVE HEART FAILURE

The common causes of heart failure in the neonate include rhythm disturbances and congenital cardiovascular malformations. Table 9-1 lists common congenital heart lesions and the age at which congestive heart failure is likely to occur. In the infant with cyanotic congenital heart disease, congestive heart failure usually occurs with lesions that have large amounts of pulmonary blood flow or regurgitant atrioventricular (AV) valves. The ultimate management of heart failure is to treat the underlying congenital malformation; however, medical management is essential to stabilize the infant and enable surgical correction to be performed with a reduced risk. The standard medical management includes the principles of rate control, preload control, afterload control, and improvement in contractility. Because of the high resting heart rate of the neonate, one cannot use increasing heart rate to increase cardiac output in the neonate. In fact, chronic supraventricular tachycardia, frequently the result of an atrial ectopic focus, is a cause of congestive cardiomyopathy.

Preload control is the mainstay of symptomatic therapy for heart failure. This is accomplished with the use of diuretics. The most common diuretic used to treat heart failure in the infant is furosemide (Lasix). Table 9-2 lists many of the commonly used diuretics and current dose recommendations. One diuretic that may have more benefit than just symptomatic therapy is spironolactone (Aldactone).[23,24] Recent evidence suggests that in addition to causing fluid retention aldosterone can cause myocardial fibrosis. There are now a number of clinical trials in adults that suggest that chronic blockade of mineralocorticoid receptors results in improved cardiac remodeling.[24] It is important when considering the use of diuretics to avoid too much diuresis. If the child's preload is reduced below their preload reserve, cardiac output will decrease (see Fig. 9-1).

Afterload agents work by decreasing ventricular loading, predominately by reducing systemic vascular resistance. The pharmacologic agents that are most useful in altering afterload are vasodilators (see Table 9-2). These agents are important therapeutic agents in the treatment of infants with heart failure secondary to a large left to right shunt, severe atrioventricular and semilunar valve regurgitation, dilated cardiomyopathy, and postoperative low-output states.[25–29] Angiotensin-converting enzyme inhibitors are the most commonly used class of afterload reducing agents.[30–33] In addition to reducing ventricular afterload, in adults with congestive cardiomyopathy, they have been shown to also improve cardiovascular remodeling.[24] Another means of afterload control is low-dose beta-receptor blockade. Low-dose beta-blockade has been used successfully in the treatment of congestive cardiomyopathy. This agent works by interfering with the deleterious effects of increased sympathetic activity.[34,35]

With gram-negative septic shock or anaphylactic shock, it may be necessary to increase systemic afterload. In this situation, although systemic blood flow is high, because of severe vasodilation, the cardiac output is not high enough to maintain arterial pressure. The pharmacologic agents that are used in this situation are epinephrine, norepinephrine, and vasopressin.[36,37]

The final group of agents used to treat congestive heart failure in infants and young children are agents that increase the inotropy of the heart (see Table 9-2). The oldest agent in this class is digitalis. Digoxin is still the most commonly used chronic inotropic agent. It increases contractility by inhibiting the sodium-potassium-ATPase pump, resulting in an increase in intracellular sodium, which, in turn, stimulates calcium entry into the cell by the sodium-calcium exchanger; the increased intracellular calcium leads to increased contractility. Recent studies have suggested that digitalis also helps heart failure by inhibiting sympathetic nerve traffic and thus decreasing cardiac metabolic demands.[38] In addition to digoxin, there are other intravenous inotropic agents, the majority of which stimulate the beta-adrenergic receptor in the heart, which, in turn, increases production of adenyl cyclase activity and ultimately contractility. These agents are especially useful in managing severe acute congestive heart failure and cardiogenic shock. Depending on the individual agent, blood pressure can be either increased or slightly decreased. For example, dopamine can cause alpha-receptor stimulation with some degree of vasoconstriction,[39] whereas dobutamine tends to produce more systemic vasodilatation and either slightly decreases or has no effect on systemic pressure.[38,40] Milrinone is another intravenous inotrope that is frequently used in the infant. Milrinone is a phosphodiesterase inhibitor and increases contractility by inhibiting the breakdown of cyclic 3′5′-adenosine monophosphate (c-AMP). Besides being a positive inotropic agent, it reduces afterload as well. Thus

**Medications Used to Treat Congestive Heart Failure**

| *Class* | *Drug* | *Dose* | *Dosing Interval* | *Comments* |
|---|---|---|---|---|
| Diuretic | Hydrochlorothiazide | 2.0-3.0 mg/kg up to 50 mg/day | bid | Will increase uric acid level |
| | Furosemide | 0.5-2.0 mg/kg up to 6 mg/kg/day | qd or bid | |
| | Spironolactone | 1.0-3.3 mg/kg | bid | Potassium-sparing, used with causing with CEI |
| | Metolazone | 0.2-0.4 mg/kg | qd | |
| ACE | Benazepril | 0.2 mg/kg up to 10 mg/day | qd | Contraindicated in pregnancy, check serum potassium, creatinine. Cough and angioedema are side effects |
| | Captopril | 0.3-0.5 mg/kg up to 6 mg/kg | tid | |
| | Enalapril | 0.08 mg/kg up to 5 mg/day | qd-bid | |
| | Lisinopril | 0.07 mg/kg up to 40 mg/day | qd | |
| ARB | Irbesartan | 6-12 years: 75-150 mg/day | qd | Contraindicated in pregnancy, check serum potassium, creatinine |
| | Losartan | 0.7 mg/kg/day up to 50 mg/day | qd | |
| Beta-blocker | Metoprolol | 1.0-2.0 mg/day up to 6.0 mg/kg/day | qd | |
| Vasodilator | Hydralazine | 0.75 mg/kg up to 7.5 mg/kg | qid | Tachycardia, fluid retention, lupus-like syndrome |
| | Prazosin | 0.05-0.1 mg/kg up to 0.5 mg/kg | tid | |
| Inotrope | Digoxin | Digitalizing dose 20-40 μg/kg depending on age<br>Maintenance dose 5-10 μg/kg | bid | |
| | Dobutamine | 2.0-20 μg/kg/min IV | | |
| | Dopamine | 2.0-20 μg/kg/min IV | | |
| | Milrinone | Loading dose 0.05-1 mg/kg then 0.5-0.75 μg/kg/min | | |
| | Epinephrine | 0.05-2 μg/kg/min IV | | |

ACE, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; CEI, converting enzyme inhibitor.

milrinone is likely to lower blood pressure slightly. It is also useful in producing some degree of pulmonary artery vasodilation and is therefore an ideal agent for the infant with severe congestive heart failure and pulmonary artery hypertension.[20]

If pharmacologic therapy is not enough to maintain adequate cardiac output, mechanical devices can be used to support the circulation. The most commonly used mechanical support device is extracorporeal membrane oxygenation. More recently ventricular assist devices have been used in infants with end-stage cardiomyopathy as a bridge to cardiac transplantation.[22,41,42]

## ABNORMALITIES IN CARDIAC RHYTHM

### Heart Block

Both slow and fast heart rates can severely compromise the cardiovascular circulation of an infant. Complete heart block may be either congenital or acquired and occurs in 1 per 20,000 live births.[43–45] There is a strong association between maternal connective tissue disease and congenital complete heart block. A mother with systemic lupus erythematosus has a 1 in 20 risk of having a child with complete heart block if she is anti-Ro positive.[46] Maternal immunoglobulin G antibodies to soluble ribonucleoprotein antigens (anti-Ro and anti-La) cross the placenta after the 12th to 16th week of gestation. This transfer of antibodies results in an inflammatory response in the fetal heart, particularly the conduction system, with destruction of the atrioventricular node.[45–51] Complete heart block in the neonate may or may not need treatment. The decision of whether to place a pacemaker in an infant with heart block depends on the presence of in utero heart failure (hydrops) or the development of postnatal congestive heart failure. Heart rate alone is usually not an indication for pacemaker placement; however, if the infant's heart rate remains at less than 50 beats/minute, a pacemaker is frequently required. Some forms of congenital heart disease also have a high incidence of heart block. These lesions include the Ebstein anomaly of the tricuspid valve and corrected transposition of the great arteries.

### Tachyarrhythmias

Tachyarrhythmias can also occur in the infant and young child and cause heart failure. The most common type of tachyarrhythmia is supraventricular tachycardia. The incidence of paroxysmal supraventricular tachycardia is 1 in 250 to 1000 children.[4] It occurs most commonly in males younger than 4 months of age and frequently is even present in the fetus. The pathologic mechanism underlying the tachycardia is usually either the result of Wolff-Parkinson-White (WPW) syndrome (an accessory pathway between the atria and ventricles) or atrioventricular nodal reentry (dual conduction pathways within the atrioventricular node). If the supraventricular tachycardia is sustained, heart failure will likely occur within 24 to 48 hours. The treatment for supraventricular tachycardia, regardless of cause, is similar. If the infant becomes acidotic or hypotensive, immediate synchronized direct-current cardioversion should be performed at a dosage of 1 to 2 watt-second/kg.[52] If the infant is stable and relatively asymptomatic, then in most situations any intervention that increases AV node refractoriness is likely to work. In the infant, application of ice or an ice-water bag directly to the center of the infant's face recruits the diving reflex and stops the tachycardia. A rapid intravenous infusion of adenosine is also very effective in terminating supraventricular tachycardia.[53] The usual dose is a 100 μg/kg bolus, increasing by 100 μg-increments to a maximum of 400 μg/kg. A few serious side effects associated with adenosine administration included atrial fibrillation, ventricular tachycardia, asystole, apnea, and bronchospasm. Because of these potential side effects, adenosine should be administered in an area where cardioversion and cardiopulmonary resuscitation can be performed.

Children with supraventricular tachycardia and mild to moderate congestive heart failure may be initially treated with adenosine; however, other pharmacologic agents, such as digoxin, amiodarone, and procainamide may be helpful if adenosine fails to convert the tachycardia. Table 9-3 lists many of the commonly used antiarrhythmic agents and current dose recommendations. In infants, the intravenous route is the preferred method for administration of digoxin. The digitalizing dose interval may be given as frequently as every 2 to 4 hours. If tachycardia persists after three doses, one more dose equivalent to one fourth of the total digitalizing dose may be given. If the tachycardia has still not converted vagal stimulation or adenosine may be effective in terminating the tachycardia after digitalization. The maintenance dose of digoxin should be determined according to the total digitalizing dose required to terminate the tachycardia and is one eighth of the total digitalizing dose twice daily. Digoxin should be avoided in patients with a wide QRS tachycardia and when WPW syndrome is considered as a possible cause. Digoxin in the presence of WPW with atrial fibrillation can result in an acceleration of the ventricular response and resultant ventricular fibrillation.

Esmolol or propranolol, which may further depress cardiac function, should be used with caution in the critically ill infant with congestive heart failure. Once the tachycardia has been terminated and the congestive heart failure controlled, beta blockers can be used as effective long-term antiarrhythmic therapy in infants with supraventricular tachycardia.

Amiodarone is now being used with increasing frequency for the emergency treatment of supraventricular tachycardia, especially in the postoperative patient. Intravenous administration of amiodarone has been reported to terminate the tachycardia within 2 hours of the initial bolus in more than 40% of patients.[54,55] The major side effects of amiodarone include hypotension, decreased ventricular function, and bradycardia.

Intravenous procainamide can be very effective in patients with refractory supraventricular tachycardia. The combination of procainamide and a beta blocker is especially effective in treating refractory atrial flutter in the neonate.

Verapamil, although an effective agent to treat supraventricular tachycardia in the adult, is contraindicated in the infant with congestive heart failure. Use of verapamil in infants has resulted in cardiovascular collapse and death.[56,57]

In our institution, we frequently use esophageal overdrive pacing to convert supraventricular tachycardia in the infant. Esophageal pacing has the advantage of not only treating the arrhythmia but also helping to make a definitive diagnosis of the tachycardia. Overdrive pacing involves pacing the atrium via the esophagus at a rate slightly higher than the rate of the tachycardia. With cessation of pacing, sinus rhythm will usually return. Esophageal pacing is effective in most forms of supraventricular tachycardia, including atrial flutter.[58,59]

**TABLE 9-3**

**Commonly Used Pharmacologic Agents to Treat Tachyarrhythmias**

| *Drug* | *Dosage* | *Onset of Action* | *Potential Adverse Effects* | *Drug Interactions* | *Cardiovascular Contraindications* | *Comments* |
|---|---|---|---|---|---|---|
| Adenosine | 100-150 μg/kg given rapid IV; double dose sequentially to maximum of 300 μg/kg | < 5 sec | Dyspnea, bronchospasm, headache, chest pains, AV block/asystole, PVCs, atrial fibrillation, torsades de pointes, hypotension | Theophylline-adenosine is less effective<br>Digoxin: increases risk of VT<br>Diazepam-potentiated effects of adenosine | Prolonged QT interval<br>Second- or third-degree AV block, except in the presence of pacemaker<br>Sick sinus syndrome | Have defibrillator available when administering, in the event of ventricular rate acceleration, torsade de pointes, or VF |
| Amiodarone | Bolus: 5 mg/kg during 10 min<br>Infusion of 10-15 μg/kg/day | Within 5 min of initial bolus | Hypotension, sinus arrest, or bradycardia, AV block | Digoxin: increases digoxin levels<br>Procainamide: causes increased levels of amiodarone<br>Warfarin: increases INR | Sick sinus syndrome or AV block, except if pacemaker present<br>Cardiogenic shock | Closely monitor blood pressure, heart rate and rhythm<br>Hypotension can be treated with volume and calcium |
| Esmolol | Load: 500 μg/kg during 1-2 min<br>Maintenance: 50-200 μg/kg/min | Within 1-2 min | Hypotension, dizziness, headache, nausea, bronchospasm, decreased cardiac output | Digoxin: increases level<br>Morphine: causes increased esmolol level | Sinus bradycardia, second- or third-degree heart block, cardiogenic shock, overt heart failure | Use with caution in patients with decreased renal function, diabetes, or asthma |
| Procainamide | Load: infants 7-10 mg/kg during 45 min, older children 12 mg/kg<br>Infusion 40-50 μg/kg/min, occasionally may need up to 100 μg/kg/min | Within 30 min | Hypotension, increased ventricular response with atrial flutter, bradycardia, asystole, depressed ventricular function, fever myalgia, AV block, confusion, dizziness and headache | Amiodarone: causes increased concentration of procainamide<br>Digoxin: causes increased digoxin levels | Second- and third-degree AV block without pacemaker<br>Congestive heart failure<br>Prolonged QT interval | Continuous ECG and BP monitoring<br>Monitor potassium levels; if potassium decreases arrhythmias may increase |

AV, atrioventricular; BP, blood pressure; ECG, electrocardiogram; INR, international normalization ratio; PVCs, premature ventricular contractions; VF, ventricular fibrillation; VT, ventricular tachycardia.

Ventricular tachycardia is extremely unusual in the newborn. It is most commonly seen in infants with intracardiac tumors, such as rhabdomyomas and in infants with long QT syndrome.

## MANAGEMENT OF SELECTIVE TYPES OF CONGENITAL HEART DISEASE

Certain types of congenital heart disease are frequently associated with other congenital lesions that require general surgical procedures to be performed in the newborn period. For example, tetralogy of Fallot and ventricular septal defects are common in infants with tracheoesophageal fistulas, anal atresia, and other lesions common to the VATER complex (vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia). Interrupted aortic arch, truncus arteriosus, and tetralogy of Fallot are frequently present in infants with the DiGeorge syndrome. Hypoplastic left heart syndrome has been reported to occur in infants with congenital diaphragmatic hernia. More than 60% of infants with Down syndrome have congenital heart disease (patent ductus arteriosus, ventricular septal defects, atrioventricular septal defects, and tetralogy of Fallot). Because of the strong association of congenital heart disease with other congential anomalies that require general surgery in the newborn period, a cardiology consultation and echocardiogram are frequently necessary prior to the surgical procedure. The exact management of the infant depends on the type of congential heart disease.

In infants with restricted pulmonary blood flow, such as seen with tetralogy of Fallot and/or pulmonary atresia, ductal patency is necessary in order to maintain adequate oxygenation. If a ductus was present in fetal life, it can usually be maintained patent with the administration of prostaglandin $E_1$, at a starting dose of 0.1 to 0.05 μg/kg/minute. If the ductus is patent, I use low-dose prostaglandin (0.02 to 0.03 μg/kg/minute) to maintain its patency; if the ductus is virtually closed, I start with a higher dose of prostaglandin until patency is achieved and then cut back to low-dose therapy. Side effects associated with prostaglandin administration include apnea, seizures, fevers, hypotension, and flushing. Once the infant has been stabilized, then more definitive therapy can be contemplated. At our institution, whenever possible, we choose complete repair of these lesions rather than palliation, with a systemic to pulmonary artery shunt.

In infants with hypoplastic left heart syndrome initial management requires that an atrial septal defect be present and that ductal patency be maintained. In these infants, systemic blood flow is directly related to pulmonary artery resistance, and oxygen saturation is inversely related to pulmonary

vascular resistance (i.e., as pulmonary resistance decreases, pulmonary blood flow increases, resulting in higher oxygen saturation and lower systemic blood flow). The ideal systemic oxygen saturation in an infant with hypoplastic left heart syndrome is about 80%. When oxygen saturations are in the high 80s to low 90s, the ratio of pulmonary to systemic blood flow is usually greater than 4:1, and systemic hypoperfusion is usually present; when oxygen saturation is in the high 70s to low 80s, the pulmonary to systemic flow ratio is nearly balanced. Ideally, I like to let these infants maintain spontaneous respirations, and I withhold supplemental oxygen. In some cases, it may be necessary to cause pulmonary vasoconstriction, which can be accomplished by placing the infant in a mixture of room air and nitrogen. The lower inspired oxygen concentration will cause pulmonary artery vasoconstriction, which will result in a reduction in pulmonary blood flow and maintenance of adequate systemic perfusion. Once the infant has been stabilized, it is my policy to perform Norwood palliation. In some selected cases, cardiac transplantation may be the best surgical option for the infant.

Infants with ventricular septal defects or atrioventricular septal defects usually have no symptoms from their heart disease during the first month of life. Congestive heart failure from a ventricular septal defect is usually the result of excess pulmonary blood flow. The two major determinants of left to right shunt flow across a ventricular septal defect are the size of the defect and the ratio of pulmonary arteriolar to systemic arteriolar resistance. In a term infant, it usually takes from 4 to 6 weeks for the pulmonary resistance to drop to normal levels; thus infants with large septal defects do not usually develop heart failure until the second month of life. Causes of early heart failure in an infant with a ventricular septal defect include prematurity and other associated cardiac lesions. The two lesions most often associated with the early development of congestive heart failure are the presence of a co-arctation of the aorta and, in the case of atrioventricular septal defect, the presence of significant atrioventricular valvular regurgitation.

CHAPTER 10

# Sepsis and Related Considerations

Allison L. Speer, Tracy C. Grikscheit, Jeffrey S. Upperman, and Henri R. Ford

Despite advances in neonatology and pediatric critical care, sepsis remains a challenging problem for the health care provider. Sepsis is a leading cause of morbidity and mortality in infants and children, and, unfortunately, its incidence continues to rise.[1,2] In their most recent reports, the Centers for Disease Control and Prevention and the National Center for Health Statistics cited septicemia as the tenth leading cause of death and bacterial sepsis of the newborn as the eighth leading cause of infant death in the United States.[3] In addition, sepsis-related health care costs represent a significant economic burden to society, with almost $17 billion spent annually in the United States alone.[4]

There are only a handful of epidemiologic studies of sepsis and even fewer regarding pediatric sepsis. One of the challenges to the study of sepsis has been the lack of standardized terminology. Consistent definitions may be crucial for early diagnosis and goal-directed therapies to improve mortality from sepsis. Furthermore, they may enhance the design and evaluation of future trials. The first part of this chapter outlines the evolution of sepsis terminology as well as its epidemiology. Emerging therapies for sepsis are typically aimed at enhancing or modulating the immune system or destroying the invading microbe. Therefore it is important to fully understand host defense mechanisms as well as microbial virulence. The second section covers the pathogenesis of sepsis, with a focus on the determinants of infection: host defense mechanisms and bacterial virulence. The third part of this chapter examines the diagnosis of sepsis, with a focus on the Goldstein consensus criteria[5] and the PIRO system (*P*redisposing conditions, the nature and extent of the *I*nsult or *I*nfection, the magnitude of the host *R*esponse, and the degree of concomitant *O*rgan dysfunction).[6] The fourth and final part discusses principles of management, with concentration on the Surviving Sepsis Campaign (SSC)[7,8] and the American College of Critical Care Medicine (ACCM)[9]/Pediatric Advanced Life Support (PALS)[10] guidelines for the management of pediatric and neonatal sepsis.

## Sepsis Terminology and Epidemiology

### TERMINOLOGY

Historically, confusing terminology and a lack of standardized definitions had obscured diagnosis and treatment as well as interpretation of clinical research trials on sepsis and its related syndromes. The American College of Chest Physicians/Society of Critical Care Medicine (ACCP/SCCM) 1991 Consensus Conference established the current definitions of sepsis and its related syndromes with the goal of improving early diagnosis and thereby facilitating early therapeutic intervention.[11] They also reasoned that the ACCP/SCCM 1992 consensus criteria, or the Bone criteria, would help to standardize research protocols, which would enable improved application of information derived from clinical studies.

Sepsis is defined as the development of the systemic inflammatory response syndrome (SIRS) resulting from a confirmed infection. According to the Bone criteria, SIRS is characterized by the presence of two or more of the following: (1) temperature greater than 38° C or less than 36° C, (2) heart rate greater than 90 beats per minute, (3) respiratory rate greater than 20 breaths per minute or $Pa_{CO_2}$ less than 32 mm Hg, or (4) an alteration in the white blood cell count, such as greater than 12,000/mm$^3$, less than 4,000/mm$^3$, or greater than 10% immature neutrophils (bands). When sepsis is associated with acute organ dysfunction, it is referred to as severe sepsis.[11] Septic shock, by contrast, is defined as sepsis-induced hypotension (<90 mm Hg or reduction by 40 mm Hg or more from baseline in the absence of other causes) persisting despite adequate fluid resuscitation, along with signs of organ hypoperfusion, such as lactic acidosis, oliguria, or acute alteration in mental status. However, SIRS may also occur in the absence of infection as a result of trauma, burns, pancreatitis, or other triggers (Fig. 10-1). Septicemia and septic syndrome are confusing and ambiguous terms that should no longer be used.

According to Bone and colleagues,[11] detection of altered organ function in an acutely ill patient constitutes a syndrome that is termed multiple organ dysfunction syndrome (MODS). In contrast to organ failure, organ dysfunction is a dynamic process and a continuum of physiologic derangements that evolve with time. They argue that terms such as *sequential organ failure*[12] or *multiple systems organ failure*[13] are inadequate and should

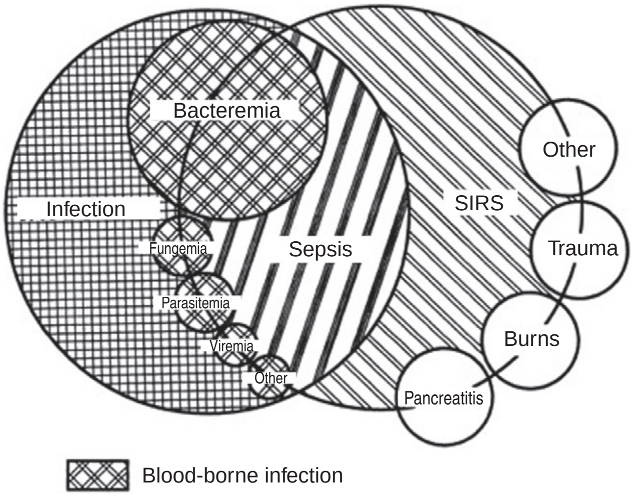

**FIGURE 10-1** The interrelationship between systemic inflammatory response syndrome (SIRS), sepsis, and infection. (Used with permission from Bone RC, Balk RA, Cerra FB, et al: Definitions for sepsis and organ failure and guidelines for the use of innovative therapies in sepsis. Chest 1992;101:1644-1655.)

be eliminated from use. MODS develops by two relatively distinct, but not mutually exclusive, pathways that may be described as either primary or secondary. Primary MODS is the direct result of a well-defined insult in which organ dysfunction occurs early and can be directly attributed to the insult itself. Secondary MODS develops as a consequence of the host response (SIRS) in organs remote from the initial insult, typically after a latent period following the inciting injury.

The Bone criteria have been widely adopted in both clinical practice and research trials.[14–17] A MEDLINE search dated January 1992 to May 2010 yielded more than 50,000 publications using SIRS as a keyword. Despite this proliferation of articles, analysis of a recent physician attitudinal survey revealed that only 22% (114 of 529) of intensivists and 5% (26 of 529) of other physicians defined sepsis according to the ACCP/SCCM 1992 consensus criteria.[18] The failure to adopt these criteria and the concurrent growth of clinical trial data provided the impetus for a review of the 1992 definitions of sepsis and its related conditions. The 2001 International Sepsis Definitions Conference, sponsored by the SCCM, European Society of Intensive Care Medicine, ACCP, American Thoracic Society, and the Surgical Infection Society, undertook this task. These experts and opinion leaders ultimately upheld the ACCP/SCCM 1992 consensus criteria and expanded the list of signs and symptoms of sepsis to reflect clinical bedside experience (Table 10-1).[6]

## EPIDEMIOLOGY

The ACCP/SCCM 1992 consensus criteria have been applied in several epidemiologic surveys of sepsis during the last 15 years.[2,4,14,19–22] Although standardized terminology is now used, information on the incidence of sepsis and patient outcomes continues to be limited, and published results are conflicting. Two European studies reported the incidence of sepsis in adult intensive care units (ICUs) and drew some interesting conclusions regarding prognosis. Brun-Buisson and colleagues reported the incidence of severe sepsis in adult ICUs in French public hospitals to be 6.3%,[19] while Alberti and colleagues found a higher adult ICU-specific incidence of infection in Europe (21.1%). They stratified the data into the following categories: infection without SIRS (17.9%), sepsis (28.3%), severe sepsis (23.9%), and septic shock (29.9%), according to the ACCP/SCCM 1992 consensus criteria.[20] Alberti and colleagues identified the majority of infections to be gram-negative bacilli, followed by gram-positive cocci. However, even though the incidence of community-acquired (11.9%) versus hospital-acquired (9.2%) infection

*Infection is defined as a pathologic process induced by a microorganism.
†$Svo_2$ saturation $>$ 70% is normal in children (normally, 75% to 80%), and CI 3.5 to 5.5 is normal in children; therefore NEITHER should be used as signs of sepsis in newborns or children.
‡Diagnostic criteria for sepsis in the pediatric population are signs and symptoms of inflammation plus infection with hyperthermia or hypothermia (rectal temperature $>$ 38.5° C or $<$ 35° C), tachycardia (may be absent in hypothermic patients), and at least one of the following indications of altered organ function: altered mental status, hypoxemia, increased serum lactate level, or bounding pulses.
aPTT, activated partial thromboplastin time; BPM, beats per minute; CRP, C-reactive protein; INR, international normalized ratio; MAP, mean arterial blood pressure; SBP, systolic blood pressure; SD, standard deviation(s); $Svo_2$, mixed venous oxygen saturation; WBC, white blood cell.

was similar, nosocomially infected patients had poorer outcomes.[20] Interestingly, Brun-Buisson and colleagues demonstrated that patients with culture-negative, clinically suspected severe sepsis had the same 28-day mortality (60%) as patients with documented infection (56%).[19]

Before 2000, only two epidemiologic studies had been conducted in the United States that used the ACCP/SCCM 1992 consensus criteria.[21,22] Neither study provided accurate information on population incidence (including children) or the costs of care. In 1995, Rangel-Frausto and colleagues published a prospective epidemiologic study of the sequential progression of SIRS to sepsis, severe sepsis, and, finally, septic shock in a single institutional cohort.[21] They demonstrated a stepwise increase in positive blood cultures (17%, 25%, 69%, respectively) and in mortality rates along the hierarchy from SIRS (7%), to sepsis (16%), severe sepsis (20%), and septic shock (46%).[21] Interestingly, Rangel-Frausto and colleagues confirmed the findings of Brun-Buisson and colleagues that culture-negative patients had similar morbidity and mortality rates as culture-positive patients.[21] Another U.S. study by Sands and colleagues, however, reported very different results from the European epidemiologic studies. Their prospective, multi-institutional, observational study involving eight academic tertiary care centers, published in 1997, estimated the hospital-wide incidence of sepsis at 2.0%, with ICU patients accounting for 59%.[22] Bacteremia was documented in only 28% of the study population, with gram-positive organisms as the most frequent isolates. The 28-day mortality was 34%.[22] The lower incidence of sepsis, bacteremia, and the improved mortality rates compared with the European studies are likely due to the fact that this study enrolled patients hospital-wide, including healthier non-ICU patients in addition to sicker ICU patients. The differences in types of bacteria responsible for sepsis in the U.S. study by Sand and colleagues versus the European study by Alberti and colleagues may reflect geographic as well as institutional differences.

In an effort to better define the incidence, costs, and outcomes of sepsis in the United States, two important studies using the ACCP/SCCM 1992 consensus criteria were published in 2001[4] and 2003.[2] Angus and colleagues conducted a large observational cohort study to determine incidence, costs, and outcomes of severe sepsis.[4] Using 1995 state hospital discharge records from seven large states, they estimated 3.0 cases per 1,000 population, 2.26 cases per 100 hospital discharges (51.1% from the ICU),[4] and a national incidence of 751,000 cases per year. Major differences were identified between children and adults. The incidence of severe sepsis increased greater than100-fold with age (0.2/1000 in children to 26.2/1,000 in patients $>$ 85 years old). The annual total cost nationally was $16.7 billion, with an average cost per case of $22,100.[4] Costs were higher in infants, nonsurvivors, ICU patients, surgical patients, and those with more organ failure.[4] The mortality of severe sepsis also increased with age (10% in children to 38.4% in patients $>$ 85 years old, and 28.6% overall).[4]

Martin and colleagues published an epidemiologic study in the *New England Journal of Medicine* in 2003 that analyzed sepsis from 1979 to 2000 using a nationally representative sample of all nonfederal acute care hospitals in the United States.[2] They suggested that Angus and colleagues may have overestimated the incidence of severe sepsis by a factor of 2 to 4, because the estimated number of deaths exceeded the combined numbers of deaths reported in association with nosocomial bloodstream infections and septic shock. Martin and colleagues identified more than 10 million cases of sepsis occurring during approximately 750 million hospitalizations over the 22-year study period. The incidence of sepsis increased from 82.7 cases per 100,000 population to 240.4 cases per 100,000 population, for an increase of 8.7% per year. Martin and colleagues suggested that possible reasons for a true increase in the incidence of sepsis included increasing microbial resistance, the epidemic of human immunodeficiency virus (HIV) infection, and the increased use of invasive procedures, immunosuppressive drugs, chemotherapy, and transplantation.

Martin and colleagues[2] identified several other important changes that occurred during the 22-year study period. Gram-negative infections predominated until 1987, when gram-positive bacteria became more prevalent, increasing by an average of 26.3% per year. In 2000, gram-positive bacteria accounted for 52.1% of sepsis cases, whereas gram-negative bacteria were responsible for 37.6%. Of note, fungal organisms increased by 207% during the study period. Despite a decline in mortality rates from sepsis from 1979 to 2000, the increased incidence of sepsis resulted in a significant increase in the number of in-hospital deaths resulting from sepsis, increasing from 43,579 (21.9 per 100,000 population) to 120,491 (43.9 per 100,000 population). Racial disparities were also striking, with nonwhites having almost twice the risk of sepsis as whites. The highest risk was among African-American men, in whom sepsis occurred at the youngest age and resulted in the most deaths. Martin and colleagues did not focus on the pediatric population. The significant differences between pediatric and adult patients observed in the study by Angus and colleagues[4] and the scarce data on the epidemiology of sepsis in children became the incentive for a follow-up study by the University of Pittsburgh research group.

Using the same 1995 hospital discharge and population database that Angus and colleagues had studied, Watson and colleagues estimated 42,364 cases of pediatric severe sepsis per year nationally (0.56 cases per 1,000 population per year).[14] The incidence was 15% higher in boys than in girls and highest in infants (5.16/1000) compared with older children (0.20/1000 in those 10 to 14 years of age).[14] Half of all children had underlying comorbidity.[14] The majority of infectious causes were either respiratory (37.2%) or primary bacteremia (25.0%), although this varied by age, with bacteremia being more common in neonates and respiratory infections predominating in older children.[14] The mean length of stay (LOS) was 31 days with very-low-birth-weight (VLBW) newborns, weighing less than 1500 g at birth, accounting for 40% of the total hospital days.[14] Estimated annual total costs were $1.97 billion nationally, with a mean cost of $47,050, which is significantly more than the $22,100 cost per case for adults and children combined quoted by Angus and colleagues.[14] Thirty-one percent of the costs were incurred by VLBW newborns.[14]

Watson and colleagues demonstrated that hospital mortality was 10.3% (4,383 deaths nationally or 6.2 per 100,000 population), and more than one fifth were low-birth-weight newborns weighing less than 2500 g at birth.[14] Not surprisingly, hospital mortality was higher in children with neoplasms, HIV infection, and those undergoing surgical

procedures.[14] The risk of death increased with increasing number of dysfunctional organs (7.0% with single-organ failure to 53.1% for patients with greater than or equal to four-organ systems failing).[14] Although sepsis-associated mortality in children has fallen from 97% in 1966[23] to 10.3% in 1995[14] and remains lower than adult sepsis-associated mortality, without a doubt, sepsis is still a significant health problem in infants and children.

## Pathogenesis

The pathogenesis of sepsis is summarized in Figure 10-2. Bacterial invasion secondary to barrier failure leads to the local release of lipopolysaccharide (LPS), with consequent formation of an LPS–lipopolysaccharide binding protein (LBP)–CD14–Toll-like receptor-4 (TLR-4) complex on neutrophils, macrophages, and endothelial cells. Signaling via this complex results in activation of the complement system, clotting cascade, as well as various inflammatory cells. This process leads to the release of inflammatory mediators, which up-regulate adhesion molecules and promote chemotaxis of neutrophils and macrophages. The activated cells release microbicidal agents typically designed for bacterial killing but which may promote distant organ injury and SIRS if the inflammatory process is "uncontrolled." Predictably, immunocompromised infants and children, as well as preterm and term neonates who classically have significant host defense impairment, are particularly vulnerable to infections. Such infections may elicit an inflammatory response, which may be exaggerated at times and result in significant host tissue destruction. Failure to control either the infection itself or the host inflammatory response may follow a predictable course along the sepsis continuum: SIRS, sepsis, severe sepsis, septic shock, MODS, and, ultimately, death.[21]

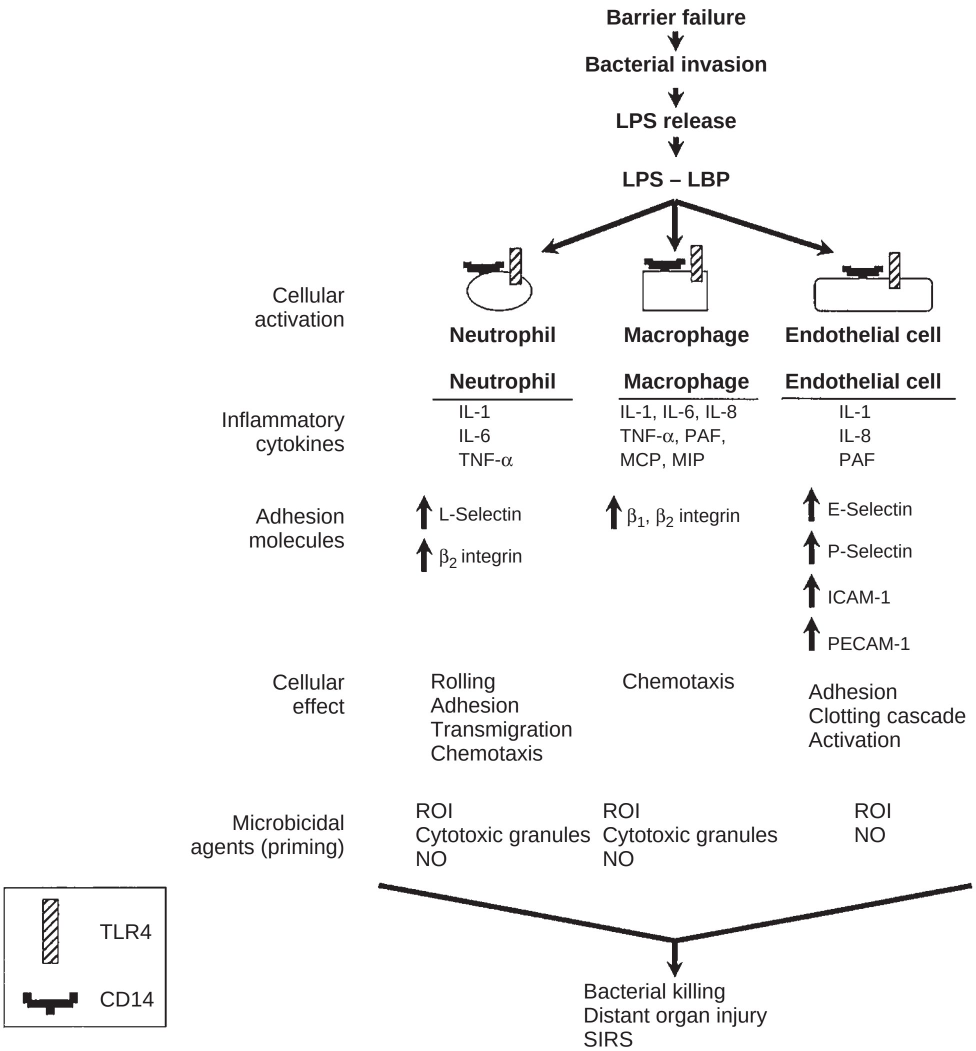

FIGURE 10-2 Pathogenesis of systemic inflammatory response syndrome (SIRS). Bacterial invasion secondary to barrier failure leads to the local release of lipopolysaccharide (LPS), with consequent formation of an LPS–lipopolysaccharide binding protein (LBP)–CD14–Toll-like receptor 4 (TLR-4) complex on neutrophils, macrophages, and endothelial cells, resulting in cellular activation. Inflammatory cytokines are released, up-regulate adhesion molecules, and promote chemotaxis of neutrophils and macrophages. (The complement system, clotting cascade, and lymphocyte population may also be activated, but this is not shown in the diagram.) The activated cells release microbicidal agents typically designed for bacterial killing, but they may be injurious and promote distant organ injury and SIRS if the inflammatory process is uncontrolled. ICAM, intercellular adhesion molecule; IL, interleukin; MCP, monocyte chemotactic protein; MIP, macrophage inflammatory protein; NO, nitric oxide; PAF, platelet-activating factor; PECAM, platelet-endothelial cell adhesion molecule; ROI, reactive oxygen intermediate (or species); TNF, tumor necrosis factor.

This section on pathogenesis examines the determinants of infection: host defense mechanisms and bacterial virulence. Host defense mechanisms include barriers to infection and host immunity. The host immune system classically mounts a well-orchestrated response aimed at destroying the invading microbe. Both cellular immunity (neutrophils, monocyte-macrophages, and lymphocytes) and humoral factors (immunoglobulins, complement, and cytokines) will be discussed, because they represent the final common pathway for the development of SIRS. Bacterial virulence is then examined in detail. Impairment or failure of the intrinsic host defense mechanisms and significant virulence of invading microbes increase the likelihood of successful establishment of infection and development of sepsis. This section ends with a separate discussion of impaired neonatal host defense mechanisms.

## HOST DEFENSE MECHANISMS

### Barriers to Infection

Host defense mechanisms begin with anatomic barriers to infection: the presence of indigenous microbial flora on the skin, oropharynx, respiratory, gastrointestinal, and genitourinary tracts. These ubiquitous host bacteria prevent colonization by foreign or pathogenic microbes by blocking adherence to the epithelial barrier or by competing for nutrients. Each organ system has additional local protective mechanisms as well. The largest organ in the body, the skin, limits bacterial replication by maintaining a relatively acidic environment as well as undergoing regular desquamation, which severely hinders bacterial adherence. Gastric acidity impedes bacterial replication and colonization. Intestinal mucus and peristalsis as well as the cilia of the respiratory epithelium prevent bacterial adherence. Immunoglobulin A (IgA)-rich secretions in the oropharynx, nasopharynx, and tracheobronchial tree also impair bacterial adherence to the mucosa. For infection to occur, there must be either a breach in the integrity of the normal protective barrier or a sufficiently virulent microbe must penetrate the barrier (Fig. 10-3). Barrier failure may be caused by trauma or direct tissue injury, surgery, malnutrition, burns, immunosuppression, shock, and reperfusion injury following ischemia.[24] For example, during ischemia, consumption of adenosine triphosphate results in the accumulation of adenosine diphosphate, adenosine monophosphate, inosine, and hypoxanthine. Xanthine oxidase activity is also increased, but its effect is initially blunted because oxygen is required to oxidize hypoxanthine to xanthine. However, during reperfusion, oxygen is supplied, hypoxanthine is oxidized,

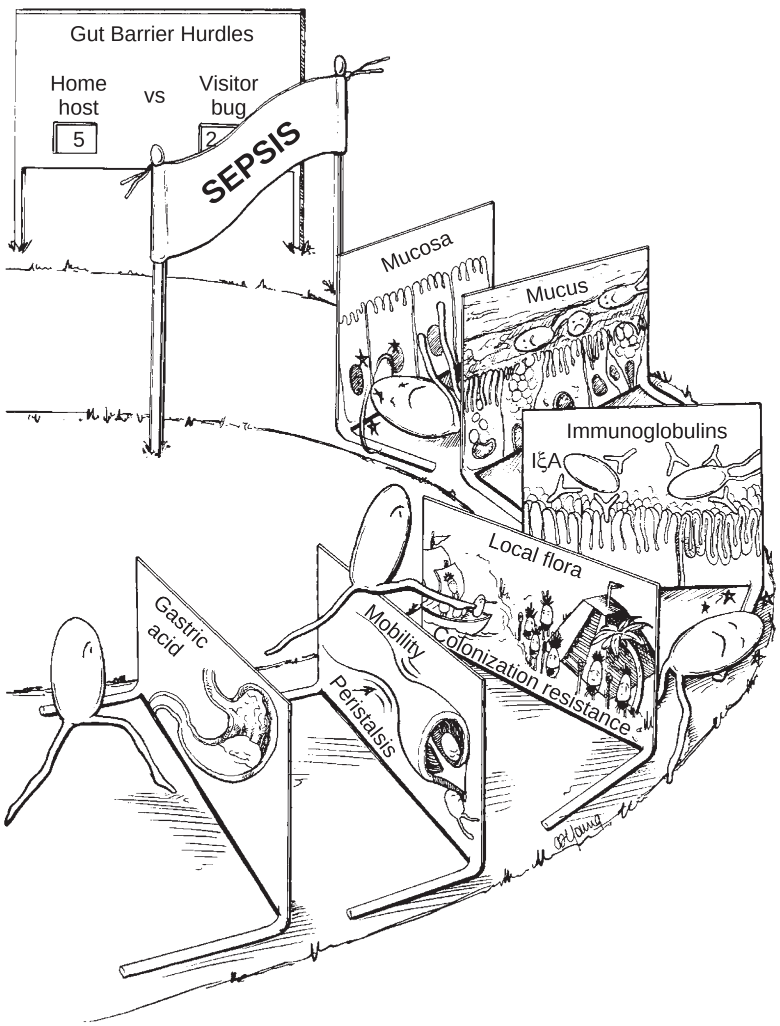

**FIGURE 10-3** The gut barrier is envisioned as a series of hurdles that bacteria must overcome to penetrate the epithelial layer and disseminate systemically. First hurdle: Gastric acid lowers intragastric pH, promoting a hostile environment for bacterial growth. Second hurdle: Coordinated peristalsis continually sweeps bacteria downstream, thus limiting their attachment to the mucosal surface. Third hurdle: Indigenous microbial flora (aerobes and anaerobes) prevent the overgrowth of pathogenic Gram-negative aerobic bacteria. Fourth hurdle: IgA, a nonbactericidal immunoglobulin, coats and aggregates bacteria, preventing their attachment to the mucosal surface. Fifth hurdle: Intestinal mucus forms a weblike barrier to prevent bacterial attachment to the enterocyte.

and toxic reactive oxygen intermediates (ROIs), or species such as superoxide ($O_2^-$) and hydrogen peroxide ($H_2O_2$), are formed. These ROIs can mediate direct tissue injury and thus result in gut barrier failure.[25–28] This results in adherence of bacteria, with subsequent penetrance and internalization. The development of clinical infection (bacterial survival and replication within the host) is dependent on the virulence of the microbe and its ability to evade both the local cellular and humoral host defense mechanisms.

## Cell-Mediated Immunity

***Neutrophils*** Neutrophils constitute the first line of defense in response to infection, tissue injury, or other triggers of inflammation. Egress from the circulation into the tissues is a highly regulated process that involves complex interactions between receptors on the phagocytes and the vascular endothelial cells. These interactions are partially governed by cytokines or other inflammatory mediators. The sequence of events occurs as follows: (1) neutrophil adherence to the endothelium, (2) migration of the neutrophil through the endothelium to the site of injury or inflammation (diapedesis), and (3) stimulation or priming of the neutrophil for killing.

Neutrophil adherence is regulated by adhesion molecules on both the neutrophil and the endothelial cell. There are three classes: selectins, integrins, and the immunoglobulin superfamily. Selectins direct the first step in the adhesion cascade, which involves the rolling of the neutrophil along the vascular endothelium. Specifically, leukocyte (L)-selectin binds endothelial (E)-selectin and platelet (P)-selectin, which are both present on activated endothelial cells.[29]

Migration of the neutrophil to the site of inflammation requires the formation of a firm adhesion between the neutrophil and endothelial cell. This step is governed by the $\beta_2$ integrin CD11b/CD18 on the neutrophil and the intercellular adhesion molecule-1 (ICAM-1) on the endothelial cell.[30] Interestingly, patients with leukocyte adhesion deficiency are susceptible to recurrent bacterial infections, because they lack the $\beta_2$ integrin receptor CD11b/CD18. Their neutrophils fail to adhere to the endothelium and therefore diapedesis cannot occur.[31]

Lipopolysaccharide released by bacteria enhances neutrophil–endothelial interactions directly and indirectly. LPS stimulates the release of inflammatory mediators, such as tumor necrosis factor-$\alpha$ (TNF-$\alpha$), interleukin-1 (IL-1), and interferon-$\gamma$ (IFN-$\gamma$), which upregulate E-selectin and ICAM-1 expression on endothelial cells.[29,32] In addition, LPS forms a complex with LBP, which then binds to the CD14 molecule and TLR-4 on the neutrophil (and monocyte) and leads to up-regulation of the $\beta_2$ integrin CD11b/CD18. Thus LPS plays an important role in neutrophil adhesion and migration.[33,34]

After the firm adhesion step, neutrophil diapedesis is regulated by platelet-endothelial cell adhesion molecule-1 (PECAM-1), which normally maintains the vascular permeability barrier and modulates transendothelial migration of neutrophils and monocytes.[35–38] Antibodies to PECAM-1 lead to leaky barriers and inhibit neutrophil transmigration.[39] In addition to PECAM-1, neutrophil egress requires the presence of a chemotactic gradient through the extracellular matrix. A wide variety of chemotaxins abound at sites of inflammation, such as small bacterial peptides, monocyte chemotactic protein-1 (MCP-1), platelet-activating factor (PAF), and leukotriene $B_4$. Probably the two most important chemotaxins for neutrophil diapedesis are IL-8 and C5a. Interaction between specific receptors on the neutrophil and the chemotaxin evokes a cascade of secondary intracellular signaling events: translocation of protein kinase C from the cytoplasm to the cell membrane, protein kinase C–dependent phosphorylation, and an increase in free calcium in the cytosol. This results in conformational changes in the cytoskeleton of the neutrophil that allow its transendothelial egress and rapid movement toward the chemotactic gradient.[40] As one would expect, specific monoclonal antibodies against adhesion molecules disrupt the neutrophil–endothelial cell interaction and inhibit neutrophil chemotaxis, thus potentially impairing the ability to fight bacterial infection.[41]

The final step in the neutrophil response to infection is the phagocytosis of the microbe with subsequent intracellular killing. Phagocytosis is greatly enhanced by prior opsonization of the bacteria with specific immunoglobulins. This results in complement activation, the deposition of additional ligands or receptors on the bacterial surface, and the facilitation of neutrophil adherence to the microbe. This interaction results in the complete internalization of the microbe into endosomal compartments known as phagosomes. Prior stimulation or priming of the neutrophil by inflammatory cytokines or chemotaxins activates it for more efficient killing. Bacteria are then killed by the fusion of lysosomes containing potent microbicidal agents with the phagosome. In the phagolysosome, both oxygen-dependent and oxygen-independent pathways facilitate microbial killing.

The major oxygen-dependent mechanisms involve the formation of ROIs by the enzyme nicotinamide adenine dinucleotide phosphate oxidase. The active form of the enzyme is assembled in the cell membrane and catalyzes the reduction of molecular oxygen ($O_2$) to superoxide ($O_2^-$), the so-called respiratory burst. Superoxide is converted to hydrogen peroxide ($H_2O_2$) by superoxide dismutase. $H_2O_2$, in turn, can react with superoxide in the presence of iron or other metals to give the potent ROI hydroxyl radical ($^\circ OH$). Alternatively, $H_2O_2$ can react with chloride ($Cl^-$) in the presence of myeloperoxidase, an enzyme found in the cytoplasmic granules, to give the highly reactive hypochlorous acid (HOCl). HOCl, in turn, reacts with endogenous nitrogen-containing compounds to form the powerful oxidizing agents chloramines, which account for much of the neutrophil's cytotoxicity.[42,43]

The principal oxygen-independent microbicidal pathway is affected mainly by a number of peptides contained in specific cytoplasmic granules, including lysozyme, elastase, lactoferrin, cathepsin, and defensins. Many of these peptides act synergistically to promote microbial killing. For instance, defensins and elastase increase bacterial membrane permeability, allowing penetration by other microbicidal peptides or ROIs.

***Monocytes-Macrophages*** The monocyte-macrophage shares many similarities with the neutrophil in host defense mechanisms because it arises from the same stem cell as the granulocyte. The stem cell gives rise to the monoblast, which differentiates into a promonocyte, and then the monocyte. Once released into the bloodstream, monocytes migrate to various tissues and organs, where they terminally differentiate into macrophages. These mature macrophages are characterized by the acquisition of specific granules containing enzymes as well as receptors for growth factors and complement.[44–46]

Macrophages play an important role in the host defense against intracellular pathogens. Like neutrophils, they migrate to sites of inflammation in response to various chemotaxins, such as C5a, bacterial peptides, foreign antigens, and cytokines (IL-1, TNF-$\alpha$, and MCP-1). They also express adhesion molecules, such as L-selectin as well as $\beta_2$ and $\beta_1$ integrins. The latter is an important distinction from the neutrophil, because it allows the macrophage to migrate to sites of inflammation in patients lacking the $\beta_2$ integrin receptor (i.e., leukocyte adhesion deficiency). Macrophages can phagocytose and kill many common bacteria, though less efficiently than the neutrophil. The macrophage's mechanisms of intracellular killing closely resemble those of the neutrophil, with both oxygen-dependent and oxygen-independent pathways. However, in addition to the production of ROIs, macrophages make a substantial amount of the potent molecule nitric oxide (NO), which is also microbicidal.

NO is the product of the conversion of arginine to citrulline by nitric oxide synthase (NOS). There are three isoforms of NOS: NOS-1 (neuronal NOS) and NOS-3 (endothelial NOS) are calcium dependent and are expressed constitutively at low levels. NOS-2 (inducible NOS or iNOS) is usually absent except when induced in response to inflammatory mediators (e.g., LPS, cytokines) and is the principal isoform found in macrophages.[47,48] NO has been shown to have both cytotoxic and cytostatic activity against a wide range of microorganisms in vitro and in vivo; these include bacteria, viruses, fungi, mycobacteria, parasites, and *Chlamydia*.[49] However, there is no clear evidence that human phagocytes produce sufficient amounts of NO to account for its antimicrobial activity.[48] In fact, data suggest that NO must react with ROIs to exert cytotoxicity.[50] The precise nature of this reaction is not completely understood. Under certain conditions NO may be cytostatic or cytotoxic, while under others, it may be cytoprotective.[48,51,52]

Following the phagocytosis of bacteria and intracellular killing, antigenic fragments derived from these microbes are processed by the macrophage and then presented to T lymphocytes in the context of major histocompatibility complex (MHC) class II molecules. This interaction elicits specific immune responses that amplify the cytokine (and cellular) response to further enhance microbicidal activity. This highly specialized function is one of the key distinguishing features of the macrophage in the host defense against microbes.

***Lymphocytes*** Although neutrophils and monocytes-macrophages represent the major effectors of the host defense against microbes, certain microorganisms are able to evade their cytotoxic arsenal. These organisms must be eliminated through different means. The lymphocytes, and, to a lesser extent, the natural killer (NK) cells form the secondary line of defense against invading microbes.

Lymphocytes arise from a hematopoietic stem cell in the bone marrow. Early in the differentiation pathway, the lymphoid progenitor cell undergoes maturation in one of two distinct compartments, where it acquires its phenotypic and functional characteristics. Certain cells leave the bone marrow to undergo a process of "education" or maturation in the thymus. These mature T cells migrate from the thymus to reside in peripheral lymphoid organs, such as the spleen, lymph nodes, and intestinal Peyer patches. Other cells undergo maturation either in the bone marrow or fetal liver, where they become committed to immunoglobulin synthesis (B cells).

Both B cells and T cells play an important role in the elimination of microbes. B cells, in particular, produce opsonizing antibodies that facilitate phagocytosis of encapsulated organisms. They also secrete other immunoglobulins, such as IgA, that play a central role in mucosal immunity by preventing bacterial adherence and invasion. In addition, B cells participate in antibody-dependent cell-mediated cytotoxicity. T lymphocytes, in contrast, are the principal effectors of cell-mediated immunity against intracellular pathogens. T-cell–mediated killing requires: (1) recognition of the inciting antigen or microbe, (2) cellular activation, (3) clonal expansion, and (4) targeted killing.

Antigen presentation and recognition are governed in part by a family of normally occurring cell surface proteins known as major histocompatibility proteins. There are two classes of MHC proteins: class I, which is expressed in virtually all nucleated cells, and class II, which is expressed primarily in antigen-presenting cells (APCs), such as macrophages, dendritic cells, and B lymphocytes. These cells phagocytose bacteria, processing or breaking down the organism into smaller fragments or peptides that are then bound to the MHC class II proteins and inserted into the cell membrane of the APCs. T cells bearing the same MHC molecules are then able to recognize this MHC-peptide complex on the APC. Interaction between this complex and specific ligands on T helper (TH) cells (CD4+) leads to cytokine production, recruitment of additional phagocytic cells, and proliferation of different classes of lymphocytes: B cells, TH cells, and CD8+ cytotoxic T lymphocytes (CTLs). Ultimately, microbial killing is promoted primarily by the CTLs. Infected cells that cannot process antigen in the context of an MHC class II protein form a complex between MHC class I molecules in the cell and antigenic peptides derived from the invading pathogen. This complex is readily recognized and targeted for destruction by the CTLs. Thus although only APCs can process antigen in the context of MHC class II molecules and elicit a TH response, all cells infected by an intracellular pathogen can present foreign antigen in association with MHC class I molecules, which serve as the target for the CTLs.

T-cell activation is dependent on two important events: stimulation by the T-cell receptor signal-transducing protein complex CD3 and simultaneous cross-linking of the CD4 or CD8 ligand to the appropriate MHC peptide complex on an APC or infected cell (CD4–MHC class II–APC and CD8–MHC class I–infected cell). T-cell activation initiates a cascade of events leading to calcium mobilization, activation of protein kinases, and transcription/translation of specific genes encoding proteins that will help to eliminate the pathogen. These proteins include perforins and serine proteases in CTLs and various cytokines in TH cells. Activated CTLs bind to cells expressing the MHC peptide complex and release cytotoxic granules, such as perforin, which can "perforate" the cell membrane creating a hole that leads to osmotic lysis. Alternatively, CTLs may release serine proteases that induce apoptosis in the infected cell without affecting the effector cell.[53–55] Similar to the CTL, NK cells, which are a variant of the lymphocyte family, can also use granule exocytosis to kill infected target cells. In addition, these cells possess Fc receptors for immunoglobulin and therefore can participate in antibody-dependent cell-mediated cytotoxicity. Two classes of TH cells have been described based on their cytokine profile: TH1

cells produce IL-2 and IFN-γ, while TH2 cells produce IL-4, IL-5, IL-10, and IL-13. Other cytokines, such as IL-3 and granulocyte-macrophage colony-stimulating factor, are produced by both TH1 and TH2 cells. TH1 cells evoke primarily a T-cell–mediated response characterized in part by recruitment of macrophages to the site of infection, followed by macrophage activation by IFN-γ.[56,57] In contrast, TH2 cytokines shift the balance toward a humoral (B-cell) response.

### Humoral Factors

Thus far, we have emphasized the importance of cell-mediated immunity in the host defense against microbes. However, this cellular response is a highly complex phenomenon that is often initiated and optimized by diverse humoral factors, including immunoglobulins, complement activation, and cytokines, which is discussed in this section.

***Immunoglobulins*** Immunoglobulins or antibodies represent a class of proteins that are synthesized by mature B lymphocytes or plasma cells, mainly as a result of cognate interaction between a TH cell and an antigen-presenting cell bearing an MHC-plus-peptide complex. This interaction may lead to cytokine synthesis and B-cell proliferation and maturation, with production of distinct classes of immunoglobulin. The primary role of antibodies in the host defense against microbes is to prevent bacterial adherence to, and subsequent invasion of, susceptible host cells. The mechanisms involved in this process include opsonization of the microbe to facilitate phagocytosis and complement activation with deposition of complement fragments on bacterial membranes to further enhance phagocytosis and subsequent bacterial killing. Neutralization of intrinsic microbial toxins or virulence factors to impede bacterial attachment to cell surfaces also occurs. There are five major classes of immunoglobulins: IgA, IgG, IgM, IgD, and IgE. Among these groups, IgG, IgM, and IgA are the predominant antibodies that mediate the host defense against microbes.

IgM is the largest of the immunoglobulins. It is the main component of the initial response to infection or antigenic stimulus. As such, it has a half-life of only 5 to 6 days, and its level declines steadily as IgG levels increase. Because of its size, IgM is found exclusively in the intravascular space, serving as an efficient bacterial agglutinin and as a potent activator of the complement system.

IgG is perhaps the most abundant antibody, constituting nearly 85% of serum immunoglobulins. It is found in both intravascular and extravascular (tissue) spaces. It is the only immunoglobulin that crosses the placenta from the mother to the fetus. IgG is the predominant class of antibody directed against bacteria and viruses. The biological potency of the molecule resides in its ability to opsonize bacteria by binding the antigen with its Fab component, while simultaneously binding the Fc receptor on the neutrophil, monocyte, or macrophage with its own Fc component. Moreover, IgG aggregates can activate the complement system.

Antibodies of the IgA isotype play a critical role in local mucosal immunity. They are synthesized by plasma cells within lymphoid tissue situated subjacent to the epithelial surfaces where they are secreted. IgA is released as a dimer and acquires a secretory component as it passes through the epithelial cell to exit at the mucosal surface in the form of secretory IgA. The latter serves as an antiseptic paint that binds pathogenic microbes and thus prevents their attachment, colonization, and subsequent invasion of tissue. Note, however, that IgG, IgM, and, to a lesser extent, IgE can also play a role in local mucosal immunity, especially in patients with congenital IgA deficiency.

***Complement System*** Although antibodies are effective at recognizing antigenic determinants on microbial pathogens, they are unable to independently kill the microorganisms. Following opsonization, they must rely on phagocytes to ingest the microbe and on complement activation to further enhance or augment their opsonic ability to neutralize and ultimately kill the ingested pathogen. There are two distinct pathways for complement activation: classical and alternative. Antigen-antibody complexes are the predominant initiators of the classical pathway. In contrast, bacterial cell wall fragments, endotoxin (or LPS), cell surfaces, burned and injured tissue, and complex polysaccharides are capable of activating the alternative (properdin) pathway. Stimulation through either pathway initiates a cascade of events that can lead to marked complement activation as a result of an elaborate amplification process. The most critical point in this cascade occurs at C3, where both pathways converge to form C3a and C3b. C3a is both a vasodilator and a chemotaxin for phagocytes. The C3b molecule, in contrast, is the most critical component of the complement cascade, because this enzyme permits dramatic amplification of the system by facilitating further cleavage of C3 to C3a and C3b, as well as enhanced C3b production by the alternative pathway. Moreover, C3b is the most potent biologic opsonin, with cell surface receptors present on most phagocytes. Deposition of C3b on the surface of bacteria can promote its lysis by activating the distal components of the complement cascade (C8 and C9), which insert into and damage the cell membrane, resulting in osmotic lysis. In the process, another even more potent chemotaxin, C5a, is released, a molecule that is also capable of inducing a respiratory burst in the phagocyte and thus facilitates bacterial killing.

***Cytokines*** The mediators that regulate the complex interactions among the various cellular effectors in the cytotoxic arsenal against microbes are generally known as cytokines. They represent a heterogeneous class of glycoproteins that are secreted by a variety of cells, including neutrophils, monocytes-macrophages, B and T lymphocytes, NK cells, endothelial cells, and fibroblasts. In general, there is extensive pleiotropy and redundancy in cytokine function. Some cytokines serve to amplify the inflammatory response, while others function to limit its extent.

Proinflammatory cytokines, such as TNF-α, IL-1, IL-6, IL-8, IL-11, and IL-18 share a number of similar properties; other cytokines that confer more specific immunity against certain pathogens, such as IL-2, IL-4, IL-12, and IL-13, also exhibit a number of similarities. Anti-inflammatory cytokines, such as IL-10 and transforming growth factor-β, neutralize the biological activities of the proximal mediators of inflammation——the monocytes-macrophages and their secretory products.

Tumor necrosis factor-α is one of the earliest inflammatory mediators released in response to infection. The predominant source of TNF-α is the monocyte-macrophage, although NK

cells, mast cells, and some activated T cells also produce it, but to a lesser extent. TNF-α exerts a number of important functions in the inflammatory response. At low levels, it may (1) enhance endothelial cell adhesiveness for leukocytes; (2) promote neutrophil chemotaxis or recruitment to sites of inflammation; (3) stimulate the production of other proinflammatory cytokines that mimic TNF function, such as IL-1, IL-6, and IL-8; (4) prime neutrophils and monocytes-macrophages for microbial killing; and (5) up-regulate the expression of MHC class I molecules on target cells to facilitate killing. However, excess or uncontrolled TNF production, as occurs in overwhelming sepsis, may contribute to profound hemodynamic instability because of cardiovascular collapse, depressed myocardial contractility, and disseminated intravascular coagulation.

Interleukin-1 is released relatively early during the inflammatory response to infection or injury. It is produced by monocytes-macrophages and by epithelial, endothelial, and dendritic cells in response to endotoxin challenge or TNF stimulation. There are two biologically active forms of the molecule: IL-1α, which may be membrane associated, and IL-1β, which is active in soluble form. They share similar properties with TNF-α, including induction of other cytokines, such as IL-2, IL-6, and IL-8. However, unlike TNF-α, they exert little or no effect on MHC class I expression, nor do they play a role in hemodynamic collapse.

Interleukin-6 is the most important regulator of hepatic production of acute phase reactants, such as C-reactive protein. It is produced by a variety of cells, including mononuclear phagocytes, TH2 cells, and fibroblasts, in response to tissue injury, infection, TNF, and IL-1. It stimulates B-cell differentiation and enhances CTL maturation. IL-6 acts through a membrane-bound receptor that can shed and continue to regulate IL-6 activity away from the site of production.[58]

Interleukin-8 is secreted by monocytes-macrophages, T cells, endothelial cells, and platelets in response to inflammation, IL-1, and TNF. It is one of the most potent chemotactic and activating factors for neutrophils. IL-8 belongs to a family of chemoattractants that includes other chemokines, such as MCP-1, MCP-2, and MCP-3; macrophage inflammatory protein (MIP-1a, MIP-1b); and RANTES (regulated on activation, normal T expressed and secreted). These mediators are released early in inflammation, mainly by monocytes-macrophages but also by neutrophils and platelets. MIP-1a and MCP-1 may act in an autocrine fashion to recruit additional mononuclear phagocytes to sites of inflammation, thus potentially amplifying the inflammatory response. Another proinflammatory macrophage product, migration inhibitory factor, appears to be induced by TNF at sites of inflammation and serves to trap macrophages at those sites and elicit further TNF-α production by them.[59] RANTES is a lymphocyte-derived chemoattractant that promotes macrophage chemotaxis, up-regulates adhesion molecules, and enhances the release of inflammatory mediators.[59] Other chemoattractants include PAF, which is secreted by endothelial cells and macrophages, and leukotriene B4. In addition to serving as a chemoattractant for neutrophils, PAF up-regulates CD11b/CD18 ($\beta_2$ integrin) on the neutrophil.[60] In general, the chemoattractants not only recruit phagocytes to sites of inflammation but also appear to prime these cells for subsequent cytotoxic effector function.[61–63]

Other cytokines that play an important role in the elimination of invading microbial pathogens include products of TH1 cells, such as IL-2 and IFN-γ, as well as products of TH2 cells, such as IL-4 and IL-13. In general, TH1 cytokines are produced in response to bacterial, viral, or protozoan infections, and TH2 cytokines are secreted mostly in response to metazoa or allergens.[64,65] IL-2, the prototypical T-cell growth factor, directly amplifies the immune response by inducing cellular proliferation. It also augments killing by activating NK cells.

Interferon-γ is perhaps one of the most important macrophage activating factors. It stimulates the macrophage to express MHC class II molecules, which is necessary for antigen processing and for amplification of the immune response. In addition, it induces NOS activity (NOS-2), which is critical for intracellular killing of invading pathogens.[49,66] IFN-γ may enhance microbial killing by inducing TNF-α production and TNF-α receptor expression by macrophages and by activating NK cells. IFN- γ is also produced by activated CTLs in response to IL-2 and antigen expressed in the context of MHC class I molecules and by NK cells in response to IL-12.

Interleukin-12, primarily a macrophage product, is the most potent inducer of IFN-γ production by NK cells. In addition, it influences the uncommitted TH cell to differentiate into the TH1 phenotype, secreting IL-2 and IFN-γ.[60] IL-12 can support most of the functions performed by IL-2, except perhaps its proliferative effect. Therefore IL-12 plays an important role in the elimination of intracellular organisms.

The role of TH2 cytokines, such as IL-4 and IL-13, is less clear. Although they partly promote monocyte differentiation and may induce the expression of adhesion molecules in the endothelium, they are mostly responsible for immunoglobulin isotype switching in B cells, leading predominantly to IgG4 and IgE production.

Cytokine production and signaling are central to the sepsis response. Yet, under similar clinical and demographic circumstances, individuals may exhibit distinct responses to an identical stimulus. One possible explanation is differential protein expression between the two patients. For example, whereas a traumatic insult in one patient may lead to overwhelming sepsis and result in admission to the intensive care unit, another individual may exhibit a more attenuated response characterized by fever and tachycardia for a couple of hours, followed by resolution of the symptoms. Proteins may be expressed differently for a number of reasons, but one significant factor may be the genetic makeup of the individual. Gene polymorphisms or single nucleotide polymorphisms are differences in nucleic acid base pairs that occur every 100 bases. The change in base pairs that occurs in the promoter region of the gene may lead to overproduction or underproduction of a gene product. Recent evidence suggests that the presence of one gene polymorphism may serve as a marker for additional protective gene polymorphisms.[67] Cytokine gene polymorphisms may explain differences in the inflammatory response among individuals.[68]

### Bacterial Virulence

Microbial pathogens possess unique biochemical properties known as virulence factors, which permit the successful establishment of infection within the host. If these virulence factors escape the host immune system, the net result will be sufficient multiplication or persistence of the microorganism within the host to cause significant damage to local tissue or

allow transmission of the microorganism to other susceptible hosts.

The first and perhaps the most critical step in the process of microbial infection is adherence of the pathogenic microorganism to the cell surface. Some organisms multiply at the site of attachment, while others use this attachment as a prerequisite for microbial invasion. Elimination of this first step may completely abrogate colonization and invasion by microbial pathogens.

The process of microbial adherence requires specific interaction between specific molecules on the surface of the bacteria, known as adhesins, and specialized receptors on the host cell. Bacterial fimbriae or pili are perhaps the best studied adhesins that have been shown to promote bacterial adherence to mucosal surfaces. Members of the Enterobacteriaceae family exhibit prominent, morphologically similar pili—type I fimbriae—that permit their attachment to the d-mannose receptor sites on epithelial cells.[69,70] Further, certain bacteria, such as *Escherichia coli,* can simultaneously express different types of adhesins—type I, X, and P fimbriae—a property that clearly enhances the microbe's ability to attach to host surfaces.[71] Other adhesins include invasins, proteins that not only mediate bacterial attachment but also facilitate entry into the host, and hemagglutinin, which is expressed on pathogens such as *Bordetella pertussis, Salmonella typhimurium,* and influenza virus.[71] The host also secretes proteins that indirectly facilitate bacterial adherence; these include proteins of the extracellular matrix, namely, fibronectin, laminin, collagen, and vitronectin. These proteins share a common peptide sequence, Arg-Gly-Asp (RGD), which is also found on many microbial pathogens that bind to mammalian cells.[72] For instance, *Staphylococcus aureus* and *Streptococcus pyogenes* are known to bind fibronectin on epithelial surfaces.[71] Fortunately, bacterial binding to extracellular matrix proteins is usually of low affinity and rarely leads to microbial invasion.

Bacterial adherence allows microorganisms to penetrate the intact epithelial barrier of the host and eventually replicate. However, the mere adherence of the bacteria may not be sufficient for subsequent entry into the host cell. Bacterial internalization requires a high-affinity interaction between adhesins and specific receptors on the cell surface. The integrin receptors appear to be the primary targets on the cell surface for these interactions, because they can bind bacterial adhesins as well as extracellular matrix proteins, such as fibronectin, laminin, collagen, and vitronectin. It is the affinity of this interaction that determines whether the microbe becomes internalized or remains adherent to the host cell surface.[72]

Other bacterial virulence factors may also facilitate internalization. For instance, the cell surface protein invasin, found on *Yersinia* species, serves a dual purpose as an adhesin and an enhancer of bacterial invasion. It binds to $\beta_1$ integrins on the cell surface, resulting in internalization of *Yersinia*. Transfer of the invasin gene to nonpathogenic *E. coli* renders the organism capable of internalization and host tissue invasion.[72,73] Another variant of the invasin gene, termed the attachment invasion locus, has been identified in *Yersinia* species that cause clinical disease but not in those species that do not cause clinical infection. This molecule may serve as a potential marker of bacterial virulence.

Once bacterial internalization has occurred, the microbe is now located in an endosomal compartment, known as a phagosome, and must escape the intracellular host defense mechanisms to multiply. For internalized bacteria to survive, (1) fusion of the host cell lysosome with the phagosome to form a phagolysosome must be avoided, (2) acidification of the phagolysosome must be prevented, or (3) the antibacterial activity of the phagolysosome must be neutralized. Successful avoidance of these host defense mechanisms permits the establishment and multiplication of the organisms within the host. Bacterial toxins may play an important role in this process either by causing direct damage to host cells or by interfering with host defense mechanisms. For instance, diphtheria toxin creates a layer of dead cells that serves as a medium for bacterial growth. *Clostridium difficile* secretes both an enterotoxin (toxin A) and a cytotoxin (toxin B) that can damage the mucosal epithelium. *Clostridium perfringens* secretes numerous exotoxins with well-defined roles in the microbe's virulence. These toxins are enzymes with specific targets; they include hyaluronidase, collagenase, proteinase, deoxyribonuclease, and lecithinase. Several organisms, such as *Haemophilus influenzae, Streptococcus pneumoniae, Neisseria meningitidis,* and other bacteria that infect the oral cavity produce proteases that are capable of neutralizing local host defense mechanisms.[74] *S. aureus* is able to neutralize ROIs, such as hydrogen peroxide, through the production of catalase.

Likewise, bacterial endotoxins have potent biological properties. LPS consists of three regions: an O-specific side chain, a core polysaccharide, and an inner lipid A region. Most of the biological properties of LPS (also known as endotoxin) are attributed to the lipid A region. In fact, lipid A is believed to be the principal mediator of septic shock. LPS (especially the lipid A component) triggers an inflammatory cascade, leading to the release of various inflammatory mediators, including arachidonic acid derivatives, leukotrienes, and proinflammatory cytokines, and complement activation. Endotoxin interacts with inflammatory cells by binding to a complex consisting of soluble and membrane-bound receptors; this leads to a cascade of signaling events that result in increased expression of proinflammatory cytokines. These inflammatory mediators are responsible for the hemodynamic and metabolic events that characterize SIRS.

Another method of evading the host defense mechanisms is for the bacteria to avoid phagocytosis or engulfment by the professional phagocytes, such as the neutrophils and macrophages. Streptococci secrete a streptolysin that inhibits neutrophil migration or chemotaxis and impairs phagocyte cytotoxicity. Encapsulated organisms cannot be eliminated unless specific opsonizing antibodies that bind to the surface of the bacteria and facilitate their attachment to the Fc receptors on the neutrophil are present. These organisms are virulent pathogens in splenectomized patients, especially those younger than 4 years, with 50% mortality for overwhelming postsplenectomy sepsis found in some studies. Finally, certain microbial pathogens may avoid phagocytosis by binding the Fc receptor of IgG with the bacterial cell wall protein A, which is found in many bacteria, including virulent strains of staphylococci. This interaction prevents binding of the Fc receptor of the IgG antibody to the Fc receptor of the neutrophil.

### Neonatal Host Defense

In general, neonates, especially premature infants, show increased vulnerability to bacterial infections and sepsis. This predisposition is closely linked to intrinsic deficiencies in the neonatal host defense apparatus. For term neonates,

production of neutrophils is near the maximal level. Neutrophils constitute approximately 60% of circulating leukocytes; 15% of these neutrophils are immature (bands). These percentages are substantially lower in premature infants. Perhaps one of the most important factors in neonates' increased propensity for bacterial infections is their relative inability to significantly increase the levels of circulating neutrophils in response to stress or infection, resulting primarily from a limited neutrophil storage pool (20% to 30% that of adults) and, to a lesser extent, to increased margination of neutrophils.[75,76] Therefore systemic infections in neonates often lead to severe neutropenia. In fact, the relative degree of depletion of the neutrophil storage pool is a predictor of fatal outcome in neonatal sepsis.[75]

In addition to an already diminished storage pool, neonatal neutrophils show decreased adhesion to activated endothelium.[77,78] This process may be due to decreased L-selectin expression on the surface of neonatal neutrophils and an inability to up-regulate cell surface $\beta_2$ integrin.[69,70] Consequently, the neutrophils are unable to form the high-affinity adhesion to the endothelium that is necessary to effectively respond to a chemotactic gradient and migrate into tissues at sites of inflammation. In fact, several studies have shown that chemotaxis of neonatal neutrophils is substantially less than that of adult neutrophils.[79,80] Further, accumulating evidence suggests that abnormal signal transduction following the binding of chemotactic receptors to membrane receptors on neonatal neutrophils may also contribute to impaired chemotaxis.

Under normal conditions, neonatal neutrophils bind, ingest, and kill bacteria as effectively as adult neutrophils do. However, in the presence of a suboptimal concentration of opsonins, neonatal neutrophils are less efficient at phagocytosis,[81] an important consideration, because neonatal serum is deficient in opsonins. Neonatal neutrophils show normal production of superoxide but a relative decrease in the amount of hydroxyl radical and in the number of specific granules (defensins).[82] Therefore they may exhibit decreased oxygen-dependent and oxygen-independent microbial killing.[82] However, the deficiencies in microbicidal activity appear to be less critical than the substantial reduction in the neonatal neutrophil storage pool and the impairment in neutrophil chemotaxis, except perhaps in the presence of a high bacterial load, when efficient microbial killing becomes crucial.

Although the neonatal neutrophil storage pool may be diminished, the number of monocytes per blood volume in term infants appears to be equal to or greater than that of adults.[83] However, migration of these monocytes to sites of inflammation is significantly delayed compared with adults. Possible explanations for this relative delay in migration include decreased generation of chemoattractant factors for monocytes, impaired monocyte chemotaxis (as has been shown for neutrophils), and inability to up-regulate adhesion molecules on the surface of neonatal monocytes. Yet numerous studies have shown that neonatal monocytes have normal chemotaxis; others suggest that they may have normal migratory capacity but fail to properly orient toward the chemotactic gradient. Similarly, there are several conflicting reports regarding the expression of adhesion molecules on the surface of neonatal monocytes. Some studies show increased expression of $\beta_2$ integrins, while others suggest that these molecules are down-regulated in activated and resting neonatal monocytes. Nevertheless, once they reach the site of active inflammation, neonatal monocytes phagocytose and kill bacteria as effectively as adult monocytes do. They probably use microbicidal mechanisms similar to adult monocytes because they can generate comparable levels of ROIs. However, data on NO production by neonatal monocytes relative to adult monocytes are scant. Activated neonatal monocytes and macrophages produce substantially less IL-6 and TNF-$\alpha$ than their adult counterparts. IL-1 production, in contrast, is equivalent.

Term neonates have a substantially greater number of circulating T lymphocytes than adults do. They also have a greater proportion of CD4+ versus CD8+ T cells compared with adults. These T cells express predominantly a virgin phenotype secondary to their relative lack of exposure to foreign antigens. However, they proliferate effectively in response to mitogenic stimuli. Stimulated neonatal T cells produce large quantities of IL-2. In contrast, production of other cytokines, such as TNF-$\alpha$, IFN-$\gamma$, IL-3, IL-4, IL-5, and IL-10, is either moderately or significantly suppressed.[84–86] Neonates show decreased T-cell–mediated (CTL) cytotoxicity; this phenomenon may be due in part to the relative lack of prior antigenic exposure and the deficiency in cytokine production. Alternatively, the relative decrease in T-cell function may be the result of impaired monocyte-macrophage chemotaxis, resulting in diminished MHC-restricted cognate interactions between antigen-presenting cells and TH cells. Thus cytokine production is significantly reduced, and the inflammatory response is not amplified.

Term neonates also show relative immaturity of B-cell function and development. Although neonatal B cells can differentiate into IgM-secreting plasma cells, they do not differentiate into IgG- or IgA-secreting plasma cells until much later. IgM is more abundant in neonatal than in adult secretions. In contrast, virtually all circulating neonatal serum IgG is derived from maternal placental transfer. In fact, it is not until the third or fourth month of life that neonatal IgG production begins to account for a greater proportion of circulating IgG. As a result, the fetus is protected against most infectious agents for which the mother has adequate levels of circulating IgG antibodies, but not against those microbes that elicit a different immunoglobulin isotype, such as *E. coli* and *Salmonella*. Premature neonates are particularly vulnerable to such infections, because they do not receive sufficient maternal IgG. IgM and secretory IgA, which is detected in neonatal secretions within the first week of life and is abundant in breast milk, may provide compensatory protection against bacterial infection.

In term neonates, the percentage of NK cells, which play an important role against intracellular pathogens by promoting target cell lysis in a non–MHC-restricted fashion, is similar to that of the adult. However, they are functionally and phenotypically immature (CD56−).[87,88] At birth, their lytic potential is only 50% of that of adult NK cells, and they do not reach mature levels until late in infancy. This phenomenon may be partly due to decreased cytokine production (especially IFN-$\gamma$) in neonates, as previously discussed.

In general, because of their reduced levels of immunoglobulins, neonates rely primarily on the alternative (antibody-independent) pathway of complement activation. However, a substantial proportion of term and preterm neonates exhibit a significant reduction in components of both the classic and the alternative pathways of complement activation. The level of C9, a terminal component of the complement system that is critical for killing gram-negative organisms, is diminished,

especially in preterm infants. The relative opsonic capacity of both term and preterm neonates is also impaired. This observation may be the result of inefficient cross-linking of the opsonin C3b after it has been deposited on the microorganism. Alternatively, it may reflect diminished levels of fibronectin, which plays an important role in cell adhesion and facilitates the binding of certain bacteria to phagocytes. Neonates also show decreased production of the potent chemotactic factor C5a. These defects further predispose term and preterm neonates to bacterial infections, because in addition to their already reduced neutrophil storage pool and their depressed levels of immunoglobulin, they cannot effectively use the most potent biologic opsonin, C3b, which is also responsible for amplification of the complement pathway. In addition, they have a decreased influx of phagocytes and impaired killing at the sites of infection owing to the decrease in C5a and in C9.

# Diagnosis

## GOLDSTEIN CRITERIA

Although definitions of the sepsis continuum have been published for adults,[6,11] no such work had been done for the pediatric population until 2002, when an international panel of 20 experts in sepsis convened to modify the published adult consensus definitions for children.[5] Physiologic and laboratory variables used to define SIRS, sepsis, severe sepsis, and MODS required modification for the different developmental stages in children. In addition, comparing pediatric sepsis studies had been very difficult because of the disparity in inclusion criteria and the myriad of pediatric definitions for the sepsis continuum in the literature before 2004. Therefore establishment of age group specific consensus definitions of the pediatric sepsis continuum should facilitate the interpretation and comparison of pediatric clinical trials. The following definitions and guidelines published by Goldstein and colleagues provide a uniform basis for diagnosing sepsis in children (Tables 10-2 to 10-4).

### Age Group–Specific Definitions for Abnormal Vital Signs and Leukocyte Count

Specific definitions for abnormal vital signs and leukocyte count were established in six clinically and physiologically meaningful age groups (see Table 10-2). Premature infants were excluded, because their care occurs primarily in neonatal intensive care units; diagnosis in this group of unique patients will be discussed later. Age groups were defined as newborn (0 days to 1 week), neonate (1 week to 1 month), infant (1 month to 1 year), toddler and preschool (2 to 5 years), school-age child (6 to 12 years), and adolescent and young adult (13 to <18 years).

### Definitions of the Pediatric Sepsis Continuum

Definitions of the pediatric sepsis continuum were established (see Table 10-3). There are several key differences in the terminology of sepsis and its related syndromes between adults and children. The major distinction is that the diagnosis of pediatric SIRS requires that a temperature or leukocyte abnormality be present. This requirement reflects the fact that tachycardia and tachypnea are common presenting symptoms of many pediatric disease processes and are not specific to SIRS or sepsis. A core temperature measured by rectal, bladder, oral, or central catheter probe is required. Temperatures taken through the tympanic, toe, or axillary route are not sufficiently accurate. Notably, bradycardia may be a sign of SIRS in the newborn age group. Although a positive culture confirms the presence of infection, the definition of infection in children also includes specific clinical examination findings, such as petechiae and purpura in the setting of hemodynamic instability; fever, cough, and hypoxemia in the setting of leukocytosis and pulmonary infiltrates; or a distended tympanitic abdomen with fever and leukocytosis associated with perforated bowel.

### Pediatric Organ Dysfunction Criteria

The definition of pediatric septic shock remains problematic, because children typically maintain their blood pressure until they are gravely ill. Thus, unlike adults, there is no requirement for systemic hypotension to make the diagnosis of septic shock, because shock may occur long before hypotension is present in children. Pediatric septic shock is defined as sepsis and cardiovascular organ dysfunction, as noted in Table 10-4. Although adult organ dysfunction criteria have been applied to various pediatric populations, they may be inappropriate for children. Thus the consensus conference established pediatric organ dysfunction criteria (see Table 10-4) based on those used in the Pediatric Logistic Organ Dysfunction, Pediatric-MODS, and Multiple Organ System Failure scores as well as the criteria used in the open-label recombinant human activated protein C study.[5]

**TABLE 10-2**
**Age Group Specific Definitions for Abnormal Vital Signs and Leukocyte Count**

| *Age Group* | *HR (Beats/Minute)* | *RR (Breaths/Minute)* | *SBP (mm Hg)* | *WBC count (WBCs × $10^3$/mm)* |
|---|---|---|---|---|
| Newborn (0 day-1 week) | >180 or <100 | >50 | <65 | >34 |
| Neonate (1 week-1 month) | >180 or <100 | >40 | <75 | >19.5 or <5 |
| Infant (1 month-1 year) | >180 or <90 | >34 | <100 | >17.5 or <5 |
| Toddler/preschool (2-5 years) | >140 | >22 | <94 | >15.5 or <6 |
| School-age child (6-12 years) | >130 | >18 | <105 | >13.5 or <4.5 |
| Adolescent/young adult (13 to <18 years) | >110 | >14 | <117 | >11 or <4.5 |

HR, heart rate; RR, respiratory rate; SBP, systolic blood pressure; WBC, white blood cell.

**TABLE 10-3**
**Definitions of the Pediatric Sepsis Continuum**

**Systemic Inflammatory Response Syndrome (SIRS)***

The presence of at least two of the following four criteria, **one of which must be abnormal temperature or leukocyte count:**

1. Core† temperature of > 38.5° C or < 36° C.
2. Tachycardia, defined as a mean heart rate > 2 SD above normal for age in the absence of external stimulus, chronic drugs, or painful stimuli; or otherwise unexplained persistent elevation over a 0.5- to 4-hour time period **OR for children < 1 year old: bradycardia, defined as a mean heart rate < 10th percentile for age in the absence of external vagal stimulus, beta-blocker drugs, or congenital heart disease; or otherwise unexplained persistent depression over a 0.5-hour time period.**
3. Mean respiratory rate > 2 SD above normal for age or mechanical ventilation for an acute process not related to underlying neuromuscular disease or the receipt of general anesthesia.
4. Leukocyte count elevated or depressed for age (not secondary to chemotherapy-induced leukopenia) or > 10% immature neutrophils.

**Infection**

A suspected or proven (by positive culture, tissue stain, or polymerase chain reaction test) infection caused by any pathogen OR a clinical syndrome associated with a high probability of infection. Evidence of infection includes positive findings on clinical exam, imaging, or laboratory tests (e.g., white blood cells in a normally sterile body fluid, perforated viscus, chest radiograph consistent with pneumonia, petechial or purpuric rash, or purpura fulminans)

**Sepsis**

SIRS in the presence of or as a result of suspected or proven infection.

**Severe Sepsis**

Sepsis plus one of the following: cardiovascular organ dysfunction OR acute respiratory distress syndrome OR two or more other organ dysfunctions. Organ dysfunctions are defined in Table 10-4.

**Septic Shock**

Sepsis and cardiovascular organ dysfunction as defined in Table 10-4.

Modified and used with permission from Goldstein B, Giroir B, Randolph A, et al: International pediatric sepsis consensus conference: Definitions for sepsis and organ dysfunction in pediatrics. Pediatr Crit Care Med 2005;6:2-8.
*See Table 10-2 for age group specific definitions for abnormal vital signs and leukocyte count.
†Core temperature must be measured by rectal, bladder, oral, or central catheter probe.
Modifications from the adult definitions are in **boldface**; SD, standard deviation(s).

## DIAGNOSIS OF NEONATAL SEPSIS

The diagnosis of neonatal sepsis, particularly in premature newborns and VLBW infants, remains a challenge. As previously discussed, the neonate's host defense mechanism is markedly impaired, and this problem is even more pronounced in the preterm neonate. These infants may not manifest the same clinical signs as older patients. Sepsis should be suspected in any newborn with temperature instability, apnea, respiratory distress or tachypnea, cardiovascular instability (including tachycardia, bradycardia, and hypotension), reduced perfusion or poor color, feeding intolerance or diarrhea, and poor tone or lethargy, particularly in the presence of a maternal history of premature onset of labor, prolonged (>24 hours) rupture of membranes, clinically proven chorioamnionitis, colonization of the genital tract with pathogenic bacteria (e.g., group B *Streptococcus* or *E. coli*), urinary tract infection, or sexual intercourse near the time of delivery, because these are all independent risk factors for the development of neonatal infection. In fact, these risk factors increase the rate of systemic infection more than 10-fold.[89]

**TABLE 10-4**
**Pediatric Organ Dysfunction Criteria**

**Cardiovascular Dysfunction**

Despite administration of isotonic intravenous fluid bolus ≥ 40 mL/kg in 1 hour:

Decrease in BP (hypotension) < 5th percentile for age or systolic BP < 2 SD below normal for age*

OR

Need for vasoactive drug to maintain BP in normal range (dopamine > 5 μg/kg/min or dobutamine, epinephrine, or norepinephrine at any dose)

OR

Two of the following:

Unexplained metabolic acidosis: base deficit > 5.0 mEq/L
Increased arterial lactate > 2 times upper limit of normal
Oliguria: urine output < 0.5 mL/kg/hr
Prolonged capillary refill: >5 seconds
Core to peripheral temperature gap > 3° C

**Respiratory**†

$Pao_2/Fio_2$ < 300 in absence of cyanotic heart disease or preexisting lung disease

OR

$Paco_2$ > 65 torr or 20 mm Hg over baseline $Paco_2$

OR

Proven need‡ or >50% $Fio_2$ to maintain saturation ≥ 92%

OR

Need for nonelective invasive or noninvasive mechanical ventilation§

**Neurologic**

Glasgow Coma Score ≤ 11

OR

Acute change in mental status with a decrease in Glasgow Coma Score ≥ 3 points from abnormal baseline

**Hematologic**

Platelet count < 80,000/mm$^3$ or a decline of 50% in platelet count from highest value recorded during the past 3 days (for chronic hematology/oncology patients)

OR

International normalized ratio > 2

**Renal**

Serum creatinine ≥ 2 times upper limit of normal for age or twofold increase in baseline creatinine

**Hepatic**

Total bilirubin ≥ 4 mg/dL (not applicable for newborn)

OR

ALT 2 times upper limit of normal for age

Modified and used with permission from Goldstein B, Giroir B, Randolph A, et al: International pediatric sepsis consensus conference: Definitions for sepsis and organ dysfunction in pediatrics. Pediatr Crit Care Med 2005;6:2-8.
*See Table 10-3.
†Acute respiratory distress syndrome must include a $Pao_2/Fio_2$ ratio ≤ 200 mm Hg, bilateral infiltrates, acute onset, and no evidence of left heart failure. Acute lung injury is defined identically, except the $Pao_2/Fio_2$ ratio must be ≤ 300 mm Hg.
‡Proven need assumes oxygen requirement was tested by decreasing flow with subsequent increase in flow if required.
§In postoperative patients, this requirement can be met if the patient has developed an acute inflammatory or infectious process in the lungs that prevents him or her from being extubated.
ALT, alanine transaminase; BP, blood pressure; SD, standard deviation(s).

## BIOCHEMICAL MARKERS

Although the Goldstein consensus criteria establish important and useful definitions for the sepsis continuum in children, these are largely based on clinical and some laboratory findings.

Current research targets to improve the diagnosis of pediatric sepsis include various biochemical inflammatory markers. These may prove to be objective criteria and perhaps more reliable than some physiologic variables. Investigators have reported elevated sedimentation rate, C-reactive protein, base deficit, IL-6, procalcitonin level, adrenomedullin, soluble CD14, soluble endothelial cell/leukocyte adhesion molecule 1, MIP, and extracellular phospholipase $A_2$ as potential biochemical markers of SIRS.[90–104] Although some of these markers are sensitive, most lack specificity, and none of them is sufficiently robust to add to the consensus definition of SIRS at this time. However, in the future, it may be possible to incorporate biochemical and immunologic markers in the diagnostic criteria for pediatric SIRS.

## PIRO SYSTEM

An emerging concept in sepsis research is the PIRO system, which stratifies patients on the basis of their *P*redisposing conditions, the nature and extent of the *I*nsult or *I*nfection, the magnitude of the host *R*esponse, and the degree of concomitant *O*rgan dysfunction.[6] The PIRO system is analogous to the tumor-node-metastasis (TNM) system for oncology in that it can be used to assess risk and predict outcome in septic patients, assist with enrollment of patients into clinical trials, and determine the likely patient response to specific therapies. Specifically, the PIRO system should be able to discriminate morbidity arising from infection and morbidity arising from the response to infection based on a patient's I and R scores and their outcomes. Thus the PIRO system has the potential to help researchers develop and clinicians choose the most appropriate treatments for septic patients, because therapeutics that modulate the host response may adversely affect the body's ability to contain an infection.

A recent retrospective analysis of two large global databases of patients with severe sepsis (PROWESS-840 patients and PROGRESS-10,610 patients) was undertaken to generate and validate the PIRO system. In PROWESS, the correlation between the PIRO total score and in-hospital mortality rates was 0.974 ($P < 0.0001$), and in PROGRESS it was 0.998 ($P < 0.0001$). The investigators concluded that the PIRO system appears to accurately predict mortality, can develop into an effective model for staging severe sepsis, and may prove useful in future sepsis research.[105] Brilli and colleagues suggest that a modified PIRO system for pediatric sepsis should be developed and applied to future clinical pediatric sepsis trials, assuming the adult PIRO system is proven to be successful and adds a useful new dimension to clinical trials.[106,107]

# Management

## PREVENTION

Given the rising incidence of sepsis and growing health care burden, management of pediatric sepsis should begin with prevention. In neonates, early onset sepsis can potentially be prevented or reduced with appropriate prenatal and peripartum management, especially in complicated pregnancy. Active management of early postpartum newborns based on their risk profile with antibiotic prophylaxis is also important. Prevention of neonatal late onset sepsis and sepsis in older children is dependent on infection control practices that reduce hospital-acquired infection, such as frequent handwashing, contact precautions, invasive device care, sterilization of equipment, and epidemic control methods. Although good outcome studies of individual interventions are difficult because of power restrictions, intervention bundle studies indicate that combined implementation of infection control techniques reduces the risk of nosocomial infection.[108,109] One pediatric study by Costello and colleagues found that an intervention bundle in their pediatric cardiac ICU reduced the central-line–associated bloodstream infection rate from 7.8 infections per 1000 catheter-days to 2.3 infections per 1000 catheter-days.[110] Furthermore, Brilli and colleagues were the first to demonstrate a significant, sustained reduction in pediatric ventilator-associated pneumonia (VAP) rates following the use of an intervention bundle. After implementation of their VAP prevention bundle, VAP rates decreased from 7.8 cases per 1,000 ventilator days in fiscal year 2005 to 0.5 cases per 1,000 ventilator days in 2007.[111]

## EARLY GOAL-DIRECTED THERAPY

### Surviving Sepsis Campaign

After prevention, the cornerstone of treatment is early diagnosis and goal-directed therapeutic interventions. In 2002, the European Society of Intensive Care Medicine, International Sepsis Forum, and SCCM launched the surviving sepsis campaign (SSC) in an effort to improve sepsis outcomes by establishing evidence-based guidelines to standardize care. These internationally accepted guidelines (endorsed by 11 professional societies) were published in 2004 and updated in 2008.[7,8] Previous studies have found that the development and publication of guidelines are infrequently integrated into bedside practice in a timely fashion and may not change clinical behavior.[112–117] Recognizing that guideline implementation is a significant challenge, Levy and colleagues conducted the SSC performance improvement initiative at 165 sites internationally to assess the impact of guideline compliance on the hospital mortality of 15,022 patients. Compliance increased linearly over the 2-year study period and unadjusted hospital mortality decreased from 37% to 30.8% in the same period. The adjusted odds ratio for mortality improved the longer a site participated in the campaign. The authors commented that the campaign was associated with a sustained, continuous quality improvement in sepsis care and a reduction in reported hospital mortality rates, although these findings do not necessarily reflect cause and effect.[118] Although the SSC guidelines primarily pertain to the adult population, both the 2004 and 2008 publications address pediatric considerations in sepsis.

### American College of Critical Care Medicine/ Pediatric Advanced Life Support Guidelines

The same year the SSC was launched, the ACCM published their clinical practice parameters for hemodynamic support of pediatric and neonatal patients in septic shock.[9] Multiple

studies have reported that these guidelines are useful, effective, and improve outcomes in infants and children with sepsis.[10] For instance, Han and colleagues demonstrated that although resuscitation practice among community physicians was consistent with the ACCM/PALS guidelines in only 30% of patients, when practice was in agreement with guideline recommendations, a lower mortality was observed (8% vs. 38%). Notably, every hour that went by with persistent shock was associated with a greater than twofold increase in odds of mortality.[119] In a retrospective study of the 2003 Kids' Inpatient Database, including nearly 3 million pediatric discharge records, overall hospital mortality from severe sepsis was estimated to be 4.2%, 2.3% in previously healthy children, and 7.8% in children with comorbidities.[120] This lower mortality rate is distinct from the previous estimate of 10.3% by Watson and colleagues, using 1995 hospital discharge and population data. Survival from severe sepsis in 2003 may have improved, in part, as a result of guideline implementation.[14] In a randomized controlled trial, de Oliveira and colleagues reported that treatment adhering to the ACCM/PALS guidelines with central venous oxygen saturation ($Scvo_2$) goal-directed therapy resulted in reduced 28-day mortality for severe sepsis and septic shock (11.8% vs. 39.2%, $P = 0.002$).[121] These studies support the implementation of the early, goal-directed therapy recommended by the ACCM/PALS guidelines.

The ACCM/PALS guidelines were updated in 2007 with continued emphasis on (1) first-hour fluid resuscitation and inotrope drug therapy directed to restore threshold heart rate (HR), normal blood pressure (BP), and capillary refill less than or equal to 2 seconds and (2) subsequent intensive care unit hemodynamic support directed to achieving $Scvo_2$ greater than 70% and cardiac index (CI) of 3.3 to 6.0 L/minute/m$^2$. The changes recommended were few but include the following: (1) the use of peripheral inotropes (not vasopressors) until central access is attained is recommended, because mortality increased with delay in establishing central access and subsequent inotrope use. (2) Etomidate is not recommended for children with septic shock unless it is used in a randomized controlled trial; atropine and ketamine may be used for invasive procedures in children with septic shock, but no recommendation is made for sedative/analgesic use in newborns with septic shock. (3) Cardiac output (CO) may be measured not only with a pulmonary artery catheter, but also with Doppler echocardiography, a pulse index contour CO catheter, or a femoral artery thermodilution catheter. Therapy should be directed to maintain a CI 3.3 to 6.0 L/min/m$^2$ or superior vena cava (SVC) flow greater than 40 mL/min/kg in VLBW infants. (4) Several new potential rescue therapies, including enoximone, levosimendan, inhaled prostacyclin, and intravenous (IV) adenosine, should be further evaluated in the appropriate patient settings. (5) Fluid removal is recommended using diuretics, peritoneal dialysis, or continuous renal replacement therapy in adequately fluid resuscitated patients who cannot maintain fluid balance by native urine output, which can be identified by the development of new-onset hepatomegaly, rales, or greater or equal to 10% body-weight fluid overload.

## SURVIVING SEPSIS CAMPAIGN AND AMERICAN COLLEGE OF CRITICAL CARE MEDICINE/PEDIATRIC ADVANCED LIFE SUPPORT RECOMMENDATIONS AND MANAGEMENT ALGORITHMS

The recommendations of both the updated SSC and ACCM/PALS guidelines for the management of pediatric and neonatal sepsis are summarized in two algorithms: the time-sensitive, goal-directed stepwise management of hemodynamic support for infants and children (Fig. 10-4) and for newborns (Fig. 10-5) in septic shock. These recommendations and management algorithms are discussed in detail below.

### Initial Resuscitation

Once the diagnosis of sepsis is made, aggressive early intervention should ensue. The principal objective is to restore oxygen delivery to the tissues in view of the decreased peripheral oxygen utilization and the increased oxygen demand. This goal can be achieved by ensuring that the patient is adequately resuscitated. Evidence suggests that children who present with sepsis are often grossly underresuscitated.[119,122] Contrary to adult septic shock, low CO, not low systemic vascular resistance (SVR), is associated with mortality in pediatric septic shock.[123–132] Therefore children frequently respond well to aggressive volume resuscitation, with attainment of the therapeutic goal of a CI 3.3 to 6.0 L/minute/m$^2$.[124,132] Ceneviva and colleagues demonstrated that outcome can be significantly improved when aggressive fluid resuscitation is used for fluid-refractory, dopamine-resistant septic shock.[124,132] Additionally, they make an important point: Unlike adults, children with fluid-refractory shock are frequently hypodynamic and respond to inotrope and vasodilator therapy; because hemodynamic states are heterogeneous and change with time, an incorrect cardiovascular therapeutic regimen should be suspected in any child with persistent shock.[132]

***Airway, Breathing, and Circulation*** During the first 15 minutes of the initial resuscitation, the airway, breathing, and circulation, or ABCs, should be maintained or restored. The airway must first be secured followed by establishment of oxygenation and ventilation. Finally, assessment of perfusion and blood pressure should be performed. Hypoglycemia and hypocalcemia should also be corrected during these first 15 minutes.[10] Missed hypoglycemia can result in neurologic devastation. It is crucial to rapidly diagnose and promptly treat hypoglycemia with appropriate glucose infusion in the septic patient.[10] A 10% dextrose-containing isotonic intravenous (IV) solution can be run at maintenance rate and titrated as needed to provide age appropriate glucose delivery to prevent hypoglycemia. The target plasma glucose concentration is greater than or equal to 80 mg/dL. Hypocalcemia is a frequent, reversible cause of cardiac dysfunction.[133,134] Calcium replacement therapy should be aimed at normalizing ionized calcium concentration, because serum calcium is often bound to albumin and may appear falsely low in malnourished patients.[10]

***Crystalloid Versus Colloid*** Fluid infusion is best begun with boluses of 20 mL/kg isotonic saline or colloid, and initial volume resuscitation commonly requires 40 to 60 mL/kg but

Crit Care Med 2009;37:666-688.)

can be as much as 200 mL/kg.[119,122,131,135–145] Of note, large volumes of fluid for resuscitation in children have not been shown to increase the incidence of acute respiratory distress syndrome[122,146] or cerebral edema.[122,147] The use of either crystalloid or colloid is acceptable, because three randomized controlled trials have compared the use of colloid versus crystalloid resuscitation in children with dengue shock and found no difference in mortality.[144,145,148]

***Blood Products*** The use of blood transfusion during resuscitation is less well defined. Two small pediatric observational studies have looked at the use of blood to restore intravascular volume; however, no recommendations were made by the investigators.[149,150] A recent randomized controlled trial by Lacroix and colleagues found that a lower transfusion threshold can decrease transfusion requirements without increasing adverse outcomes in stable critically ill children. They demonstrated similar outcomes in 637 pediatric patients managed with a transfusion threshold of hemoglobin (Hb) 7 g/dL versus 9.5 g/dL (38 vs. 39 patients developed new or progressive MODS, and 14 vs. 14 patients died within 28 days).[151] However, these results should be interpreted with caution. Their study population was stable critically ill children defined by mean arterial pressure (MAP) not less than 2 standard deviations (SD) below normal mean for age and no escalation of cardiovascular treatment for at least 2 hours prior to enrollment. Therefore these results may not be applicable to unstable children in septic shock with severe hypoxemia, hemodynamic instability, active blood loss, or cyanotic heart disease.[152] Children in septic shock may benefit from early blood transfusion to restore preload and achieve minimum $Scv_{O_2}$. Although the task force members for the updated ACCM/PALS guidelines report the use of conservative goals for blood transfusion in routine clinical illness (consistent with the randomized controlled trial by Lacroix and colleagues[151]), they suggest that transfusion to a goal Hb greater than 10 g/dL to achieve an $Scv_{O_2}$ greater than 70% is warranted in children with septic shock.[10] They base their recommendation on the previously mentioned report by de Oliveira and colleagues that the use of the 2002 ACCM/PALS guidelines and continuous $Scv_{O_2}$ monitoring improved mortality (11.8% vs. 39.2%) and that the treatment group received more blood transfusions directed toward improving $Scv_{O_2}$ to greater than 70% (45.1% vs. 15.7%).[121]

Fresh frozen plasma (FFP) may be used to correct abnormal prothrombin time and partial thromboplastin time, but should be infused, not pushed as a bolus, because it may produce acute hypotensive effects resulting from vasoactive kinins and high citrate concentration.[10] FFP has been proposed as an adjunctive therapy for septic neonates, especially premature neonates who are deficient in IgG, IgM, IgA, and complement. However, no benefit was found when FFP was administered prophylactically to infants with suspected infection.[153]

***Antibiotics*** Broad-spectrum antibiotics should be administered after appropriate cultures have been obtained during the initial resuscitation period.[8,10] The SSC guidelines recommend that at least two blood cultures be obtained before antibiotics are begun, with at least one drawn percutaneously and one drawn through each vascular access device unless it was inserted recently (<48 hours).[8,154] Cultures of other sites, preferably quantitative, such as urine, cerebrospinal fluid, respiratory secretions, wounds, or other body fluids should also be obtained before antibiotic therapy if not associated with a significant delay in antibiotic administration. Acquiring appropriate cultures prior to antibiotic administration is essential to confirm infection and the responsible pathogens, which will later allow de-escalation of antibiotic therapy after receipt of the susceptibility profile. However, it should not prevent prompt administration of antimicrobial therapy.[8] In the presence of septic shock, each delay of an hour in administering effective antibiotics is associated with a measurable increase in mortality of 7.6%.[155] The SSC guidelines recommend starting IV antibiotics as early as possible, certainly within the first hour of recognition of septic shock and severe sepsis.[8]

It is also imperative that the initial empirical antimicrobial therapy be broad enough to cover all likely pathogens and penetrate in adequate concentrations into the presumed source of sepsis. Failure to initiate appropriate antibiotics against the pathogen that is subsequently identified as the causative organism correlates with increased morbidity and mortality.[156–159] Equally important is the subsequent tailoring of the antibiotic regimen once the causative pathogen and its susceptibilities are identified. This helps to reduce the development of antimicrobial resistance and the likelihood of superinfection with resistant organisms such as *Candida* species, *Clostridium difficile*, or vancomycin-resistant *Enterococcus faecium*.[8]

Selection of appropriate antibiotic therapy is challenging because dynamic epidemiology, multidrug-resistant bacteria, and opportunistic infection make optimal broad-spectrum antimicrobial coverage a moving target. In term and preterm neonates, group B streptococcus and *Escherichia coli* account for most of the bacterial isolates.[160] Although the incidence of coagulase-negative *Staphylococcus aureus* and *Candida* species infections in neonates is rising,[161] historically, the most common organisms identified in adults and older children include *E. coli, Pseudomonas aeruginosa, Klebsiella*, and *Bacteroides* species. However, the epidemiology is constantly changing, now with an increase in gram-positive isolates.[2,162] It is diffcult to define the epidemiology of infective organisms because it changes with time, is unique to each hospital, and varies by patient age.

The RESOLVE trial, a randomized controlled trial that found a lack of proof of efficacy and an increased risk of bleeding of recombinant human activated protein C in pediatric sepsis, may have inadvertently provided some current data on the global bacteriology of pediatric sepsis.[162] The study enrolled 477 patients, aged between 38 weeks corrected gestational age and 17 years, from 104 study sites in 18 countries between November 2002 and April 2005. The most common site of infection was the lung in approximately 37%, followed by the blood in just less than one third of patients. Pure gram-positive infections were more common than pure gram-negative infections, consistent with the data of Martin and colleagues on the rising incidence of gram-positive infections beginning in 1987.[2] The most frequent isolates in lung infections were *Staphylococcus aureus,* followed by *Pseudomonas aeruginosa* and *Candida albicans*. *Neisseria meningitides* and coagulase-negative *Staphylococcus* were the most common cause of bacteremia.

The SSC guidelines recommend empiric antimicrobial therapy for not more than 3 to 5 days, with reduction to the most appropriate single therapy as soon as the susceptibility profile is known. The duration of antibiotics should

*Perfusion pressure is defined as [mean arterial pressure – central venous pressure] or [mean arterial pressure – intra-abdominal pressure].
BPM, beats per minute; HR, heart rate.

typically be 7 to 10 days unless the patient has an undrainable focus of infection, immunologic deficiency, or a slow clinical response.

***Source Control*** In addition to early broad-spectrum antimicrobial therapy, obtaining emergent source control immediately following initial resuscitation is crucial.[163] Source control includes drainage of abscesses, debridement of infected necrotic tissue, and removal of a potentially infected device after other vascular access has been established.[164] Of course, the selection of optimal source control methods must weigh the benefits and risks of the specific intervention, because it may cause further complications, such as bleeding, fistulas, and inadvertent organ injury. Ideally, source control should be accomplished with the least amount of physiologic disturbance possible.[165]

***Resuscitation Goals*** During resuscitation, several clinical signs and hemodynamic variables can be used to direct treatment to the goal of normal perfusion. Initial fluid resuscitation and inotrope drug therapy are directed toward maintaining threshold HR and perfusion pressure appropriate for age (Table 10-5) and capillary refill less than or equal to 2 seconds. Perfusion pressure is defined as MAP minus central venous pressure (CVP) or MAP minus intra-abdominal pressure (IAP). Subsequent intensive care unit hemodynamic support is directed to goals of $Scvo_2$ greater than 70% and CI 3.3 to 6.0 L/min/$m^2$.[10] Goal urine output is greater than 1 mL/kg/hour in children and greater than 2 mL/kg/hour in neonates. Of note, in VLBW newborns, a MAP of 30 mm Hg is considered the absolute minimum tolerable blood pressure, because a MAP less than 30 mm Hg is associated with poor neurologic outcome and survival in this population.[166] Because blood pressure does not necessarily reflect CO, it is recommended that normal CO and/or SVC flow, measured by Doppler echocardiography, be a primary goal in these extremely premature infants.[167–177]

***Fluid-Refractory Shock*** If shock is not reversed with fluid alone, the algorithm (see Figs. 10-4 and 10-5) proceeds to the treatment of fluid-refractory shock (see Table 10-6 for hemodynamic definitions of shock). Fluid boluses should be continued unless new onset hepatomegaly or rales develop, which suggest fluid overload. Diuretics, peritoneal dialysis, or

**TABLE 10-6**
**The American College of Critical Care Medicine Hemodynamic Definitions of Shock**

**Shock**
Decreased perfusion manifested by altered decreased mental status
Decreased urine output < 1 mL/kg/hr

**Cold Shock**
Shock plus the following:
Capillary refill > 2 seconds
Diminished peripheral pulses
Mottled cool extremities
Low CI with either high SVR and normal BP or low SVR and low BP

**Warm Shock**
Shock plus the following:
Flash capillary refill
Bounding peripheral pulses
High CI with low SVR and low BP

**Fluid-Refractory Shock**
Shock persists despite ≥ 60 mL/kg fluid resuscitation (when appropriate)

**Catecholamine-Resistant Shock**
Shock persists despite use of catecholamines
- Dopamine up to 10 μg/kg/min
- Epinephrine 0.05-0.3 μg/kg/min
- Norepinephrine

**Refractory Shock**
Shock persists despite goal-directed use of inotropic agents, vasopressors, vasodilators, and maintenance of metabolic (glucose and calcium) and hormonal (thyroid, hydrocortisone, insulin) homeostasis

BP, blood pressure; CI, cardiac index; SVR, systemic vascular resistance.

continuous renal replacement therapy are indicated for patients who have been adequately fluid resuscitated but cannot maintain subsequent fluid balance by native urine output. No large randomized controlled trial has been performed comparing continuous renal replacement therapy with intermittent dialysis. A retrospective study of 113 critically ill children reported that patients with less fluid overload before continuous venovenous hemofiltration had better survival.[178] Therefore the SSC guidelines recommend instituting continuous venovenous hemofiltration before significant fluid overload occurs. The updated 2007 ACCM/PALS guidelines are consistent with the SSC guidelines and recommend intervention for 10% body-weight fluid overload. Fluid-refractory shock mandates the addition of an inotrope to fluid resuscitation through a second peripheral IV line or through intraosseous (IO) access until central access is obtained. In the case of peripheral infiltration with any catecholamine, its adverse effects may be antagonized by local subcutaneous infiltration of phentolamine (1 to 5 mg diluted in 5 mL of normal saline).[10]

First-line inotrope support in children includes: mid-dose dopamine (5 to 9 μg/kg/minute), dobutamine, or epinephrine (0.05 to 0.3 μg/kg/minute). Dobutamine is preferred when there is low CO with adequate or increased SVR.[132,179–192] This is in contrast to the first-line agent in adults,

norepinephrine, which is used in fluid-refractory vasodilated, and often hypotensive, septic shock.[193–196] Again, the majority of adults with fluid-refractory, dopamine-resistant shock have high CO and low SVR, while children with this condition predominantly have low CO.[10] Dobutamine or mid-dosage dopamine can be used to increase cardiac contractility in patients with impaired contractility on echocardiogram with normal blood pressure.[10] Dobutamine- or dopamine-refractory low CO shock may be reversed with epinephrine infusion.[132,197–200] Epinephrine is more commonly used in children than in adults.

The next step in fluid-refractory shock is the establishment of a definitive airway, if needed, and central vascular access for subsequent inotrope and vasopressor infusion. The work of breathing uses up to 40% of CO. Therefore intubation and mechanical ventilation can help to reverse shock in the pediatric population.[10] The updated 2007 ACCM/PALS guidelines recommend volume loading and peripheral or central, inotropic/vasoactive drug support before and during intubation if there is hypovolemia and cardiac dysfunction. Etomidate is not recommended. The sedative/induction regimen of choice is ketamine, with atropine pretreatment and benzodiazepine postintubation. A short-acting neuromuscular blocker can be used to facilitate intubation as long as airway patency can be maintained.[10] Once the airway and central vascular access are obtained, vasopressors should be initiated. Cold shock (see Table 10-6) is treated with central dopamine, or, if resistant, central epinephrine. Although dopamine remains the first-line vasopressor for fluid-refractory hypotensive shock in the setting of low SVR, it may not work as well in patients less than 6 months old. Dopamine causes vasoconstriction by releasing norepinephrine from sympathetic vesicles as well as acting directly on alpha-adrenergic receptors. Because infants less than 6 months old have immature sympathetic innervation, their releasable stores of norepinephrine are reduced. However, dopamine-resistant shock usually responds to high-dose epinephrine or norepinephrine.[132,201–203] Warm shock (see Table 10-6) is reversed by infusing central norepinephrine. Some committee members who updated the 2007 ACCM/PALS guidelines advocate the use of low-dose norepinephrine as a first-line agent for fluid-refractory hypotensive, hyperdynamic shock. Although the use of norepinephrine as a first-line agent for fluid-refractory shock is more common in adults than in children, there is no level I evidence to recommend one catecholamine versus another.[8] However, most guidelines recommend dopamine and norepinephrine as first-line agents, followed by epinephrine, phenylephrine, or vasopressin.[8]

### Stabilization and Continued Resuscitation

***Catecholamine-Resistant Shock*** If shock is not reversed with fluid and catecholamines, the algorithm (see Figs. 10-4 and 10-5) then proceeds to the treatment of catecholamine-resistant shock (see Table 10-6 for hemodynamic definitions of shock). Care is now directed within the pediatric intensive care unit (PICU) or neonatal intensive care unit (NICU). For those patients at risk for absolute adrenal insufficiency, steroids should be initiated at this time. Management of catecholamine-resistant shock then depends on whether a patient has cold or warm shock and what are his or her specific hemodynamics.

**Steroids** Unlike adults, children are at higher risk for absolute adrenal insufficiency.[10] If a child is at risk of absolute adrenal insufficiency or adrenal pituitary axis failure and remains in shock despite epinephrine or norepinephrine infusion, then hydrocortisone can be administered. High-risk pediatric patients include those with purpura fulminans and Waterhouse-Friederichsen syndrome, congenital adrenal hyperplasia, prior recent steroid use for chronic illness, and children with pituitary or adrenal abnormalities. Hydrocortisone should ideally be administered after obtaining a blood sample for subsequent determination of baseline cortisol concentration. Absolute adrenal insufficiency in children is defined by basal cortisol of less than 18 μg/dL and a peak adrenocorticotropic hormone (ACTH)-stimulated cortisol concentration of less than 18 μg/dL.[10]

There is a lack of data on steroids for septic shock in the pediatric literature. The few studies that have been published demonstrate variable results. In a randomized controlled trial of 98 children with dengue shock, hydrocortisone therapy resulted in improved mortality (18.75% vs. 44%).[204] A second randomized controlled trial of 97 pediatric patients with dengue shock syndrome reported that response to a single IV dose of hydrocortisone (50 mg/kg) as measured by mortality, duration of shock, and amount of replacement fluids required was virtually identical between the two groups.[205] It was concluded that hydrocortisone was of no value in the treatment of dengue shock syndrome. Of note, both studies were underpowered, did not measure cortisol levels in these children, but did match the two cohorts for age, sex, and illness severity. Thus it is difficult to conclude if steroids truly provide a survival benefit. In fact, some investigators have reported that steroid therapy may be harmful for children with sepsis. In a recent retrospective cohort study using the Pediatric Health Information System database, investigators reported that the use of any corticosteroids in children with severe sepsis was associated with increased mortality (30% vs. 18%, odds ratio 1.9, 95% confidence interval 1.7 to 2.2).[206] An important limitation of this study is the lack of illness severity data. Although steroids may have been given preferentially to more severely ill children with a presumed higher probability of mortality, steroid use was an independent predictor of mortality in multivariate analysis.[206] Taking these studies and several case series under consideration, the updated 2007 ACCM/PALS guidelines continue to recommend hydrocortisone only for pediatric patients with absolute adrenal insufficiency, as defined by peak cortisol concentration of less than 18 μg/dL following corticotropin stimulation, or adrenal-pituitary axis failure and catecholamine-resistant shock.[10]

The steroid dose continues to be controversial, but the current recommendation is between 2 mg/kg/day (stress dose) and 50 mg/kg/day (shock dose) of IV hydrocortisone as a continuous infusion or as intermittent boluses, with a plan to wean off as tolerated to minimize potential long-term toxicities such as developmental delay.[10] Although the SSC guidelines now recommend IV hydrocortisone for adult septic shock patients if BP is inadequate with appropriate fluid resuscitation and vasopressor therapy and without cortisol testing, whether this approach should be adopted in pediatric and/or neonatal sepsis without classical adrenal or hypophyseal pituitary axis insufficiency depends on the results of pending prospective randomized clinical trials.[8,10]

**Cold Versus Warm Shock** Management of catecholamine-resistant shock can be divided into three groups: (1) cold shock with low CI, high SVR, and normal BP; (2) cold shock with low CI, low SVR, and low BP; and (3) warm shock with high CI, low SVR, and low BP. The goals for the treatment of catecholamine-resistant shock are the same as mentioned previously: attainment of a normal perfusion pressure (MAP minus CVP) for age, as well as maintenance of $Scvo_2$ greater than 70% and CI 3.3 to 6.0 L/min/$m^2$.

Cold shock with low CI, high SVR, and normal BP is first treated with fluids and epinephrine. Normotensive pediatric patients with a low CO and high SVR require afterload reduction to improve blood flow by increasing ventricular emptying. If $Scvo_2$ remains less than 70%, a short-acting vasodilator should be initiated with volume loading. Sodium nitroprusside or nitroglycerin are first-line vasodilators in patients with epinephrine-resistant septic shock and normal BP, and it may reduce ventricular afterload and result in an improved CO.[207–212] If there is continued low CO, or toxicity develops (e.g., cyanide, isothiocyanate, or methemoglobin toxicity), then a type III phosphodiesterase inhibitor should be used next. Type III phosphodiesterase inhibitors are rarely used in adults with septic shock, because catecholamine-refractory low CO and high SVR is uncommon; however, this hemodynamic state is present in a majority of children with fluid-refractory, dopamine-resistant shock. Therefore use of type III phosphodiesterase inhibitors, such as milrinone and inamrinone (formerly amrinone), is an alternative approach to improve CO and lower SVR in the pediatric population.[213–219] Their mechanism of action is to increase intracellular cyclic adenosine monophosphate (cAMP) by blocking its hydrolysis. This ultimately has the same effect as beta-adrenergic agonists, because they increase intracellular cAMP by stimulating its production. One limitation of type III phosphodiesterase inhibitors is their long half-lives, requiring loading doses with fluid boluses to reach steady state as well as the possibility of slowly reversible toxicities, such as hypotension, tachyarrhythmias, or both, particularly in the setting of abnormal renal (milrinone clearance) or liver (inamrinone clearance) function.[8]

Other vasodilators that have been used in children include prostacyclin, pentoxifylline, dopexamine, and fenoldopam.[220–225] Pentoxifylline, in particular, has been shown to decrease production of TNF and increase survival in murine endotoxin shock,[226] and a randomized controlled trial reported improved outcome with the use of daily 6-hour pentoxifylline infusions in very premature infants with sepsis.[227,228] A Cochrane analysis concurs that this vasodilator and anti-inflammatory agent is a promising therapy deserving evaluation in a multicenter trial.[229] Finally, levosimendan should be considered as a rescue therapy for recalcitrant low CO catecholamine-resistant shock. Levosimendan increases calcium/actin/tropomyosin complex binding sensitivity and has some type III phosphodiesterase inhibitor and adenosine triphosphate-sensitive potassium channel activity. This drug therefore allows improved contractility at a fundamental level, because one of the pathogenic mechanisms of endotoxin-induced heart dysfunction is desensitization of calcium/actin/tropomyosin complex binding.[230–235]

Cold shock with low CI, low SVR, and low BP is also first treated with fluids and epinephrine, but if hypotension persists, norepinephrine should be considered to increase SVR. If $Scvo_2$ is still less than 70%, dobutamine or milrinone should be considered to increase $Scvo_2$ by improving cardiac contractility. Finally, enoximone or levosimendan should be considered as well. Enoximone is a type III phosphodiesterase inhibitor with 10 times more $\beta_1$ than $\beta_2$ cAMP hydrolysis inhibition. Therefore it can increase cardiac contractility with a lower risk of undesired hypotension than milrinone or inamrinone.[236–238] Levosimendan, in the setting of cold shock with low CI, low SVR, and low BP, when added to norepinephrine, will improve CO and $Scvo_2$ as well.

Warm shock with high CI, low SVR, and low BP is treated first with fluids and norepinephrine. Again, some committee members for the updated 2007 ACCM/PALS guidelines advocate the use of low-dose norepinephrine as a first-line agent for fluid-refractory hypotensive (low SVR) hyperdynamic (high CO) shock.[10] If the patient remains hypotensive, the use of vasopressin, terlipressin, or angiotensin can help to restore BP. In patients with vasodilatory septic shock and hyporesponsiveness to catecholamines, vasopressin has been shown to increase MAP, SVR, and urine output.[239–249] Terlipressin, a long-acting form of vasopressin, has demonstrated similar effects with reversal of vasodilated shock as well.[247,250] Angiotensin has been reported to increase BP in patients refractory to norepinephrine, although its clinical role remains to be defined.[251] If $Scvo_2$ remains less than 70%, low-dose epinephrine should be considered to improve cardiac performance as the above potent vasoconstrictors can reduce CO.

***Persistent Catecholamine-Resistant Shock*** If shock is not reversed with fluid, catecholamines, steroids, and other adjunctive therapies the algorithm (see Figs. 10-4 and 10-5) then proceeds to the treatment of persistent catecholamine-resistant shock (see Table 10-6 for hemodynamic definitions of shock). It is important at this point to rule out and correct several potential occult conditions: (1) pericardial effusion requiring pericardiocentesis, (2) pneumothorax requiring thoracentesis or tube thoracostomy, (3) hypothyroidism requiring thyroid hormone replacement therapy, (4) ongoing blood loss requiring hemostasis and/or transfusion, (5) increased intra-abdominal pressure requiring diuretics and/or peritoneal drainage for IAP greater than 12 mm Hg and surgical decompression for greater than 30 mm Hg, (6) necrotic tissue requiring debridement, or (7) excessive immunosuppression or immune compromise mandating a wean of immunosuppressants and restoration of immune function. In addition, therapy can be guided to the goal of CI 3.3 to 6.0 L/min/$m^2$ by the use of pulmonary artery, pulse contour cardiac output, or femoral arterial thermodilution catheters and/or Doppler ultrasonography. Once these feasibly reversible causes are addressed and monitoring has been optimized, if shock persists, the algorithm (see Figs. 10-4 and 10-5) advances to refractory shock and extracorporeal membrane oxygenation (ECMO) as an alternative to consider.[10]

***Refractory Shock*** Extracorporeal membrane oxygenation is a viable therapy for refractory pediatric and neonatal septic shock, although its long-term impact is not known.[8,10] Most centers use refractory shock or $Pao_2$ less than 40 mm Hg after maximal therapy as an indication for ECMO support.[10] Persistent hypotension and/or shock with venovenous ECMO should be treated with dopamine/dobutamine or epinephrine.

Inotrope requirements will usually diminish after venoarterial ECMO. Neonates (80%) and children (50%) have similar survival whether or not the indication for ECMO is refractory respiratory failure or refractory shock from sepsis.[10] Although ECMO survival is similar in pediatric patients with and without sepsis, thrombotic complications can be more common in sepsis.[10]

One U.S. study analyzed 655 patients from a national registry to examine the influence of sepsis on survival from ECMO.[252] The study found that systemic sepsis does not independently influence survival in pediatric ECMO and concluded that although neurologic complications occur more frequently in septic patients on ECMO, this therapy should not be withheld solely because of sepsis. Another study examined the use of ECMO in 12 patients from the United Kingdom and Australia with refractory cardiorespiratory failure resulting from meningococcal disease.[253] The pediatric risk of mortality score ranged from 13 to 40 (median 29, median predicted risk of mortality 72%), and overall, 8 of the 12 patients survived, with six leading functionally normal lives at a median of 1 year (4 months to 4 years) of follow-up. There is a role for ECMO therapy in pediatric and neonatal patients with refractory septic shock, although it remains to be better defined.

## OTHER CONSIDERATIONS

### Intravenous Immunoglobulin

A promising adjuvant therapy in the treatment of sepsis is the administration of polyclonal intravenous immunoglobulin (IV Ig). A recent randomized controlled trial of polyclonal IV Ig in 100 pediatric sepsis syndrome patients aged 1 to 24 months demonstrated a significant reduction in mortality, LOS, and progression to complications such as disseminated intravascular coagulation.[254] The SSC guidelines therefore recommend consideration of IV Ig in pediatric severe sepsis, although more studies may be needed to validate this therapy.

### Recombinant Human Activated Protein C

Recombinant human activated protein C (rhAPC), also known at drotrecogin alfa (activated), or Xigris, is indicated for the reduction of mortality in adult patients with severe sepsis who have a high risk of death (Acute Physiology and Chronic Health Evaluation, or APACHE, II score $\geq 25$) or MODS and no contraindications. rhAPC is contraindicated in clinical situations where bleeding could lead to significant morbidity or death, such as active internal bleeding, recent (<3 months) hemorrhagic stroke, recent (<2 months) intracranial/intraspinal surgery or severe head trauma, trauma with an increased risk of life-threatening bleeding, presence of an epidural catheter, or intracranial neoplasm or mass lesion.[8] The evidence that rhAPC reduces mortality in adult patients with a high risk of death and does not benefit patients at a lower risk of death, but rather increases risk of serious bleeding, is based on the PROWESS[6] (stopped early for efficacy) and ADDRESS[255] (stopped early for futility) randomized clinical trials. An open-label study (EVAO) in children with severe sepsis demonstrated that pharmacokinetics and pharmacodynamics of rhAPC are similar to that in adults.[256] Before EVAO was completed, a global open-label trial in adults and children with severe sepsis (ENHANCE) was initiated to gather additional data for mortality and safety.[257] In the ENHANCE study, the 28-day mortality rate for children was 13.4%, and 5.9% had serious bleeding events during rhAPC infusion, such as central nervous system (CNS) bleed in 2.7% of children.[258] This was followed by the only randomized placebo-controlled trial of rhAPC in children, the RESOLVE (*RE*searching severe *S*epsis and *O*rgan dysfunction in children: a g*L*obal perspecti*VE*) trial, which was stopped early for futility.[162] Because of the low mortality rate of children with sepsis, the primary end point for efficacy in the RESOLVE trial was a reduction in the **c**omposite **T**ime to **C**omplete **O**rgan **F**ailure **R**esolution (CTCOFR) score. The RESOLVE trial showed no significant difference between groups in CTCOFR score or in 28-day mortality. This is quite different from the adult data in the PROWESS trial, which demonstrated a statistically significant reduction in 28-day mortality. It is also important to point out that although there was no difference in the incidence of serious bleeding events between the RESOLVE study groups, more rhAPC patients had CNS bleeding than placebo patients. Furthermore, four of the five patients in the rhAPC group with a CNS bleed were younger than 60 days and weighed less than 4 kg. The SSC guidelines therefore recommend against the use of rhAPC in children because of lack of proof of efficacy and increased risk of bleeding.[8]

## NEONATAL SEPTIC SHOCK

Although the algorithms for time-sensitive, goal-directed stepwise management of hemodynamic support are similar for pediatric patients (see Fig. 10-4) and newborns (see Fig. 10-5) with septic shock, there are several important differences between children and neonates that the clinician should consider.

During the initial resuscitation period, it is crucial to distinguish septic shock from cardiogenic shock resulting from closure of a patent ductus arteriosus in newborns with ductal-dependent complex congenital heart disease. These patients should be started on prostaglandin infusion until an echocardiogram is performed to rule out complex congenital heart disease.

Neonatal septic shock is also complicated by the physiologic transition from fetal to neonatal circulation. In utero, 85% of fetal circulation bypasses the lungs via the ductus arteriosus and foramen ovale. Suprasystemic pulmonary vascular resistance maintains this flow pattern in the antenatal period. However, at birth, inhalation of oxygen results in reduced pulmonary vascular resistance, which allows blood flow through the pulmonary circulation. Closure of the ductus arteriosus and foramen ovale complete this transition.

During sepsis of the newborn, both acidosis and hypoxia can increase pulmonary vascular resistance and arterial pressures, leading to persistent pulmonary hypertension (PPHN). The patency of the ductus arteriosus is maintained, ultimately resulting in persistent fetal circulation. Right ventricular work is increased and can lead to right ventricular failure with right to left shunting at the atrial/ductal levels, manifested by tricuspid regurgitation, hepatomegaly, and cyanosis. Therefore treatment of PPHN requires reduction of pulmonary artery pressures aimed at reversing right ventricular failure. After fluid resuscitation and initiation of catecholamines, if right ventricular dysfunction is present, treatment of PPHN should begin. The patient should be hyperoxygenated

with 100% oxygen, and inhaled NO should be administered as the first treatment when available. Historically, metabolic alkalization (up to pH 7.50) with $NaHCO_3$ or tromethamine was instituted until inhaled NO was available, but this is no longer a common practice. Inhaled NO's greatest effect is typically seen at 20 ppm. Refractory PPHN may be treated with inhaled prostacyclin and/or IV adenosine with variable response.[10]

Key differences in fluid resuscitation between children and neonates include the type of fluid used as well as the rate of infusion. Although crystalloid or colloid can be used to resuscitate children with septic shock and the use of blood transfusion is suggested for Hb less than 10 g/dL to achieve $Scvo_2$ greater than 70% because this is associated with increased survival, the recommendation for neonates is crystalloid for Hb greater than 12 g/dL and packed red blood cells for Hb less than 12 g/dL. Ideally, all packed red blood cells should come from one donor, to limit transfusion reaction risks. Indications for diuretics and complete renal replacement therapy are the same. Furthermore, standard volume resuscitation and vasopressor therapy practices for preterm infants in septic shock use a more cautious, graded approach. This is likely because of anecdotal reports of hemorrhage after rapid shifts in blood pressure in preterm infants at risk for intraventricular hemorrhage (<30 weeks' gestation). Finally, rapid fluid administration can further increase left to right shunting, with ensuing pulmonary edema in the case of VLBW infants who are unable to close their ductus arteriosus because of immature muscle constriction. The majority of these infants are treated medically with indomethacin and the minority with surgical ligation.

Other considerations in neonates include external warming, because their mechanisms of thermogenesis are immature. Also, newborns are at increased risk of hypoglycemia because of reduced glycogen stores and muscle mass for gluconeogenesis; therefore appropriate dextrose infusion should be initiated to maintain serum glucose concentration with frequent monitoring.[10]

Management of pediatric and neonatal sepsis is challenging. It is clear that early diagnosis and time-sensitive, goal-directed therapies are associated with decreased morbidity and mortality in children with sepsis. Emerging novel therapies and improved understanding of existing treatments through both experimental studies and clinical trials will continue to improve current management in an effort to maximize patient survival.

CHAPTER 11

# Surgical Implications of Hematologic Disease

Kelly Walkovich and Raymond J. Hutchinson

Hematologists and pediatric surgeons frequently interact with each other in the comprehensive management of pediatric surgical patients. The evaluation and management of anemia, thrombocytopenia, platelet dysfunction, clotting factor deficiencies, and thrombosis are the common meeting grounds; in addition, maintenance of indwelling central venous lines and the judicious use of transfusion therapy often raise questions of interest to both groups of physicians. The most important considerations in each of these areas are discussed here.

## Anemia

An inadequate mass of red blood cells (RBCs), resulting in insufficient delivery of oxygen to the tissues, can occur for three major pathophysiologic reasons:[1] inadequate production or maturation of RBCs in the bone marrow (e.g., Diamond-Blackfan anemia, transient erythroblastopenia of childhood), loss of red cell mass as a result of bleeding (e.g., gastrointestinal blood loss from Meckel diverticulum) or splenic sequestration (as seen in sickle cell diseases), or (3) RBC destruction (hemolytic disorders).[1] Clearly, a thorough history and physical examination provide invaluable data when planning the workup for a pale child or for the evaluation of a low hematocrit or hemoglobin concentration noted on a complete blood cell count (CBC). In pediatric medicine and surgery, individual and family histories are particularly relevant because of the frequency of congenital and genetic anemias.

In taking the medical history, items of importance include evidence of intrauterine bleeding in the mother or neonatal hemolysis (e.g., from placental abruption or erythroblastosis fetalis, respectively), history of neonatal jaundice or neonatal bleeding, the rate of development of pallor, the presence of scleral icterus, and a history of rectal bleeding. The family history is relevant for identifying other family members with history of anemia or treatment for anemia, splenectomy, or cholecystectomy. A complete physical examination includes assessment for jaundice and degree of pallor, documentation of the size of the spleen and lymph nodes, evaluation for signs of bleeding (including testing the stool for blood), and assessment of cardiovascular stability.

The CBC yields much information regarding the causes of anemia. It provides information regarding two lineages in addition to the red cell lineage: the white cell (myeloid) and the platelet (megakaryocytic). Involvement of more than one hematopoietic lineage often indicates a production problem occurring in the bone marrow; hence, bone marrow aspiration and biopsy are typically done early in the workup of children with multiple cytopenias. The mean corpuscular volume (MCV) allows the classification of anemias into microcytic, normocytic, and macrocytic categories; this can be a useful diagnostic clue and can facilitate a directed workup. Similarly, a mean corpuscular hemoglobin concentration that exceeds 36 is highly suggestive of the presence of a large number of spherocytes, as seen in hereditary spherocytosis.[2] The RBC distribution width index provides information about the size distribution of circulating red cells, allowing the physician to categorize the red cell population as homogeneously small or large or as heterogeneous. This information, when coupled with the MCV, allows a more cost-effective workup. Figure 11-1 provides an algorithm for the workup of a patient with anemia.

### NONHEMOLYTIC ANEMIAS

Underproduction of RBCs because of marrow failure or as a result of deficiency of an essential nutrient, such as iron, is a common mechanism that can lead to severe degrees of anemia. Such severe anemia may present a dilemma when evaluating a patient for a surgical procedure.

#### Marrow Failure

One major clue to the existence of bone marrow failure is the presence of multilineage cytopenias. The concomitant existence of anemia with neutropenia or thrombocytopenia suggests (1) the existence of primary marrow failure resulting from constitutional aplastic anemia (Fanconi anemia) or acquired aplastic anemia or (2) failure of the bone marrow as a result of infiltrative disease, which occurs in cases of acute

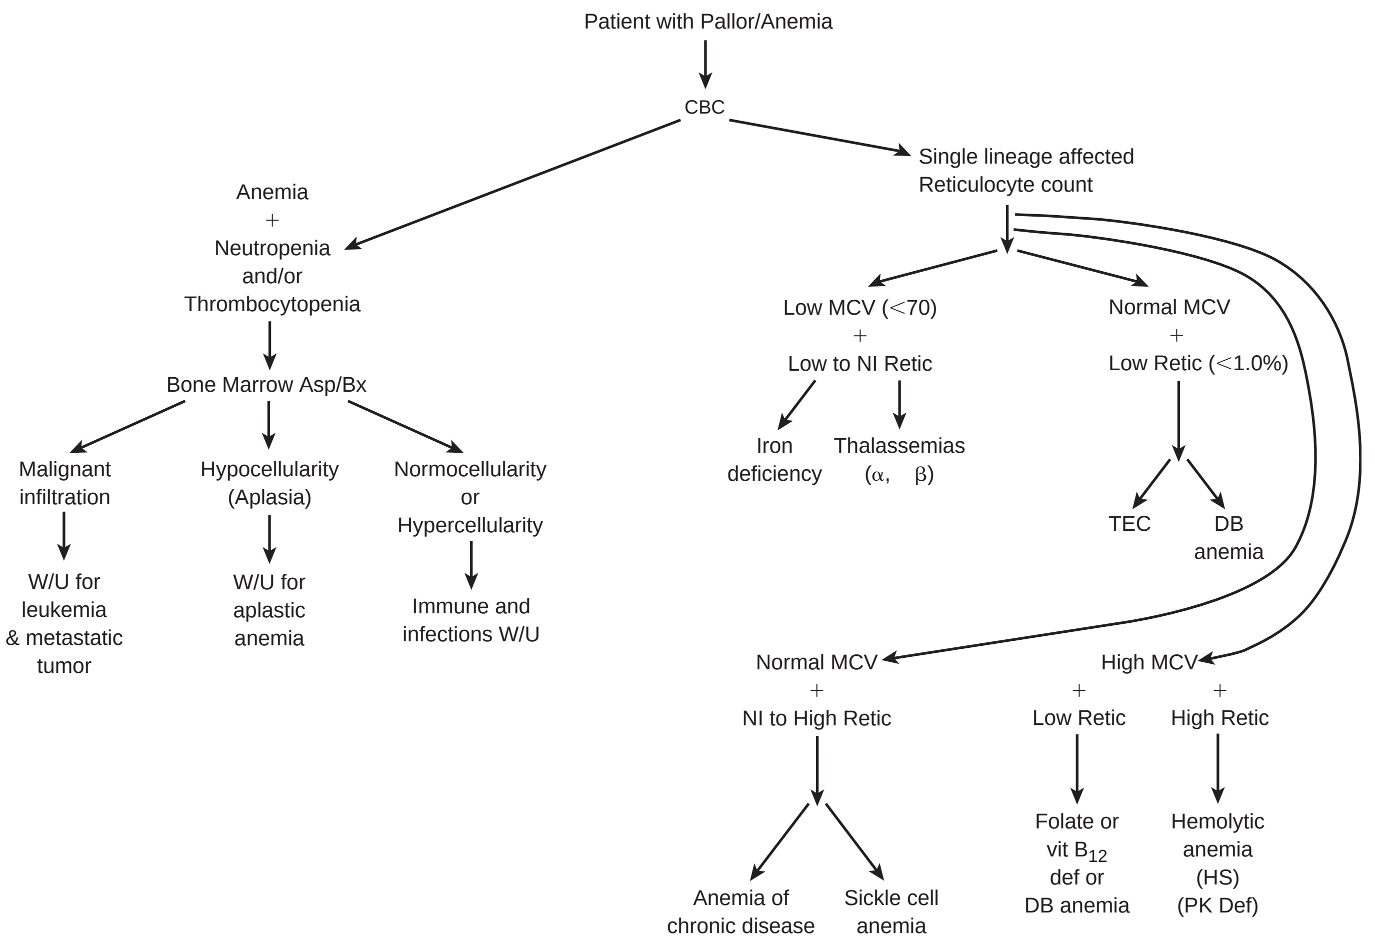

**FIGURE 11-1** Algorithm for the workup of a patient with anemia. Asp/Bx, aspirate/biopsy; CBC, complete blood count; DB, Diamond-Blackfan; Def, deficiency; HS, hereditary spherocytosis, MCV, mean corpuscular volume; Nl, normal; PK def, pyruvate kinase deficiency; Retic, reticulocyte; TEC, transient erythroblastopenia of childhood; W/U, workup.

leukemia or metastatic neuroblastoma. Bone marrow aspiration and biopsy can often quickly resolve uncertainty regarding the diagnosis.

Fanconi anemia is transmitted in an autosomal recessive pattern but affects boys slightly more often than girls (1.2:1).[3] The hematologic presentation is variable, with a single cell lineage often affected early, followed by evolution to multilineage aplastic anemia. The age at presentation ranges from birth to 55 years (median, 6.5 years).[3] Patients affected by Fanconi anemia often exhibit congenital malformations (e.g., cutaneous hyperpigmentation, anomalies of the thumb and radial side of the forearm, microsomy, mental retardation).[4] They are predisposed to malignancies (e.g., leukemia and liver tumors) as a consequence of the associated chromosomal breakage.[5–7] Additional genetic cytopenic syndromes that can progress to multilineage involvement, and thus bear consideration when discussing aplasia, are congenital (CAMT) amegakaryocytic thrombocytopenia, Shwachman-Diamond neutropenia, and dyskeratosis congenita.[3]

Acquired aplastic anemia is idiopathic in at least 50% of cases; commonly observed associations include occurrence after hepatitis B or after the use of drugs such as chloramphenicol, sulfonamides, phenothiazines, and anticonvulsants.[8] Although administration of anabolic steroids (oxymetholone) can lead to improvement in the blood counts of patients with Fanconi anemia,[3] their use is now largely restricted to patients who are not candidates for stem cell transplantation because of concern regarding a negative impact on the outcome of transplantation.[9] Multiagent immunosuppressive therapy with cyclosporine and intravenous antithymocyte globulin, with or without corticosteroids, produces durable responses in approximately 75% of patients with severe acquired aplastic anemia.[10,11] For children with Fanconi anemia or severe acquired aplastic anemia, allogeneic hematopoietic stem cell transplantation offers a potentially curative treatment option.[9,11] Granulocyte colony-stimulating factor (G-CSF) is used in neutropenic patients with Fanconi anemia with benefit,[3] whereas its use in patients with severe acquired aplastic anemia is of uncertain benefit.[12]

Anemia associated with single-lineage erythroid hypoplasia is characterized by normal white blood cell and platelet counts, a low reticulocyte count (<1.0%), and the absence of erythroid precursors on marrow aspirate smears. Two conditions should come to mind when confronted with this clinical picture: Diamond-Blackfan anemia (congenital hypoplastic anemia) and transient erythroblastopenia of childhood (TEC). The former condition is characterized by elements of persistent fetal erythropoiesis, such as a high fetal hemoglobin percentage on hemoglobin electrophoresis, increased erythrocyte adenosine deaminase activity, retained expression of fetal red cell

antigen i, and high MCV of red cells.[13] Patients with TEC usually do not exhibit these features.[14] TEC resolves within 2 to 8 weeks, which is consistent with suppression due to a presumed viral cause.[15–17] Corticosteroids are the mainstay of therapy for Diamond-Blackfan anemia; prednisone 2 mg/kg per day is used initially, followed by tapering to alternate-day dosing or less frequently as the patient's condition allows.[13] Patients with Diamond-Blackfan anemia occasionally become transfusion dependent; in rare cases, patients require allogeneic bone marrow transplantation.[18–20] Although RBC transfusions are occasionally required for patients with TEC, most do not require therapy because recovery is sufficiently rapid.

### Blood Loss

Anemia is an important manifestation of acute and chronic hemorrhage. Significant acute hemorrhage is usually accompanied by signs of cardiovascular stress, consisting of peripheral vasoconstriction, hypotension, tachycardia, and oliguria.[21] If the patient loses more than 30% of the total blood volume, hypovolemic shock often occurs. After acute hemorrhage, it may take several hours before the full effect on the hemoglobin and hematocrit levels can be assessed; a precipitous drop in these values within 1 to 2 hours of the hemorrhage usually indicates blood loss in excess of 20% of the total volume.[22]

Conversely, chronic blood loss resulting from low-grade, slow, or intermittent bleeding is usually not associated with the symptoms of cardiovascular stress. Patients with chronic anemia often exhibit a compensated picture that may not require intervention with transfusion. When transfusion is unavoidable, a judicious approach should be taken because multiple transfusions carry notable risks, including transmission of viral infection[23] and transfusion hemosiderosis.[24]

Sequestration of blood in the spleen is another mechanism of significant blood loss that can lead to anemia.[25] Splenomegaly caused by hemolytic anemias, portal vascular anomalies, or primary pathologic conditions of the liver can lead to sequestration of blood in dilated splenic sinusoids.

The therapeutic approach to the management of patients with anemia resulting from blood loss varies according to the rate at which the anemia developed. To restore blood volume and oxygen carrying capacity to a patient who has lost a large amount of blood, it may be necessary to transfuse a unit of blood quickly. This can usually be accomplished safely, even in young children, over a 15- to 30-minute period, as long as the volume and rate of delivery are adjusted to the child's size and estimated blood loss. Excessive volume expansion can usually be prevented through careful monitoring of the heart rate, arterial blood pressure, venous pressure, and core and peripheral temperatures.[21] Patients with chronic anemia that has gradually reached a level that compromises cardiopulmonary status should receive transfusions of RBCs in amounts that are appropriate to restore cardiopulmonary function to a compensated level. Overtransfusion should be avoided; this is particularly relevant for children with chronic anemia requiring repeated transfusions. For such children, frequent transfusions may result in transfusion hemosiderosis; the greater the number of RBC units transfused, the greater the iron load transfused. After the serum ferritin level exceeds 1000 μg/L, transferrin becomes saturated, and patients are at risk for cardiac and hepatic iron deposition[24]; these patients should be considered for chelation therapy with intravenous or subcutaneous deferoxamine[24] or oral deferasirox (Exjade).[26] Patients in whom moderate anemia develops from blood loss or aggressive hemolysis should undergo slow transfusion back to the baseline level in aliquots of 5 to 10 mL/kg over 2 hours each, with time allowed between aliquots for reequilibration and reassessment of the patient's cardiac status.

### Nutritional Anemias

Iron-deficiency anemia results from inadequate intake of dietary iron, poor absorption, misutilization as a result of defective transport, loss of iron through bleeding, or sequestration of iron in an atypical location (e.g., the lungs in cases of pulmonary hemosiderosis). The age of the patient influences whether he or she will become iron deficient. In infants, who experience rapid expansion of blood volume during growth, 30% of the iron required for hemoglobin production must come from the diet. In adult men, only 5% is derived from the diet,[27] and the remainder is generated by RBC degradation.

The American Academy of Pediatrics[28] recommends dietary iron intake of 1.0 mg/kg per day to a maximum of 15 mg/day for full-term infants, starting by age 3 months. Preterm infants weighing between 1500 and 2500 g require 2 mg/kg per day from dietary and supplemental sources to a maximum of 15 mg/day, starting no later than 2 months of age. Recommendations for very-low-birth-weight infants are even higher: 4 mg/kg per day for those weighing less than 1500 g at birth. In older children and adults, dietary iron requirements vary, depending on growth and gender:

4 to 10 years: 10 mg/day
11 to 16 years: 18 mg/day
Adult men: 10 mg/day
Adult women: 18 mg/day

The peak age range for the development of nutritional iron deficiency is 6 months to 2 years. During this period, children make the transition from being dependent on breast milk or iron-fortified formula to a mixed diet of milk (often cow's milk) and solid foods. Depending on which foods constitute most of the child's diet, dietary iron may be adequate or inadequate. Children who depend heavily on cow's milk, at the expense of solid foods, are especially prone to iron-deficiency anemia. The typical presentation for such children is the gradual development of pallor, a hemoglobin concentration of 3.0 to 6.0 g/dL, and an MCV of 45 to 60 fL. Older individuals are much less likely to experience iron-deficiency anemia, especially from an inadequate diet, unless they participate in fad diets.

Consumption of unprocessed cow's milk by infants, intestinal parasitic infestations, and preexistent iron deficiency may lead to intestinal blood loss. The use of aspirin or aspirin-containing medications may increase intestinal blood loss sufficiently to cause anemia. Other anatomic sources of blood loss and iron deficiency include the following: (1) in the perinatal period–fetal-maternal hemorrhage, placental injury at delivery, and twin-to-twin transfusion through placental communications; (2) in older children—Meckel diverticulum, intestinal duplication, hemorrhagic telangiectasia, and, rarely, bleeding ulcers or gastroesophageal reflux.

The diagnosis of iron deficiency is made by confirming the existence of microcytic, hypochromic anemia in the context of a clinical situation that suggests a possible cause of the deficiency. The low MCV and mean corpuscular hemoglobin concentration should be corroborated with a careful review

of the blood smear. Serum iron studies that measure the serum iron level, total iron-binding capacity, and serum ferritin level finalize the diagnosis. The typical pattern consists of a low serum iron level, high total iron-binding capacity, and low serum ferritin level, consistent with low total-body iron stores. Finally a therapeutic trial of iron should result in an increasing reticulocyte count within 1 week, and the hemoglobin and hematocrit levels should rise soon thereafter.

Treatment consists of the administration of oral iron (ferrous sulfate) at a dose of 6 mg/kg per day of elemental iron. Because ferrous sulfate is only 20% elemental iron, this fact must be taken into consideration when calculating the dose (e.g., a 325-mg tablet of ferrous sulfate contains 65 mg of elemental iron). The iron must be continued for 3 to 4 months. Correction of the anemia, correction of microcytosis, and elevation of the free erythrocyte protoporphyrin level usually occur within that period.[29]

## HEMOLYTIC ANEMIAS

The sickle cell diseases, β-thalassemia, hereditary spherocytosis, and glucose-6-phosphate dehydrogenase and pyruvate kinase deficiencies all have potential ramifications for pediatric surgeons.

### Sickle Cell Diseases

The sickle hemoglobinopathies present early in life with episodes of painful crisis, acute chest syndrome, bacteremia, and splenic sequestration.[30] In a report of the Cooperative Study of Sickle Cell Disease, patients with homozygous sickle cell anemia and those with sickle cell–hemoglobin C disease demonstrated significant incidence rates of painful crisis, acute chest syndrome, and bacteremia; however, all 20 deaths in a cohort of 694 infants followed for 10 years occurred among the patients with homozygous sickle cell anemia.[30] It was also clear from this study that most hand-foot syndromes occurred among the homozygous sickle cell anemia patients in the first 3 years of life.

Several sequelae of the sickle cell disorders are of interest to pediatric surgeons. Painful vasoocclusive crises occasionally masquerade as acute abdominal events that typically require surgical intervention (e.g., appendicitis). Because painful crises are usually accompanied by an elevated leukocyte count, this parameter is not useful in distinguishing appendicitis from a painful crisis. Serial examinations and collaborative evaluation with a hematologist who is skilled in the evaluation of patients with sickle cell diseases reduce the frequency of unnecessary and potentially harmful surgical interventions during painful crises.

Acute chest syndrome can represent a life-threatening situation. Correction of this process requires rapid transfusion to raise the oxygen carrying capacity of the blood and lower the percentage of hemoglobin S to reverse the sickling process; often this is accomplished by exchange transfusion.

For patients with repeated episodes of splenic sequestration, the surgeon may be called on to remove the spleen to reduce the risk of subsequent sequestration, which is characterized by rapid drops in hemoglobin concentration, hematocrit value, and platelet count. At times, progressive sequestration may lead to hypovolemic shock and have life-threatening implications. Historically, splenectomy was justified only after two episodes of sequestration because of concern for splenectomy in young patients (younger than 4 years).[25] However, recent work suggests that splenectomy can safely be performed after one major episode of sequestration.[31] Similarly, the development of symptomatic cholelithiasis usually dictates that cholecystectomy be performed.[32] Patients with sickle cell anemia have a high incidence of perioperative morbidity.[33] Complications that occur at an increased rate in patients with sickle cell disease undergoing surgery include painful crises, acute chest syndromes, and transfusion reactions due to erythrocyte alloimmunization.

Another consideration for pediatric surgeons managing patients with sickle cell diseases is related to the percentage of sickle hemoglobin and the safety of general anesthesia. In the past, RBC transfusion to lower the percentage of sickle hemoglobin to less than 30% was the preferred approach. However, data suggest that patients do just as well with a more conservative approach that aims at achieving a preoperative hemoglobin level of 10 g/dL but does not attempt to lower the hemoglobin S level below an arbitrary cutoff point.[34] Care should be taken to ensure adequate blood oxygenation during a surgical procedure, but excessive transfusion should be avoided.

Further, reducing preoperative transfusions reduces the risk of alloimmunization and transfusion reactions. The development of non-ABO erythrocyte antibodies occurs in 8% to 50% of patients with sickle cell disease, varying with the number of RBC transfusions administered.[35] Clearly, the development of these antibodies adds complexity to surgical procedures and increases the risk of reactions with subsequent transfusions. RBC phenotyping with matching for E, C, and Kell group antigens is recommended because it reduces the risk of alloimmunization.[36,37] Several published studies have questioned the benefit of aggressive preoperative transfusion, suggesting that young patients undergoing low-risk surgery do not require transfusion.[34,38] For others, a conservative transfusion regimen designed to increase the plasma hemoglobin concentration to 10 g/dL offers as much benefit as an aggressive regimen aimed at decreasing the hemoglobin S concentration, with a lower risk of complications.[34]

Postoperative complications of surgery vary, depending on the type of surgical procedure performed, the age of the patient, the status of disease activity and disease-related organ dysfunction, the presence of infection, evidence of chronic lung disease, pregnancy in female patients, and the genetic form of sickle cell disease.[33] Preoperative assessment of lung function with a chest radiograph, oxygen saturation determination, and pulmonary function tests, and of renal function with serum blood urea nitrogen and creatinine measurements, blood pressure measurement, and screening for urinary infection and proteinuria, offer useful strategies for decreasing intraoperative risks.

### β-Thalassemia

β-Thalassemia is characterized by the inability to synthesize normal amounts of β-chain hemoglobin polypeptide,[39] resulting in ineffective erythropoiesis. Patients with homozygous β-thalassemia become dependent on RBC transfusions early in life. As a consequence of extramedullary hematopoiesis, splenomegaly is a frequent finding. Splenic sequestration of RBCs often leads to an enhanced transfusion requirement. When the RBC transfusion requirement exceeds 250 mL/kg per year, splenectomy should be considered because it often reduces the transfusion requirement.[40]

### Hereditary Spherocytosis and Erythrocyte Enzyme Deficiencies

Hereditary spherocytosis and RBC enzyme deficiencies, such as glucose-6-phosphate dehydrogenase and pyruvate kinase deficiencies, result in hemolytic anemia, often associated with gallstone formation. When cholelithiasis is symptomatic, cholecystectomy is necessary. In the case of hereditary spherocytosis, when patients maintain a relatively high reticulocyte count (>10%) in the presence of moderate to severe anemia, splenectomy should be considered when patients reach the age of 5 to 6 years.[41] Splenectomy reduces the risk of the development of gallstones, and it minimizes the chance of a precipitous drop in the hemoglobin concentration when a patient with hereditary spherocytosis experiences a viral infection. Partial splenectomy may offer an alternative in the future, with the definitive risks and benefits yet to be determined, possibly in a randomized clinical trial.[42] The therapeutic value of splenectomy also needs to be considered in patients with other types of hemolytic anemia, such as pyruvate kinase deficiency and refractory autoimmune hemolytic anemia.

# Thrombocytopenia and Disorders of Platelet Function

Bleeding manifestations attributable to platelets can either be the result of quantitatively too few platelets, (i.e. thrombocytopenia), or qualitatively abnormal platelets (i.e. dysfunctional platelets).

Thrombocytopenia is defined as a platelet count less than 150,000/μL, although clinically significant manifestations are generally apparent only at platelet counts less than 100,000/μL. Thrombocytopenia can have either a genetic or an acquired origin.

## GENETIC THROMBOCYTOPENIA

Although rare, several genetic conditions should be considered when thrombocytopenia is diagnosed early in life. Both thrombocytopenia with absent radii (TAR) and CAMT present in the newborn period and are inherited in an autosomal recessive fashion with normal platelet size. As the name implies, TAR is a clinical diagnosis based on variable thrombocytopenia, ranging from 10,000 to 100,000/μL in association with limb abnormalities, most commonly bilateral radius aplasia.[43] No underlying molecular mechanism for TAR has been identified. The thrombocytopenia generally improves over the first year of life, requiring only supportive care with platelet transfusions, and progression to bone marrow failure is rare. Although the thrombocytopenia is expected to resolve within the first year, it should be noted that in the original case series of TAR patients published in 1969, 35% mortality was observed due to intracranial and gastrointestinal bleeds, with the majority of deaths occurring before age 1 year.[44] In addition, many other skeletal abnormalities as well as nonskeletal abnormalities—macrocephaly, short stature, facial dysmorphism, renal malformations, cardiac defects, and capillary hemangiomas—are common in patients with TAR and often require subspecialist care. In contrast, CAMT often presents within the first year of life with more severe thrombocytopenia and elevated serum thrombopoietin levels, and a distinct lack of megakaryocytes in the bone marrow in the absence of other congenital malformations.[43,45] Most patients with CAMT experience bone marrow failure within the first few years of life; patients are also at an increased risk of myelodysplasia and acute leukemia. Bone marrow transplant, preferably with a matched sibling donor, is the only definitive treatment for CAMT. Other bone marrow failure syndromes, in particular Fanconi anemia, can present as isolated thrombocytopenia in infancy before progression to a complete aplastic state. However, the classic physical stigmas of Fanconi anemia (i.e., anomalies of the forearm and thumb, as well as chromosomal breakage analysis with diepoxybutane or mitogen C testing) typically permits distinction between the diagnoses.[3]

In addition, familial thrombocytopenias, including conditions with reduced or increased platelet size, can be appreciated in early childhood. Wiskott-Aldrich syndrome is an X-linked familial microthrombocytopenia due to a defect in the WAS protein, which manifests as thrombocytopenia with small-volume platelets, eczema, and frequent infections due to T-lymphocyte abnormalities and immunoglobulin M deficiency.[46,47] Autoimmune conditions and malignancies, particularly B-cell dyscrasias, are common in patients with Wiskott-Aldrich syndrome.[48] The more rare macrothrombocytopenias can either be related to other disease entities (e.g., velocardiofacial syndrome or pseudo–von Willebrand's disease) or to isolated *MYH-9* macrothrombocytopenia with leukocyte inclusions, hearing loss, or nephritis, or a combination of these conditions.[49]

## ACQUIRED THROMBOCYTOPENIA

Acquired thrombocytopenia can arise from a number of sources, for example, intrauterine exposure to maternal antibodies with antiplatelet surface antigen specificity arising from exposure to certain therapeutic drugs, various viral infections, or the existence of a maternal autoimmune state. Likewise, certain classes of drugs are more likely to induce thrombocytopenia, including antibacterial drugs (e.g., trimethoprim-sulfamethoxazole), anticonvulsant drugs (e.g., phenytoin, carbamazepine), and antipsychotic drugs (e.g., chlorpromazine). Three disorders merit special mention: neonatal alloimmune thrombocytopenia, immune thrombocytopenic purpura, and heparin-induced thrombocytopenia (HIT).

Neonatal alloimmune thrombocytopenia (NAIT) is the most common cause of severe thrombocytopenia in fetuses and newborns.[50] NAIT occurs when an infant's mother becomes sensitized to a foreign paternal platelet antigen inherited by the infant and expressed on platelets during gestation. The mother develops an antiplatelet IgG titer when the maternal-fetal blood barrier breaks down, allowing the infant's platelets to enter the maternal circulation; IgG antibody then crosses back through the placenta to the infant. Platelet counts less than 50,000/μL should prompt consideration for screening for NAIT. The platelet antigen most frequently responsible for this sensitization is PLA1, an antigen for which 98% of the population is positive. Random platelet transfusions generally do not provide a sustained rise in the infant's platelet count, especially when a common antigen, such as PLA1, has led to sensitization; such transfused platelets are rapidly destroyed. Despite their rapid destruction, random

donor platelets may be useful if other treatments are not readily available, especially if the bleeding is life-threatening. As such they are generally the first line of treatment in suspected cases of NAIT. Conversely, the use of maternal platelets (i.e., PLA1 or other specific antigen-negative platelet) typically leads to a sustained rise in the infant's platelet count; when the mother's postpartum condition allows platelet pheresis, this can be a lifesaving intervention. Platelet transfusion is recommended in well, term infants with a platelet count less than 30,000/μL and for premature infants with a platelet count less than 50,000/μL. In infants with intracranial hemorrhage, a platelet count greater than 100,000/μL is the goal. Besides platelet transfusions, intravenous immunoglobulin (IVIG) 1 g/kg per day for 1 to 3 days depending on response, plus/minus intravenous (IV) methylprednisolone 1 mg/kg (maximum 30 mg) every 8 hours, can be administered for marked thrombocytopenia.[51] NAIT usually resolves in 2 to 4 weeks. It should be noted that unlike Rh disease, NAIT can occur with the mother's first pregnancy, and no preventive measures similar to Rh immune globulin (Rhogam) exist. Like Rh disease, however, NAIT is anticipated to be worse with each subsequent pregnancy.[51]

Immune thrombocytopenic purpura occurs in children and adolescents of all ages, but the majority of patients are between 2 and 10 years of age. It often occurs after a viral infection and is believed to be caused by a misdirected antiviral immune response, with antibodies cross-reacting with platelets and leading to splenic consumption.[52] It is a clinical diagnosis based on the acute onset of isolated thrombocytopenia that is frequently concurrent with the abrupt onset of petechiae, bruising, or mucous membrane bleeding, or a combination of these conditions, in an otherwise healthy child. Unlike adults, the majority of children will have spontaneous remission, with at least two thirds of patients having a normal platelet count within 6 months.[53] However, because of the severity of the thrombocytopenia (often <10,000/μL platelets) and the small, less than 1%, associated risk of intracranial hemorrhage,[54] many children are treated with IVIG 0.8 to 1 g/kg IV, anti-D immunoglobulin 75 μg/kg, or oral prednisone.[55] All three treatments can provide a temporary increase in platelet counts. One should note that anti-D immunoglobulin has been reported to cause brisk hemolysis leading to rare renal failure or death, so care should be taken to provide adequate hydration and to monitor for hemoglobinuria.[56] Before prednisone is used, consideration should be given to performing a bone marrow aspiration to rule out leukemia, because leukemia may be partially, but inadequately, treated by prednisone. Platelet transfusions are only clinically indicated in life-threatening bleeding situations and should be used concurrently with IVIG 0.8 to 1 g/kg IV and methylprednisolone 30 mg/kg (maximum 1 g) IV. In children with refractory, symptomatic immune thrombocytopenic purpura, splenectomy or rituximab can be considered.

HIT is an immune-mediated side effect of heparin therapy characterized by thrombocytopenia and paradoxical increased risk for thrombosis. Although previously considered rare in neonates and children, HIT is now recognized to occur in up to 1% to 2% of certain pediatric patient populations, particularly those receiving cardiac surgery or intensive care unit (ICU) care, or both.[57] The thrombocytopenia usually begins 5 to 10 days after the heparin is initiated, although it can occur within the first 48 hours if the patient has previously received heparin.[58] Unlike most other drug-induced thrombocytopenias, which classically lower the platelet count to less than 10,000/μL, HIT typically drops the platelet count by at least 50%, with a resultant platelet count ranging from 20,000 to 150,000/μL, with a median platelet count of 50,000/μL.[59] It should be noted that 10% of patients with HIT have platelet nadirs in the normal range[60]; thus, a normal platelet count does not nullify a diagnosis of HIT. Thrombosis can also precede thrombocytopenia.[60] The risk for HIT is greater with therapeutic rather than prophylactic doses of heparin, for bovine- than for porcine-derived heparin, and for unfractionated as opposed to low-molecular-weight heparin (LMWH).[61]

To make a diagnosis of HIT, both clinical and laboratory features must be present: a triggering agent (i.e., a form of heparin), a significant fall in platelet count with the typical timing, and the identification of heparin-dependent antibodies. A clinical score to assess the pretest probability of HIT has been proposed[62] and is frequently used despite not being validated in a pediatric population. Treatment of HIT requires immediate discontinuation of heparin once HIT is suspected. In addition, because of the risk of significant thrombosis, transition to an alternative anticoagulant is recommended. Warfarin should not be used as a substitute for heparin during an acute HIT episode because it can result in an abrupt decrease in protein C levels, placing the patient at greater risk for thrombotic complications.[63] LMWH to replace unfractionated heparin should also be avoided because of the appreciable cross-reactivity between the two agents. Instead, the alternative agents danaparoid,[64] lepirudin,[57] argatroban[65] or fondaparinux[66] should be considered.

## DISORDERS OF PLATELET FUNCTION

Cutaneous or mucous membrane bleeding despite a normal platelet count suggests the presence of a disorder of platelet function, which may be either acquired or inherited.

Medications are a common cause of acquired platelet function defects. Aspirin, although rarely used in children because of the risk of Reye syndrome, is well documented to inhibit platelet cyclooxygenase irreversibly, resulting in deficiency of thromboxane $A_2$ and inhibition of platelet aggregation.[67] Since platelets are unable to synthesize new proteins, the action of aspirin is permanent and lasts the life of the platelet. Unlike aspirin, ibuprofen is a reversible cyclooxygenase inhibitor, and although data is limited there is some evidence to suggest that platelet function may normalize within 24 hours of cessation of regular ibuprofen use.[68]

Of the inherited platelet dysfunction disorders, von Willebrand disease is the most prevalent.[69] This disorder is characterized by mucosal bleeding caused by abnormal platelet adhesion and aggregation that arises from subnormal levels of factor VIII activity and von Willebrand factor. A number of variants of von Willebrand disease are known to exist; most are transmitted in an autosomal dominant fashion. Recombinant factor VIII/von Willebrand factor concentrate is the treatment of choice to normalize hemostasis. Desmopressin (DDAVP), a synthetic analog of the antidiuretic hormone vasopressin, which transiently increases levels of factor VIII and von Willebrand factor by releasing them from storage pools in the blood can also be used to minimize bleeding. Care should be taken with desmopressin

use because patients are at risk for the development of hyponatremia and seizures. Particular attention should be given to the amount of perioperative fluid the patient receives, and serum sodium levels should be measured during the perioperative period. If factor VIII/von Willebrand factor concentrate is not available, cryoprecipitate can be used. Each unit of cryoprecipitate contains 80 to 100 U of factor VIII and 80 U of von Willebrand factor. A dose of cryoprecipitate providing 10 U of factor VIII/kg of body weight is generally sufficient to achieve adequate hemostasis for surgery. It should be noted that cryoprecipitate is a second-line agent, since during the processing of cryoprecipitate there is no viral inactivation. Failure to correct von Willebrand disease deficiencies before a patient undergoes surgery increases the risk for mucosal bleeding or surface bleeding, or both.

Two other rare inherited platelet dysfunction disorders are Bernard-Soulier syndrome and Glanzmann thrombasthenia.[69] Both conditions are due to a defect in platelet adhesion and can result in severe bleeding. In Bernard-Soulier syndrome the defect is in the GPIb-IX-V platelet surface complex, whereas in Glanzmann thrombasthenia the defect is in the platelet membrane complex GPIIb-IIIa. The two diagnoses can be differentiated by platelet aggregation testing, as Bernard-Soulier syndrome classically demonstrates no agglutination in response to ristocetin but shows otherwise normal agglutination, but Glanzmann thrombasthenia shows a normal ristocetin response despite an absent response to other agents. For bleeding episodes, platelet concentrate transfusion is the appropriate corrective measure. However, patients quickly become resistant to platelet transfusions because of the high risk of alloimmunization.

# Disorders of Coagulation

In evaluating children for bleeding tendencies, the physician should begin with a review of items relevant to a bleeding history. Specifically, this includes inquiring about the occurrence of frequent, large (greater than quarter-sized) bruises in unusual places or after minor trauma, oozing or frank bleeding from the umbilical stump, gum bleeding, epistaxis, hemarthroses, menorrhagia, hematuria, gastrointestinal bleeding, or intracranial bleeding. Moreover, bleeding symptoms from procedures (such as a hematoma with intramuscular injections) and history of bleeding with circumcision, dental extractions, or other surgical procedures should be ascertained. A history of anticoagulation use (i.e., aspirin, heparin, enoxaparin [Lovenox], warfarin) should be obtained. Finally, taking a family history of bleeding tendencies is essential, and that history can either enhance or reduce the probability of diagnosing a bleeding disorder in the patient being evaluated.

The physical examination also provides important information. Bleeding in the skin or mucous membranes (gingival bleeding, petechiae, ecchymoses), soft tissues (hematomas), joints, or on funduscopic examination should be noted.

A good initial laboratory screening panel includes a CBC, prothrombin time (PT), and activated partial thromboplastin time (aPTT) (Table 11-1). Historically, a bleeding time has also proved useful. However, since the bleeding time is subject to considerable variation related to the experience of the person performing the test, the patient's skin temperature, and the length and depth of the incision, the bleeding time is now rarely used. If it is used, the normal range for the bleeding time is 3.5 to 11.5 minutes. Times in the 12- to 15-minute range should be viewed circumspectly, whereas values in excess of 15 minutes are prolonged and abnormal. The CBC is useful to determine the presence of an adequate number of platelets. The PT detects deficiencies of factor VII and factors in the common pathway (Fig. 11-2). The normal range for the PT is 11 to 12 seconds. The most sensitive of the global screening tests is the aPTT. The aPTT detects deficient clotting factors in the intrinsic and common pathways. However, mild deficiencies of factors VIII and IX will not be recognized, and deficiencies of factor VII and factor XIII will not be detected at all by the aPTT.

Specific assays to determine the presence of a single factor deficiency are available. If a satisfactory determination cannot be achieved despite attempts to identify one or more factor deficiencies, a search for a plasma inhibitor should be initiated. This can be accomplished by performing mixing studies with the aPTT or PT, depending on which result is more abnormal. For these studies, normal plasma is mixed with the deficient (patient) plasma in a range of ratios (1:3, 1:1, 3:1). Failure to correct the test completely at the 3:1 (normal patient) mix ratio suggests the presence of an inhibitor. In contrast, factor deficiencies should be totally corrected at the 1:3 mixture and certainly at the 1:1 mixture.

## COAGULATION FACTOR DEFICIENCIES

The most common inherited factor deficiencies include hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency). Hemophilia occurs in approximately 1 in 5000 boys, with hemophilia A accounting for 80% to 85% of the patients and hemophilia B accounting for the remaining 15% to 20%; there are no ethnic predilections.[70] These disorders are inherited as X-linked recessive traits and as such almost exclusively affect boys. Although the majority of patients will have a family history of hemophilia or a bleeding history suggestive of hemophilia, it should be noted that in a third of patients, the diagnosis of hemophilia is the result of a new mutation.[71]

Both factors VIII and IX are critical for thrombin development; thus, deficiency of either leads to bleeding manifestations characterized by oozing or delayed hemorrhage because, although the initial platelet plug is capable of forming, thrombin clot formation is delayed and not robust. Usual bleeding symptoms include bleeding with circumcision, oral bleeding (particularly in infancy from a torn frenulum), easy bruising, hemarthroses, and intramuscular hemorrhage. The frequency and severity of bleeding strongly correlate with the level of active factor. For hemophilia A and B, factor levels of less than 3% are associated with spontaneous hemorrhage into joints and soft tissues. In general factor levels greater than 30% have essentially normal hemostasis. For joint bleeding and bleeding emergencies, such as central nervous system (CNS) bleeding or hemorrhage into the psoas muscle, specific factor recombinant products should be administered rapidly to achieve 100% factor replacement.

The diagnosis of factor VIII deficiency can be made at birth with a prolonged aPTT and a confirmatory low factor VIII level. In the evaluation of factor IX deficiency, however, the physician must consider the physiologic delay in achieving normal levels of the vitamin K–dependent factors (factors II,

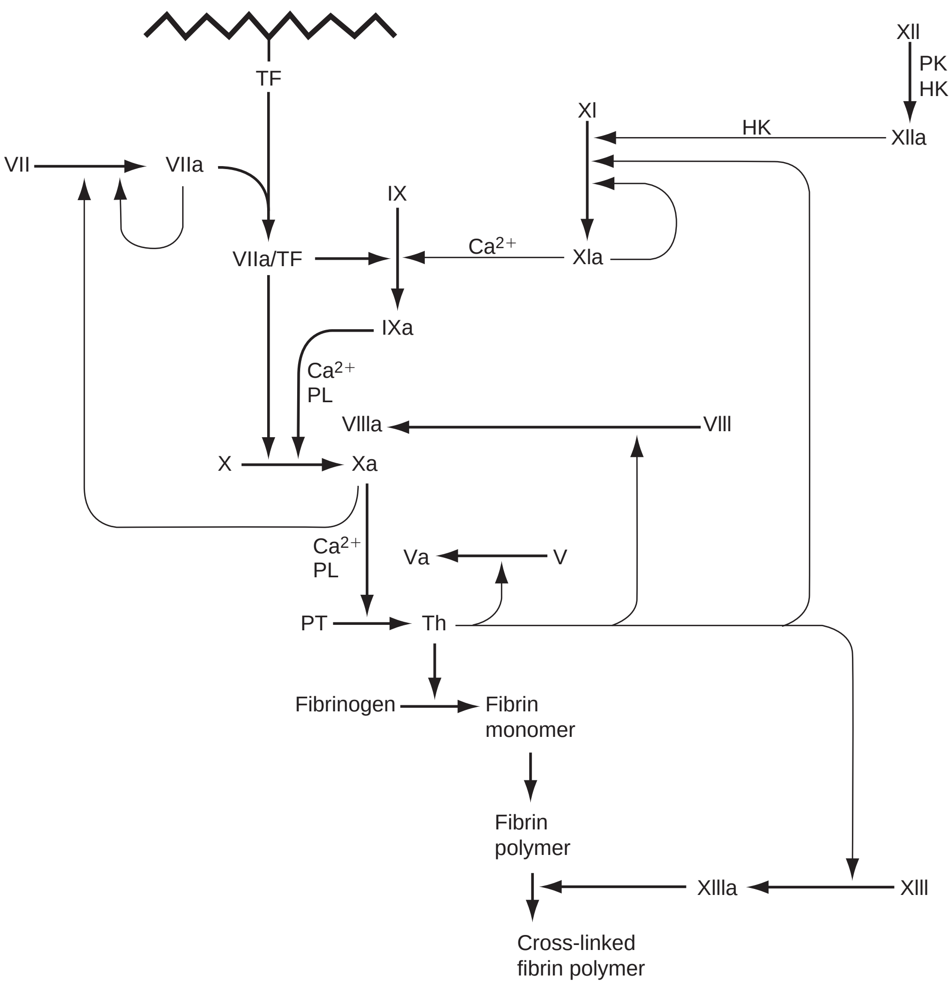

**FIGURE 11-2** Coagulation cascade. HK, high-molecular-weight kininogen; PK, prekallikrein; PL, phospholipid; PT, prothrombin; TF, tissue factor; Th, thrombin. (From Schafer AI: Coagulation cascade: An overview. In Loscalzo J, Schafer AI [eds]: Thrombosis and Hemorrhage. Boston, Blackwell Scientific, 1994.)

VII, IX, and X) in infants. Although confounding the interpretation of the factor IX level in infants, the physiologic delay does not lead to misinterpretation of the near-complete deficiency seen in severe to moderate hemophilia B. A prolonged aPTT with a subsequent factor IX level of less than 10% is consistent with a diagnosis of hemophilia B. Infants with levels in the 10% to 50% range should be retested at 3 to 6 months of age or earlier if clinically significant bleeding occurs. All newborn infants suspected of having hemophilia should have a head ultrasonogram to evaluate for intracranial hemorrhage because 1% to 2% of infants with hemophilia have been reported to have CNS bleeding.[72,73]

Once a diagnosis of hemophilia is made, patients requiring surgery should have a careful presurgical evaluation, including laboratory evaluation for the development of an inhibitor. Specific factor concentrate should be administered before surgery to achieve a level of 100 to 150 U/dL for factor VIII and 80 to 100 U/dL for factor IX, and factor levels should be maintained at 50 to 60 U/dL for 7 to 14 days postoperatively.[70] In trauma scenarios swift action should be taken to provide 100% factor correction before imaging. This is particularly true for head trauma cases because patients with hemophilia experience intracranial hemorrhage 20 to 50 times more frequently than does the general population.[74]

## OTHER FACTOR DEFICIENCIES

Besides the more common factor VIII and IX deficiencies, other factor deficiencies do occur, such as abnormalities in fibrinogen, the soluble precursor of fibrin that is mainly produced in the liver. Dysfibrinogenemias are disorders of fibrinogen function caused by structural defects in the protein; more than 300 abnormal fibrinogens have been described. In contrast, afibrinogenemia is due to a complete absence of fibrinogen.

Afibrinogenemia usually manifests in the neonatal period, with 85% of patients presenting with umbilical cord bleeding,[75] although later age at onset is not unusual. Patients with afibrinogenemia often have mucosal and other bleeding (e.g., bleeding from skin, gastrointestinal tract, and CNS), with intracranial hemorrhage reported as the main cause of death.[76] Hemarthrosis, however, is notably infrequent (particularly compared with patients with severe hemophilia), with joint bleeding observed in 25% of patients.[77] The diagnosis of afibrinogenemia is confirmed by the absence of immunoreactive fibrinogen. The partial thromboplastin time (PTT), PT, and thrombin time (TT) will all be infinitely prolonged because all these tests rely on the formation of fibrin as an end point. Generally fibrinogen levels greater than 50 mg/dL are sufficient

**TABLE 11-1**
**Tests to Detect Bleeding Disorders**

| *Test* | *Parameters Measured* |
|---|---|
| Platelet count | Platelet number |
| Bleeding time | Systemic primary hemostasis<br>Defect of platelet number or function<br>Defect in platelet-vessel wall interaction<br>Primary vascular disorder |
| Prothrombin time (PT) | Extrinsic and common pathways: factors VII, X, V; prothrombin; fibrinogen |
| Activated partial thromboplastin time (APTT) | Intrinsic and common pathways: factors XII, IX, XI, VIII, X, V; prothrombin; fibrinogen; prekallikrein; high-molecular-weight kininogen |
| Thrombin time | Fibrinogen |
| Fibrinogen quantitation | Level of fibrinogen in plasma (mg/dL) |
| Fibrin degradation products | Breakdown products of fibrinogen or fibrin-elevated with increased fibrinolysis or disseminated intravascular coagulation |
| D-dimer assay | Fibrin-specific degradation product; indicator of both thrombin and plasmin generation |
| Euglobulin lysis time | Screening test of fibrinolytic activity |
| Mixing study (using PT or APTT) | Presence of a circulating anticoagulant |
| Antithrombin III (ATIII) activity | Level of the antithrombotic ATIII |
| Protein C, protein S antigen activity | Levels of the antithrombotic proteins C and S |
| Activated protein C resistance assay | Presence of mutant, functionally deficient factor V Leiden (predisposing to thrombosis) |

Data fromSchafer AI: Approach to bleeding. In Loscalzo J, Schafer AI (eds): Thrombosis and Hemorrhage. Boston, Blackwell Scientific, 1994; Comp PC: Approach to thrombosis. In Loscalzo J, Schafer AI (eds): Thrombosis and Hemorrhage. Boston, Blackwell Scientific, 1994; and Santoro SA: Laboratory evaluation of hemostatic disorders. In Hoffman R, et al (eds): Hematology: Basic Principles and Practice. New York, Churchill Livingstone, 1991.

for hemostasis; fibrinogen concentrates, cryoprecipitate, or fresh frozen plasma, or all of these, can be used for fibrinogen replacement as needed.

Unlike afibrinogenemia, which is often diagnosed in childhood, dysfibrinogenemia is often recognized only in adulthood in patients with menorrhagia, prolonged bleeding from trauma or surgery, or abnormal screening laboratory values. The diagnosis of dysfibrinogenemia depends on assays that demonstrate that the functional contribution of fibrinogen to coagulation is abnormal. Most patients with dysfibrinogenemia do not require treatment, but fibrinogen concentrates, cryoprecipitate or fresh frozen plasma, or all of these, can be used for patients with significant bleeding.

Other recognized clotting factor deficiencies and their propensity for associated clinical bleeding are listed in Table 11-2. Deficiencies of prothrombin (factor II), factor V, and factor XI predispose to mild bleeding tendencies, whereas deficiencies of factors VII and X result in variable bleeding tendencies, with some patients demonstrating significant hemorrhagic events. Of note, deficiencies of the contact-activated factors—factor XII (Hageman factor), prekallikrein, and high-molecular-weight kininogen—are not associated with bleeding, and identification of a deficiency should not preclude required surgery.

**TABLE 11-2**
**Clotting Factor Deficiencies**

| *Deficient Factor* | *Clinical Relevance* |
|---|---|
| I | Risk of hemorrhage at levels <50 mg/dL |
| II | Mild bleeding tendency after injuries, dental extractions, surgery |
| V | Mild bleeding tendency (menorrhagia, significant bleeding after injury or surgery) |
| VII | Variable bleeding tendency (intracranial hemorrhage in newborns, menorrhagia) |
| VIII | Moderate to severe bleeding tendency at levels <5% |
| IX | Moderate to severe bleeding tendency at levels <5% |
| X | Variable bleeding tendency (neonatal hemorrhage, bleeding after trauma, menorrhagia) |
| XI | Mild bleeding tendency (menorrhagia, epistaxis, postoperative bleeding) |
| XII | Generally asymptomatic |
| Prekallikrein | Asymptomatic |
| High-molecular-weight kininogen | Asymptomatic |

## ACQUIRED DEFECTS OF COAGULATION

The most common causes of acquired hemorrhagic defects include drug-induced bleeding, disseminated intravascular coagulation (DIC), liver disease, vitamin K deficiency, massive transfusion, and acquired inhibitors to coagulation proteins.[78]

Many drugs have been associated with bleeding, the most obvious of which are the therapeutic anticoagulant medications (i.e., warfarin, heparin, low-molecular-weight heparin) and antiplatelet agents (e.g., aspirin, clopidogrel). Other medication classes, namely β-lactam antibiotics,[79] tricyclic[80] and selective serotonin reuptake inhibitor[81] antidepressants, H2-receptor antagonists,[82] and calcium channel blockers,[83] among others, have been identified as interfering with platelet function, but they rarely result in clinical bleeding. Of note, however, valproic acid, an anticonvulsant agent commonly used to treat pediatric generalized tonic-clonic and absence seizures, has been identified as having several effects on coagulation[84,85] (bone marrow suppression,[86,87] development of antiplatelet antibodies,[88] fibrinogen depletion,[89,90] and induction of factor XIII deficiency[91,92]), and has occasionally been reported to have significant bleeding complications associated with its use.

In patients with clinical bleeding due to drug-induced hemorrhagic defects, the suspected offending agent should be discontinued. Vitamin K and fresh frozen plasma should be considered to reverse warfarin coagulopathy. In addition, platelet transfusions should be used for significant or persistent bleeding, or both.

DIC is an acquired systemic disorder caused by in vivo activation of the coagulation mechanism, resulting in the transformation of fibrinogen to fibrin, which generates thrombi in the microcirculation, with secondary fibrinolysis.[78] The vast majority of DIC cases are due to sepsis from infectious causes, although leukemia and other malignancies, cavernous hemangiomas, acute anaphylaxis, snake bites,

abruptio placentae, and trauma can all be the precipitating cause. The diagnosis of DIC is facilitated by reviewing the peripheral blood smear and identifying schistocytes and thrombocytopenia. Other supporting laboratory tests include prolonged PT/aPTT and decreased fibrinogen with increased D-dimer and fibrin degradation products. A decrease in protein C, protein S, and antithrombin III (ATIII) may also be seen.

Treatment of DIC centers on the correction of the underlying cause and supportive care. Further therapy should be determined by the patient's general condition and the hemorrhagic or thrombotic manifestations. Heparin may be indicated in children with purpura fulminans and signs of thrombosis; however, routine use of heparin, particularly in less severe forms of DIC, is questionable. In the presence of decreased ATIII levels, heparin may not be effective. ATIII concentrate or fresh frozen plasma can be used as supplements. The patient's platelet count and fibrinogen level can be monitored as indices of response to therapy. For patients with primarily hemorrhagic manifestations and little, if any, thrombosis, the administration of platelets and fresh frozen plasma is indicated if bleeding is moderately severe and associated with a decreasing platelet count and prolonged PT/aPTT.

Severe liver disease is often associated with significant clotting factor deficiency. The healthy liver is the site of synthesis of most coagulation factors, including fibrinogen; prothrombin; factors V, VII, IX, X, XI, XII and XIII; prekallikrein; and high-molecular-weight kininogen.[78] In addition, the liver is the source of the natural anticoagulants antithrombin III, protein C, and protein S, as well as inhibitors of fibrinolysis, antiplasmin and alpha-1 antitrypsin. Because the liver is also involved in the clearance of activated clotting factors, liver failure can lead to DIC. However, severe hepatic injury or failure is more typically associated with a hemorrhagic tendency due to the insufficient production of clotting factors. Increased fibrinolysis resulting from decreased hepatic synthesis of inhibitors may also contribute to the hemorrhagic tendency. Measuring factor VIII and factor V levels in a patient can serve as markers of liver function. High factor VIII levels (indicating a lack of liver clearance) and low factor V levels (indicating a lack of liver production) correlate with poor liver function. Treatment of the underlying liver condition and supportive care with fresh frozen plasma or specific factor concentrates, or both, is most useful.

Vitamin K stores are deficient in most normal newborns; this deficiency has the potential to result in a severe bleeding diathesis. Without early supplementation, infants may bruise, have cephalohematomas, and experience gastrointestinal or umbilical hemorrhage, and oozing from puncture sites. Platelet and fibrinogen levels are normal in these infants, but marked prolongation of the PT and aPTT is noted because of the deficiency of vitamin K, thus interfering with the development of essential calcium-binding sites on the vitamin K–dependent coagulation factors,[93] including factors II, VII, IX, and X. Administration of parenteral vitamin K leads to quick cessation of bleeding and correction of the clotting test results. Breast-feeding accentuates the vitamin K deficiency because breast milk contains far less vitamin K (2 to 15 μg/L) than does cow's milk (60 μg/L).[94] Hemorrhagic disease in newborns can be prevented by intramuscular administration of vitamin K shortly after birth. A dose of 0.5 to 1.0 mg of vitamin K1 oxide is recommended; this dose far exceeds the requirement of 25 μg.[78,95]

Although newborns rely on exogenous sources of vitamin K, older infants absorb vitamin K from the colon, and synthesis by bacteria is the primary source. In older children and adults, vitamin K is absorbed from the ileum. The daily requirement of 1 μg/kg is supplied by green leafy vegetables in the diet and is stored in the liver.[96] Thus, malabsorption resulting from cystic fibrosis, biliary atresia, chronic hemolytic anemia with secondary cholelithiasis, and obstructive jaundice, as well as other disorders leading to dysfunction of the upper small intestine, can result in vitamin K deficiency. In addition exogenous medications, namely warfarin, can lead to vitamin K deficiency. Administration of vitamin K intravenously at a dose of 5 to 10 mg leads to clinical improvement within a few hours and correction of the prolonged PT and aPTT within 24 hours.[78]

Massive transfusion therapy, defined as replacing at least one blood volume in 24 hours, can result in significant bleeding resulting from hypothermia, dilutional coagulopathy, platelet dysfunction, fibrinolysis, or hypofibrinogenemia.[97] Agents such as aprotinin, a serine protease inhibitor that modulates the systemic inflammatory response, have been used as effective hemorrhage prophylaxis in cardiac[98] and orthopedic surgeries.[99] In addition activated factor VII has been used as a rescue therapy for life-threatening bleeding.

Several acquired inhibitors to coagulation proteins are known, namely, inhibitors to factors VIII and IX, inhibitors associated with acquired Willebrand syndrome, and lupus anticoagulants (LA). The LAs are the most commonly identified in children and are often recognized after a prolonged aPTT is noted during a routine presurgical evaluation or in association with an infection.[100] The LAs are a group of antibodies against proteins bound to phospholipids; they can be identified by a noncorrecting mixing study. Generally LAs resolve spontaneously within days to weeks and do not require a change in the operative plan.[78]

## THROMBOTIC DISORDERS

The naturally occurring anticoagulants ATIII, protein C, and protein S work to contain excessive in vivo blood coagulation. Thrombosis often results when the activity of one or more of these anticoagulants is deficient.

ATIII is a physiologic inhibitor of thrombin and activated factor V. In addition ATIII is a heparin cofactor that is essential to heparin therapy and is a major inhibitor of blood clotting. This cofactor, which is synthesized in the liver, has a biologic half-life of 2 to 5 days. Congenital ATIII deficiency occurs at a frequency of 1 per 2000 to 5000 individuals.[101] Thrombotic events are often first noted in the second and third decades of life. Surgery, trauma, infection, and pregnancy predispose to thrombotic events. Large amounts of heparin may be required for effective anticoagulation in patients with ATIII deficiency because ATIII is necessary for full heparin activity. Diagnosis is made through a specific assay for ATIII. Oral anticoagulation with warfarin has been the mainstay of therapy. However, purified concentrates of ATIII are available and can be used at a dose of 50 IU/kg for the short term to prevent thrombosis in high-risk situations, such as acute thrombosis, during surgery, or during the third trimester of pregnancy.[102]

Both protein C and protein S are vitamin K–dependent plasma proteins that act in concert to inactivate procoagulants, thereby reducing the risk for thrombosis. Protein C functions

by inactivating factors V and VIII; in its active form, protein C also indirectly facilitates clot lysis.[103] Deficiency of protein C is inherited as an autosomal dominant trait. The homozygous state in infants is characterized by purpura fulminans, retinal thrombotic events with retinal detachment and loss of vision, and other thrombotic events.[104] Heterozygous deficiency of protein C is often asymptomatic during childhood but causes venous thrombosis in adolescents and young adults. Heterozygotes generally have levels of approximately 50%, but these individuals are still at risk for other thrombotic events. Diagnosis is made with a specific assay for protein C. Although it has a role in preventing thrombosis in homozygous individuals who are essentially deficient of protein C, warfarin should be used cautiously, if at all, in heterozygous individuals because their thrombotic tendency can be exacerbated by a further reduction in vitamin K–dependent protein C. In fact, heterozygotes often experience purpuric, thrombotic cutaneous lesions while receiving warfarin, which is a contraindication to its use. Further lowering of the protein C level presumably causes these side effects. Heparin should be used to treat acute venous thrombosis, and protein C concentrates are available to facilitate the management of acute thrombosis in protein C–deficient patients.

Protein S acts as a cofactor for protein C. Deficiency of protein S is associated with recurrent venous thrombosis. Heterozygotes with 35% to 50% of the normal levels of the protein experience recurrent thromboses in adolescence and early adulthood.[105] The same guidelines for use of heparin in treating venous thrombosis apply to patients who are deficient in protein S (as well as those deficient in ATIII and protein C). Caution should be exercised when warfarin is used in protein S–deficient patients.

Besides deficiencies in ATIII, protein C,and protein S, genetic mutations such as factor V Leiden or prothrombin 20210 are associated with an increased risk of venous thromboembolism. Other acquired states, such as increased factor VIII levels with significant infection or inflammatory states, anticoagulation protein deficiencies due to consumption in processes like DIC, and production of parainfectious antiphospholipid antibodies, can all contribute to a prothrombotic state.

One of the largest acquired risk factors for venous thrombosis is the presence of a central venous catheter. More than 50% of deep venous thromboses in children and greater than 80% in neonates are related to indwelling central venous catheters.[105,106] The signs and symptoms of a venous thromboembolism are dependent on the location and chronicity of the clot. For example, acute extremity deep venous thrombosis presents with unilateral limb swelling, whereas acute superior vena cava thrombosis may result in swelling of the face and neck. However, chronic venous thromboembolism may have no signs or symptoms or may have appreciable dilated superficial collateral veins or evidence of venous stasis. Venography is the gold standard for diagnosis of a clot; however, because of the invasive nature of venography, compression ultrasonography with Doppler, computed tomography, and echocardiography are used routinely to diagnosis and follow thrombi. Once a diagnosis of acute venous thromboembolism is identified, initial anticoagulant therapy most frequently relies on unfractionated heparin or LMWH. The latter has become increasingly favored because of its subcutaneous dosing, decreased need for frequent blood monitoring, and decreased risk for the development of HIT. The starting dose of LMWH in nonneonates commonly begins at 1 mg/kg with no bolus given. In full-term infants, the LMWH dose generally is increased to 1.5 mg/kg.[107] The LMWH dose should be titrated to achieve a therapeutic anti-Xa level of 0.5 to 1.0.[78] Unfractionated heparin, however, may be preferred in patients with an increased risk of bleeding or labile clinical status. Nonneonates commonly are loaded with a 50- to 75-U/kg dose of unfractionated heparin, followed by an infusion of 15 to 25 U/kg per hour. Full-term neonates generally require increased doses. The therapeutic anti-Xa range for unfractionated heparin is 0.3 to 0.7.[78] Patients with a known, resolved risk factor generally require treatment for 3 to 6 months; patients with no known clinical risk factor require 6 to 12 months of treatment; and patients with a chronic risk factor or congenital thrombophilia may require indefinite treatment.[78]

## Transfusion Therapy

Greater accessibility to improved blood products has increased the survival of critically ill patients who need enhanced oxygen delivery, intravascular volume expansion, and improved coagulability. The estimated blood volume for infants and young children weighing 10 to 30 kg is approximately 75.4 mL/kg,[108] whereas that for older children and adolescents is 55 to 75 mL/kg.[109] RBC transfusions should be used to correct pathophysiologic events that cause inadequate oxygen delivery and resultant tissue hypoxia. The decision to transfuse RBCs should be based on several factors: signs of tissue hypoxia (tachycardia, tachypnea), extent of blood loss, rate at which anemia has developed, age of the patient, and concomitant or subsequent physiologic stress that the patient may be forced to undergo (e.g., infection, pulmonary compromise, surgery). Transfused RBCs survive for a relatively long time; less than 1% of the number transfused is destroyed daily.[110]

Typically, the number of transfused cells in the recipient's circulation decreases steadily over 110 to 120 days.

Historically, whole blood was the preferred product for transfusion in patients with severe acute blood loss. However, with the increased use of blood fractionation to produce several products from each unit of blood, greater emphasis is now placed on the use of packed RBCs in conjunction with a plasma substitute, if necessary. For hemorrhage of moderate severity, packed RBCs are as effective as citrated whole blood.[108] For severe hemorrhage, plasma substitutes are required when packed RBCs are transfused to prevent an unacceptable increase in hematocrit levels.[110]

To restore blood volume and oxygen carrying capacity to a patient who has lost a large amount of blood, it may be necessary to transfuse a unit of blood quickly. This can usually be accomplished in the same way as discussed previously in the section on blood loss resulting from anemia. When replacement is less urgent, 10 to 15 mL/kg is transfused over 1 to 2 hours. Massive transfusions that involve replacing an amount of blood equal to the patient's blood volume in 24 hours carry the risk of citrate toxicity, electrolyte imbalance, decreased release of oxygen to tissues resulting from diminished RBC 2,3-bisphosphoglycerate content, pulmonary

microembolism, decreased core temperature (if massive amounts of cold blood have been transfused), and thrombocytopenia or DIC. Prevention and successful treatment of the side effects of massive transfusion require careful reassessment of the patient during and after transfusion.

Various plasma substitutes, such as dextran, modified fluid gelatin, and hydroxyethyl starch, have been used to expand plasma volume in hypovolemic patients. However, the possibility of allergic reactions and abnormal bleeding has tempered enthusiasm for their use. Perfluorocarbon compounds, in which oxygen is highly soluble, have been shown to act as effective blood substitutes for oxygen delivery in animals.[111] However, side effects, including lowered platelet count,[112] diminished macrophage function,[113] and activation of complement with resultant pulmonary changes,[114] have severely hampered the use of these compounds; they have undergone evaluation in clinical trials and are currently not recommended for clinical use.[115]

## TRANSFUSION IN PATIENTS WITH CANCER OR IMMUNODEFICIENCIES

The basic principle of transfusing to correct altered hemodynamics and insufficient delivery of oxygen applies when treating immunodeficient patients and those with cancer. No absolute value of peripheral blood hemoglobin concentration or hematocrit below which transfusion is mandated exists. In fact, absolute threshold criteria for transfusion therapy are being abandoned in many centers as a result of concerns about transfusion risks, the high cost of transfusion therapy, and the growing perception that many patients can tolerate lower hemoglobin values than previously believed without adverse physiologic effects. Clearly, the age of the patient, the rate at which hemoglobin or hematocrit values are falling, and concomitant problems influence the decision to transfuse. Children younger than 10 years tolerate hemoglobin values as low as 6 to 7 g/dL without adverse effects. Nevertheless, a rapid decline to this level usually requires RBC transfusion. Similarly, concomitant infection, space-occupying pulmonary disease, pleural effusion, cardiomyopathy, CNS insult, or injury to any major organ may mandate earlier transfusion. The immune state of the patient often warrants special consideration with respect to the type of RBC product chosen and the handling of that product. Many patients with primary immunodeficiency and those with immunodeficiency secondary to therapy should receive blood products that have been irradiated at a level of 2500 to 3000 cGy to prevent graft-versus-host disease.[116] In addition, severely immunocompromised patients, such as bone marrow transplant recipients, who are serologically cytomegalovirus (CMV) negative at the time of transfusion should receive CMV-negative or CMV-safe (leukocyte-reduced) blood products. In fact, many blood banks are releasing only leukocyte-reduced cellular products for all transfusion recipients.

## CHOICE OF RED BLOOD CELL PRODUCT

Fresh whole blood is a suitable choice for use in exchange transfusions when the whole blood being removed from the patient is being replaced (milliliter for milliliter) and when patients with massive blood loss resulting from acute hemorrhage are being treated. For patients in whom excessive increases in intravascular volume may cause problems, other RBC products are preferred.

Packed RBCs are the product of choice for patients with moderate acute blood loss or chronic anemia resulting from underproduction of RBCs or hemolysis. Advantages of packed RBCs include removal of the anticoagulant citrate and 60% to 70% of the plasma.[117] This consideration is particularly important for patients with volume overload or poor cardiac function, or both.

One advantage of washed RBCs is that 85% to 90% of the leukocytes and more than 95% of the plasma have been removed[117]; however, additional expense is incurred for the preparation of this product. Washed RBCs can be used to transfuse patients with a history of nonhemolytic transfusion reactions.

More than 90% of the white blood cells have been removed from frozen deglycerolized RBCs, with retention of minimal plasma (≈0.5% of original plasma).[117] This product is often chosen for patients who require chronic transfusions.

Leukocyte-reduced RBCs are relatively free of leukocytes (≈70% removed)[117] and may be less likely to transmit CMV and other viruses. This product is advantageous for patients with a history of transfusion reactions and for immunodeficient patients at risk for CMV disease.

Each of the products mentioned has a place in transfusion therapy. However, physicians who use these products should bear in mind the appropriate indications for each and the increased cost associated with additional processing of RBCs (e.g., washing, freezing, thawing).

## TRANSFUSION REACTIONS, TOXICITY, AND OTHER COMPLICATIONS

Citrate toxicity resulting from transfusion of the plasma anticoagulant citrate, which binds calcium, may manifest as symptomatic hypocalcemia. Development of this toxicity is the major drawback for using whole blood for rapid RBC and volume replacement.

Transfusion reactions take several forms and usually occur because of patient exposure to proteins from plasma, RBCs, white blood cells, or platelets to which the individual has a natural or an acquired sensitivity. Reactions occur in 2% to 3% of transfusions; of these, 41% are febrile and nonhemolytic, 58% are urticarial, and 1% are delayed hemolytic.[118] For patients with repeated urticaria, the use of washed or frozen RBCs in conjunction with pretreatment of the recipient with an antihistamine or corticosteroid may reduce the incidence of recurrence. Febrile nonhemolytic reactions are usually caused by acquired antibodies to plasma protein or leukocyte alloantigens and occur exclusively in patients with a history of previous transfusion or pregnancy. Pretreatment of the patient with antipyretic agents, antihistamines, or corticosteroids may alleviate symptoms. Because of the sophisticated quality control measures currently in place in modern blood banks, hemolytic reactions are rare. Fever, chills, pain in the abdomen and lower back, tachycardia, hypotension, hemoglobinuria, renal failure, and shock may be manifestations of a hemolytic reaction caused by major blood group incompatibility. When these symptoms are associated with transfusion, the infusion should be stopped, and a sample of the patient's blood should

be sent to the blood bank along with the remainder of the aborted RBC unit. Delayed transfusion reactions occur 3 to 10 days after transfusion, are caused by minor blood group sensitization from previous transfusion, and are usually less severe than reactions due to major blood group incompatibility.

The risk of transfusing infectious agents in blood products has been reemphasized by the acquired immunodeficiency syndrome (AIDS) epidemic. Although less than 5% of AIDS cases have been caused by blood transfusion, fear of acquiring the human immunodeficiency virus (HIV) from transfused blood products remains high because of the associated risk of mortality. Preferential collection of blood products from volunteer donors and HIV screening have reduced the risk for HIV transmission to 1 in 2.3 million units of blood product transfused.[119]

The risk of transmitting certain hepatitis viruses, CMV, and Epstein-Barr virus must also be considered when ordering transfusions. Screening for hepatitis B and hepatitis C has had a positive effect on reducing the risk of acquiring these viruses from transfusions; hepatitis A is not considered to be a risk of transfusion. With the use of volunteer donors and screening for the hepatitis B antigen, the incidence of transfusion-acquired hepatitis B has fallen to 1 in 280,000 transfusions.[120] The use of hepatitis B vaccine for patients who are likely to receive multiple transfusions is a recommended practice. A screening test is now used to detect the hepatitis C virus in the blood of potential donors, and the use of this test has resulted in a risk of 1 in 1.8 million for acquiring this infection through transfusion.[119] CMV is carried in transfused lymphocytes, and infusion of such lymphocytes in immunodeficient individuals can cause serious infection. Use of frozen or washed RBCs, blood products from CMV-negative donors, or leukocyte-reduced RBCs reduces the risk of acquiring CMV-related illness for immunodeficient individuals.[121,122]

Graft-versus-host disease is a potential transfusion-related problem for immunodeficient individuals. This disorder, which is well documented to occur after allogeneic bone marrow transplantation, has been recognized in an increasing number of immunodeficient patients receiving transfusions and in other patients who happen to share an HLA haplotype with the donor. Transfusion-associated graft-versus-host disease (TA-GVHD) has been reported from many countries and centers.[123,124] High fever, scaly maculopapular erythematous rash, diarrhea, hepatocellular damage with morbid elevation of liver enzyme levels, and pancytopenia characterize TA-GVHD. The disorder typically occurs in adults 8 to 12 days after transfusion, whereas in newborns TA-GVHD typically presents as fever on day 28 after transfusion.[123] Overall mortality remains greater than 90%, with most deaths occurring within 1 month of onset.[123,124] Steroids, antithymocyte globulin, cyclophosphamide, and anti–T-cell monoclonal antibodies have been disappointing in the treatment of this disease. TA-GVHD is readily avoided by irradiation of all cellular blood products to be transfused to immunodeficient patients and others at risk of TA-GVHD. Irradiation of cellular products with doses of 2500 to 3000 cGy lethally damages lymphocytes without adversely affecting the function of RBCs, platelets, and neutrophils.[123] The treated blood product is not radioactive and can be handled by hospital personnel in the usual fashion. TA-GVHD has not been demonstrated definitively to occur after transfusion of fresh frozen plasma or frozen RBCs.[124]

Transfusion-related acute lung injury (TRALI) is now the leading cause of transfusion-related morbidity and mortality worldwide,[125,126] given the reductions achieved in infectious risk and hemolytic transfusion reactions. The pathophysiology relates to transfusions of biologically active substances in the blood product; these include donor antibodies that cross-react with leukocyte antigens in the host and lipids and other biologic response modifiers that accumulate in blood during storage.[125] In 2004, the National Heart, Lung, and Blood Institute convened a working group to develop a consensus definition of TRALI.[127] The criteria include

- Satisfying the criteria for acute lung injury (ALI)[128]:
  - Hypoxemia
  - Bilateral infiltrates on chest radiograph
  - Pulmonary artery occlusion pressure less than 18 mm Hg or no clinical evidence of left atrial hypertension
- Onset of signs and symptoms less than 6 hours after transfusion
- No ALI may have been present before transfusion

The patient's clinical course should determine whether the ALI is related to the transfusion. Critically ill patients are those most at risk for TRALI, with the risk factors including septic shock, pulmonary sepsis, aspiration, multiple transfusions, drug overdose in the ICU, long-bone fracture, pulmonary contusion, cardiopulmonary bypass, and burn.[125] Further, there is an independent, dose-dependent relationship between transfusion and the subsequent development of ALI. Mortality rates range from 6% to 15%, with the rate rising to 41% for patients in the ICU.[125,126] The differential diagnosis includes transfusion-associated circulatory overload, an anaphylactoid transfusion reaction, and transfusion of contaminated blood products.[125] Signs and symptoms include severe dyspnea, tachypnea, worsening or new hypoxemia, fever, occasional hypotension, and cyanosis temporarily related to receiving a transfusion.[126] Treatment centers on ventilatory support, fluid management, and reduction in transfusions.[125] If transfusions are necessary, consideration should be given to using washed RBCs and possibly the use of male-only plasma-containing blood products.[125,126] The differentiation of TRALI from transfusion-associated circulatory overload and circulatory overload is accomplished by careful evaluation of clinical signs and symptoms.[129,130]

# Platelet Transfusion

The normal platelet count in children and adults ranges from 150,000/μL to 450,000/μL[131]; levels in newborns are occasionally as low as 100,000/μL.[132] Once released into the bloodstream, platelets circulate for approximately 8 to 10 days. Patients with platelet counts less than 10,000/μL are clearly at risk for hemorrhage,[133,134] whereas individuals with platelet counts less than 50,000/μL carry a risk for bleeding during surgical intervention.[135] Replacing circulating platelets with a transfusion of platelet concentrate reduces the risks for spontaneous bleeding in patients with platelet counts less than 10,000/μL and of intraoperative and postoperative bleeding in individuals with platelet counts less than 50,000/μL.[136]

Random donor concentrates are obtained from whole blood collections through a two-step centrifugation procedure.[137,138] An initial soft spin brings down the RBCs and leaves the platelets suspended in the supernatant plasma. The platelet-rich plasma is then centrifuged at high speeds to pellet the platelets, resulting in a platelet button that is resuspended in 50 mL of plasma. The platelet concentrate is then stored at 20°C to 24°C for up to 5 days. The pH of the concentrate should be maintained at 6.0 or higher.

Single-donor platelets are collected by apheresis techniques; approximately $3 \times 10^{11}$ platelets, which is equal to four to six individual concentrates, are contained in 200 to 3600 mL of plasma.[139] These platelets can be stored for up to 5 days. Single-donor collections are useful for transfusion in patients who have become alloimmunized to random donor concentrates. Identification of compatible single donors through trial and error or by HLA matching prospective donors often results in greater augmentation of the platelet count after transfusion for patients with alloantibodies to platelets. The use of 1-hour posttransfusion platelet counts in patients who are apparently alloimmunized to random donor platelet concentrates is of value in determining the need for single-donor or HLA-matched platelets.[140] If the patient is not septic or sequestering platelets in the spleen, failure to demonstrate an increase in the circulating platelet count 1 hour after transfusion of random donor concentrates usually indicates the existence of platelet alloantibodies. Platelet concentrates are usually used for patients with thrombocytopenia and concomitant bleeding or thrombocytopenia of sufficient magnitude to impart a significant threat of bleeding during surgery or other invasive procedures. When surgery or invasive procedures are required, administration of prophylactic transfusions to thrombocytopenic patients is reasonable for platelet counts less than 50,000/μL.[135] The same threshold for platelet transfusion is reasonable for patients with head trauma and thrombocytopenia. Many oncology centers transfuse patients with cancer in a prophylactic manner, with the threshold for transfusion ranging from 10,000 to 30,000/μL.[134,141,142] Data suggest that minimal risk for bleeding exists when the platelet count is greater than 10,000/μL provided that the patient is afebrile and uninfected. Finally, it is important to consider that platelet concentrates can be used to stop bleeding resulting from impaired platelet function (e.g., Glanzmann thrombasthenia, Bernard-Soulier syndrome) or in acquired platelet functional defects (e.g., aspirin ingestion).

To stop bleeding in a patient with thrombocytopenia, an increase in the platelet count of about 40,000/μL is thought to be necessary.[143] For children, 0.1 U of concentrate per kilogram of body weight usually produces an increment of 40,000 to 50,000/μL; similarly, 4 U/m$^2$ of body surface area accomplishes the same result.[143] In clinical practice, a minimum of 2 U of platelet concentrate is administered, even to infants. This algorithm can be applied to meet the needs of patients with thrombocytopenia undergoing surgery. A platelet count obtained 1 hour after the platelet transfusion usually provides an accurate assessment of the increment achieved; in bleeding patients, cessation of bleeding is the ultimate index. The half-life of transfused platelets averages approximately 4 days; concomitant fever, infection, or conditions favoring platelet consumption decrease platelet survival.[144] The use of ABO-compatible platelets may lengthen survival, although this is controversial.[144,145] Use of single-donor platelets or HLA-matched platelets often lengthens platelet survival in an allosensitized recipient. When a patient demonstrates increments of less than 10,000/μL on two or three successive administrations of random donor platelets, consideration should be given to using single-donor or HLA-matched platelets. However, if a patient with thrombocytopenia is a candidate for bone marrow transplantation from a related donor, use of matched platelets from family members should be avoided to prevent sensitization to minor antigens, because this might increase the potential for graft rejection.

Platelet concentrates are administered through blood filters. The standard 170-μm screen filters remove blood clots and are commonly used to administer platelet concentrates.[146,148] Contemporary microaggregate blood filters remove lymphocytes while allowing platelets to pass through. These filters may reduce the risk for febrile transfusion reactions and may prevent sensitization to HLA antigens through the removal of lymphocytes.[146] However, filters used to prepare leukocyte-reduced RBCs should not be used to transfuse platelet concentrates because they also remove most of the platelets.[147] Irradiation of platelet units to 2500 cGy is appropriate to lower the risk for GVHD in high-risk patients. Platelet function measured by in vitro assays is not altered by this dose of radiation.[148,149]

Small amounts of Rh-positive RBCs in platelet concentrates may be sufficient to stimulate the production of anti-D in Rh-negative individuals.[143,150] Administration of Rh immune globulin may prevent this sensitization in Rh-negative female recipients of platelet concentrates. Transfusion reactions caused by leukoagglutinins that combine with leukocytes and platelets may occur during or shortly after a platelet transfusion.[139,143] Fever and rigor are often associated with reactions to platelet transfusions. Decreasing the rate of infusion may reduce the risk of a febrile reaction. Acetaminophen, intravenous corticosteroids, and parenteral meperidine can be used to ameliorate this type of reaction. Allergic transfusion reactions are characterized by hives and occasional hypotension or bronchospasm.[139,143] Antihistamines and occasionally epinephrine are useful to treat allergic reactions.

A small risk for the transmission of viral infection is associated with the transfusion of platelet concentrate. In addition, because platelets are stored at room temperature, the possibility of bacterial contamination must be considered when patients who have undergone transfusion experience fever, chills, hypotension, or DIC.

# CHAPTER 12

# Nutritional Support in the Pediatric Surgical Patient

Daniel H. Teitelbaum, Imad F. Btaiche, and Arnold G. Coran

The development of modern nutritional support is the result of numerous investigators' contributions during the past 350 years. The first known person to attempt to deliver intravenous nutrition was Sir Christopher Wren, the architect of St. Paul's Cathedral in London, in 1658. Wren used hollow goose quills to infuse wine into dogs. In the 18th century, Claude Bernard, the first modern physiologist, infused numerous substrates into animals. He discovered that intravenously administered sugars could be effectively metabolized only if they were predigested by gastric juices. Thus it was then that the first understanding of the digestion of carbohydrates took hold.[1] In the 1930s, Elman[2] delivered the first successful infusion of protein, as hydrolysates of casein, into patients. In 1949, Rhoads and Vars[3] developed an apparatus for a continuous infusion of intravenous substances into dogs. It was used to definitively show that weight gain could be achieved in puppies by means of intravenous nutrition. Critical refinements in the intravenous solutions, filtration of the infusate, and the use of a central venous catheter allowed Dudrick to infuse concentrated solutions of glucose and amino acids into patients.[4–6] This technique rapidly changed the ability to parenterally nourish adult and pediatric patients. One of the most dramatic cases of the use of parenteral nutrition (PN) was in a newborn with jejunoileal atresia; the infant was maintained by this route for more than 22 months and had weight gain and increased head circumference.[6] Application of this technique in other infants led to dramatic improvements in survival of patients who previously would have died after surgical correction of their congenital anomaly. The past 50 years has led to dramatic developments in both specialized enteral and parenteral products for infants and children.

## Normal Pediatric Growth

Growth and development are unique features to pediatric patients that greatly affect the goals and objectives of nutritional support. The term newborn infant grows at a rate of 25 to 30 g per day during the first 6 months of life, leading to a doubling of the birth weight by 5 months of age.[7] The average infant triples the birth weight by 12 months. By 3 years of age, the weight is 4 times the birth weight, and by completion of the first decade, the weight increases 20-fold. Body length increases by 50% by the end of the first year of life and increases threefold at the end of the first decade of life. The preterm infant's growth pattern is quite distinct from term infants. Most nutrients are accumulated by the fetus in the third trimester of pregnancy. Thus fat accounts for only 1% to 2% of body weight in a 1-kg infant compared with 16% in a term (3.5-kg) infant. An anticipated loss of 15% of a preterm infant's birth weight is usual in the first 7 to 10 days of life, compared with a 7% to 10% weight loss for a term infant, both of which comprise a shedding of excess body water. After this initial period of weight loss, a preterm infant of less than 27 weeks' gestation gains weight at a slower rate of approximately 10 to 20 g per day, because he/she has not yet entered the accelerated weight gain of the third trimester.[8]

## Nutritional Assessment

Nutritional assessment is a critical aspect of the initial evaluation of all surgical patients.[9] The incidence of malnutrition in surgical patients has been well documented in several reviews, and this group comprises 35% to 45% of inpatients.[10] Classical work by Cooper and colleagues[11] showed that 18% to 40% of pediatric surgical patients have malnutrition. This rate of malnutrition has also been shown in other pediatric patients.[12] Aside from surgery, other patients at risk for malnutrition include those with large open wounds with concomitant loss of protein and increased metabolic needs, extensive burns, blunt trauma, and sepsis. An important question is how long the gastrointestinal tract will be dysfunctional after major surgery; this information must be integrated into the nutritional support delivered in the perioperative period. Nutritional assessment can be divided into subjective and objective components. Two basic tools are available: the Mini Nutrition Assessment[13] and the Subjective Global Assessment (SGA). The SGA is performed during the history and physical examination. This should include an evaluation of weight loss

(5% for mild to 10% for moderate to severe malnutrition), anorexia, vomiting, and physical evidence of muscle wasting (indicative of severe malnutrition), and modifications of this have been made for pediatrics, though not as well validated as for adults.[14] SGA has been shown to be an accurate mode of assessing malnutrition for both inpatients as well as non-hospitalized patients. Additionally, although not fully substantiated in young children, both of these nutrition tools have been directly correlated with Acute Physiology and Chronic Health Evaluation (APACHE) II scores and hospital mortality in surgical patients[15,16] The objective portion of the assessment begins with the basic anthropometric measurements of height, weight, and head circumference. Measurements are placed on a standardized growth curve, such as that of the National Center for Health Statistics. From these growth charts, the expected weight for height index can be calculated. As length and head circumference are less affected by excess fat or postoperative fluid fluctuations, length is an excellent indicator of long-term body growth. Acute changes in nutritional status will have a more immediate effect on body weight than length and will decrease the child's weight for height index. Chronic undernutrition, however, will result in a lag in both height and weight. These changes in growth are probably best expressed using a Z-score for weight for length ratios as well as weight, length, and head circumference for age. A number of automated and free software programs are available for such evaluations, such as from the World Health Organization (WHO Anthro [version 3.1, June 2010]). Once patients are more than 2 years of age, this can best be reflected by the child's body mass index (BMI); however, expression of BMI as a Z-score can often add a very useful perspective. Special growth charts are also available for monitoring the growth of children with special health-care needs (e.g., Down syndrome, Prader-Willi syndrome, myelomeningocele, achondroplasia, cerebral palsy). Use of these can give a very important perspective about where a child's growth should lie.[17] An increasingly important group of patients to assess nutrition on are those children with obesity.[18] Assessment of such children requires a high index of suspicion. Although BMI measures weight rather than adiposity, it is still regarded as one of the best tools to perform this assessment, and it is a fairly strong predictive of adult obesity and associated medical complications resulting from an obese state.[19]

### BIOCHEMICAL MEASUREMENTS OF NUTRITIONAL STATUS

Serum albumin level has been used as an indication of chronic nutritional status. However, albumin turnover is slow ($t_{1/2}$ of 20 days). Therefore other plasma proteins, such as prealbumin binding protein ($t_{1/2}$ of 2 days) and retinol-binding protein ($t_{1/2}$ of 12 hours) are indications of a more current nutritional status. There are no established norms for prealbumin or retinol-binding protein in infants and young children.[20] Further, visceral proteins lack specificity under stress and inflammatory conditions, and they are affected by non-nutritional factors. Therefore their levels should be interpreted in the context of nutritional history, underlying diseases, and medication therapy. Ideally, a baseline level is obtained, and then subsequent levels may be used to establish the effects of disease and/or nutritional supplementation. Other parameters that can be useful for measuring nutritional status include bone age and dental status. Malnutrition is a common cause of delayed bone maturation.[21]

### DIRECT MEASUREMENT OF BODY COMPOSITION

Various methods have been created during the past 25 years to more directly measure the body composition of adults and children. Although many of these methods are not readily accessible to most clinicians and, rather, are used for experimental purposes, some, are becoming more commonly used in pediatric clinical settings. Measurement of body water has been done for several years using isotope dilution techniques. This is based on the principle that fat is anhydrous so that most of the isotope is directed into the water compartments of the body.[22] This assumption is not always true; however, such measurements can give an excellent indication of approximate amounts of body fat and water.[23,24] Bioelectrical impedance analysis uses the measurement of the body's impedance to a flow of electrical current as a measure of total body water. Extrapolation of these measurements can allow for the determination of other body compartments, including total body adipose tissue. More recently, dual photon absorptiometry and dual energy x-ray absorptiometry have been used to measure bone mineral content and amounts of fat and body water.[25,26] The accuracy of the instruments is excellent, and because of the low amounts of radiation exposure, dual energy x-ray absorptiometry is becoming the method of choice for measuring pediatric body composition. Standards have only been established down to approximately 6 to 8 years of age[27]; therefore further work is required to understand the use of these measures in small children and infants.

## Nutritional Requirements

### ENERGY REQUIREMENTS

The energy needs of infants and children are unique. Estimates of premature infants show that a 1-kg infant has only a 4-day nutritional reserve, and a full-term infant may live for no more than 1 month without nutrition.[28,29] In children, energy is required for maintenance of body metabolism and growth. A gross estimate of calorie expenditure can be obtained by using the Dietary Reference Intakes (DRIs) for energy requirements, based on the child's age, weight, height, and physical activity, and also based on the Food and Nutrition Board, Institute of Medicine, and National Academy of Sciences guidelines (Dietary Reference Intakes: Recommended Intakes for Individuals in 2006) (http://www.iom.edu/Reports.aspx). Predictive equations (e.g., from the World Health Organization, Schofield equations, and so forth) provide an estimate of the resting energy expenditure (REE), but none are extremely accurate. Other estimates use the amount of calories per length or height for children with chronic health conditions and special health-care needs (e.g., Down syndrome, Prader-Willi syndrome, myelomeningocele, and cerebral palsy; see Table 12-13).

Energy requirements vary depending on age as well as the physiologic status of the child (Table 12-1). Periods of active growth and extreme physical activity will increase energy requirements. The average distribution of kilocalories in

**TABLE 12-1**
**Energy Requirements**

| Daily Energy Requirements (Total kcal/kg) for Pediatric Patients | |
|---|---|
| Preterm neonate | 90-120 |
| <6 months | 85-105 |
| 6-12 months | 80-100 |
| 1-7 years | 75-90 |
| 7-12 years | 50-75 |
| >12-18 years | 30-50 |

a well-balanced diet is as follows: protein, 15%; fat, 35%; and carbohydrate, 50%. Although careful clinical examination is important in making a determination of the child's status, Baker and colleagues[30] showed that the depleted state could not be reliably detected on the basis of the weight-to-height ratio, triceps skinfold, mid–upper arm circumference, hand strength, albumin concentration, total protein level, or creatinine-to-height ratio. Actual measurement or estimation of metabolic rate and energy needs is the best method of following the nutritional status. Commonly used nomograms may significantly underestimate or overestimate energy expenditure.[31–33] One of the most accurate methods of measuring energy expenditure is indirect calorimetry.[34] In indirect calorimetry, carbon dioxide ($CO_2$) production and $O_2$ consumption are measured using a metabolic cart. The sample is best measured in intubated infants, yielding a resting energy expenditure. The energy expenditure or metabolic rate, as measured in cubic centimeters of oxygen per minute, can be converted to calories per hour or per day, if the substrates are known. All measurements are only approximations of caloric needs, for which the surgeon must further adjust according to the clinical course of the patient. Such measurements give an excellent way to monitor patients, particularly those children who are in an intensive care unit setting.[35] In contrast to adults, the rise in REE post-surgery is much less. Mitchell and colleagues[33] found that the REE of postoperative cardiac patients fell to values less than those of normal healthy children who had not undergone surgery. This finding was also confirmed in the study by Letton and colleagues,[36] who examined energy expenditure in young infants in the postoperative period. These studies suggested that reliance on recommended daily allowance (RDA) values may result in overfeeding postoperative children (see the section on complications from overfeeding later). Measurements are critical, because those infants starting with poor nutritional status, or more aggressive surgery (e.g., cardiopulmonary bypass), may have significantly greater energy needs.[37] Indirect calorimetry, however, may be difficult in young infants with uncuffed endotracheal tubes, where an air leak may lead to significant inaccuracies in results. Typically, parenteral energy requirements are lower than enteral or oral requirements because of less thermogenesis with the parenteral route and absence of energy loss in stools.

## WATER

The water content of infants is higher than that of adults (75% of body weight versus 65%) and is proportional to muscle mass. Fluids provide the principal source of water; however, some water is derived by the oxidation of food and body tissues. Requirements for water are related to caloric consumption; so, infants must consume much larger amounts of water per unit of body weight than adults. In general, calorie requirements (kcal/kg/day) are matched to the amount of fluid needs mL/kg/day). The daily consumption of fluid by healthy infants is equivalent to 10% to 15% of their body weight, in contrast to only 2% to 4% by adults. In addition, the normal-content food for infants and children is much higher in water content than that of adults; the fruit and vegetables consumed by infants and children contain about 90% water. Only 0.5% to 3% of fluid intake is retained by infants and children. About 50% is excreted through the kidneys, 3% to 10% is lost through the gastrointestinal tract, and 40% to 50% is insensible loss. Estimation of daily maintenance fluid requirements in infants and children are shown in (Table 12-2).[38]

## PROTEIN

The requirement for protein in infants is based on the combined needs of growth and maintenance (Table 12-3). Two percent of the infant's body weight, compared with 3% of the adult's body weight, consists of nitrogen. The average intake of protein should comprise approximately 15% of total calories administered. Two percent of an infant's body weight, compared with 3% of an adult's body weight, consists of nitrogen. Most of the increase in body nitrogen occurs during the first year of life. The nutritional value of protein is based not only on the amount of nitrogen available but also on the amino acid composition of the protein.[39] Protein provides 4 kcal/g of energy and should be included in estimates of energy (caloric) delivery. Twenty amino acids have been identified, of which eight amino acids (phenylalanine, valine, threonine, tryptophan, isoleucine, methionine, leucine, lysine) are generally considered essential for humans, with an additional four amino acids (cysteine, tyrosine, arginine, histidine)

*Assumes normal age-related organ function.

considered conditionally essential in infants. New tissue cannot be formed unless all of the essential amino acids are present in the diet simultaneously; the absence of only one essential amino acid will result in a negative nitrogen and protein balance. Further, the use of taurine supplementation has been shown to decrease the severity of PN-associated cholestasis.[40] It has also been suggested that proline is essential in preterm infants, although this has yet to be confirmed.[41]

Protein requirements are typically based on age and adjusted based on nutritional status, stress level, severity and type of injury, kidney and liver functions, and other clinical conditions. In general, estimated protein requirements for children based on age are: 0 to 2 years, 2 to 3 g/kg/day; 2 to 13 years, 1.5 to 2 g/kg/day; and 13 to 18 years, 1.5 g/kg/day.[42] Protein requirements are markedly higher in term neonates and infants ranging from 2 to 3 g/kg/day. This estimate is based on several sources. Extrapolation of data on fetal absorption across the placenta during the last trimester indicates protein needs to be 2.2 g/kg/day.[43,44] Delivery of greater amounts of protein to neonates has generally been associated with elevated blood urea nitrogen levels. Protein requirements in premature infants are higher than term infants and range from 3 to 3.5 g/kg/day.[44,45] Such delivery is critical to provide optimal growth and neurodevelopment in infants. In very-low-birth-weight infants, this requirement may approach 3.85 g/kg/day.[46] Such added protein loads must be balanced against the immaturity of the renal system, and the development of uremia should be monitored.[47,48] In particular, taurine is essential for normal neural and retinal development.[49]

Two amino acids that may have significant benefit to the integrity of the gastrointestinal mucosa and the immune status of patients are glutamine and arginine. Although these amino acids are not truly essential, the organism may require additional usage of these during periods of stress. Glutamine has been shown to prevent PN-associated atrophy of the intestine in animals, however, and possibly in humans.[50,51] The efficacy of glutamine in bowel adaptation has been called into question.[52–54] However, a recent meta-analysis of all clinical studies using glutamine showed that glutamine dipeptide significantly reduced the length of hospital stay, and decreased risk of infectious complications rates in surgical patients.[55] Arginine has also been shown to improve nitrogen retention, wound healing, and the immune status.[56,57] However, at least in animal models, early administration of arginine has been shown to worsen the prognosis of animals, because of the activation of nitric oxide within the gastrointestinal tract.[58]

## CARBOHYDRATES

Carbohydrates provide a major and most immediate source of energy through parenteral and enteral routes. Carbohydrates can be provided in one of three ways: monosaccharides (glucose and fructose), disaccharides (lactose, sucrose, and maltose), and complex carbohydrates (starches). Because the body is capable of forming sugars from amino acids, no essential amount of carbohydrate has been defined. However, the addition of small amounts of carbohydrates prevents breakdown of somatic protein sources and thus acts as a protein-sparing substrate.[59] This effect leads to suppression of endogenous glucose production as well as to endogenous glucose oxidation, thereby preventing the oxidation of amino acids that have been derived from skeletal muscles. The body has a limited ability to store glucose, although the substrate is essential and almost continuously needed by the central nervous system. Dextrose is the most common source of carbohydrate, and it yields 3.4 kcal/g. Glucose metabolism may occur aerobically through the tricarboxylic acid cycle, theoretically yielding a maximum of 38 moles of adenosine triphosphatase (ATP)/mole of glucose. Anaerobically, glucose metabolism through the glycolytic cycle yields 2 moles of ATP/mole of glucose, with lactic acid as an end product. Glucose is formed in the liver by means of gluconeogenesis (formation of glucose from noncarbohydrates precursors), which uses alanine and other amino acids from skeletal muscle and lactic acid from the breakdown of glycogen in skeletal muscle through the Cori cycle. Immediately after a meal, glucose absorption contributes to the bulk of circulating glucose. As soon as 4 hours after the meal, these sources are rapidly depleted, and glycogen from the liver becomes a major source of energy for the next 8 to 12 hours. Newborn infants have relatively limited glycogen reserves (34 g), most of which reside in the liver. Thus relatively short periods of fasting can lead to a hypoglycemic state.

The primary enteral carbohydrate delivered to neonates and young infants is lactose.[3] Lactose is broken down into glucose and galactose in the intestines by disaccharidases (e.g., lactase), which are located along the intestinal epithelial border. Because lactose is the predominant carbohydrate of small children, lactase levels remain sufficiently high in most infants until they are at least 2 or 3 years of age. Nonlactose formulas that are soy-based and contain sucrose or corn syrup may provide adequate amounts of carbohydrates (see Enteral Nutrition later). Preterm infants may be unable to digest certain carbohydrates, particularly lactose, because lactase activity in the intestines is inadequate. Thus for premature infants, formulas that have a 50/50 mixture of lactose and glucose polymers are ideal.

Supplementation with inadequate amounts of carbohydrates may lead to a ketotic state, whereby fat and muscles are broken down for gluconeogenesis. Stable infants should receive approximately 40% to 45% of their total caloric intake as carbohydrates. Glucose intolerance does occur and is not only manifested by hyperglycemia but also commonly by hypertriglyceridemia (see the section on hyperglycemia later). Delivery of carbohydrates in amounts greater than the body can use will result in hyperglycemia and lipogenesis (see the section on complications from enteral feeding later).

## FAT

Intravenous lipids have the highest caloric density of the three major nutrients (9 kcal/g). In general, intravenous lipids should comprise between 30% to 50% of all non-nitrogen calories. Lipids have the advantage of being an excellent source of energy and essential fatty acids (EFAs). Linoleic acid is essential for neonates, older children, and adults. Deficiencies of linoleic acid may occur rapidly in neonates. Withholding lipids from the PN of a neonate for as few as 2 to 3 days may lead a biochemical deficiency of fatty acids.[60,61] A deficiency of fatty acids in infants may result when less than 1% of the caloric intake is linoleic acid; in general, 2% to 4% of dietary energy should come from essential fatty acids. Manifestations of fatty acid deficiency include scaly skin, hair loss, diarrhea, thrombocytopenia, and impaired wound

healing.[62] Absence of trace amounts of linolenic acid may also be the cause of visual and behavioral disorders. Fatty acids are an excellent source of energy to all tissues of the body except erythrocytes and the brain. With time, however, the brain can also use fatty acids as an energy source once they are converted to ketones. Fatty acids are carried into the mitochondria for β-oxidation by the carnitine transferase system (see later).

Essentially, two types of fatty acids exist: saturated and unsaturated. Saturated fatty acids lack double carbon bonds and are generally derived from animals. Unsaturated fatty acids have at least one double bond, the position of which is designated by a prefix omega (ω). The two major polyunsaturated fatty acids are linoleic acid, which is an ω-6 fatty acid, and α-linolenic acid, which is an ω-3 fatty acid. Omega-6 fatty acids are usually derived from plants, and ω-3 fatty acids are usually derived from fish oils. Both of these polyunsaturated fats are essential for the development of cell membranes and the central nervous system (CNS), as well as for the synthesis of arachidonic acid and related prostaglandins. Thromboxanes derived from ω-6 fatty acids are potential mediators of platelet aggregation, whereas thromboxanes, derived from ω-3 fatty acids, are potent anticoagulants, as well as docosahexaenoic acid (DHA), which has important roles for CNS development and modulation of inflammatory conditions. Further, ω-6 fatty acids, which form arachidonic acid, also contribute to the formation of prostaglandin (PG) $E_2$, a known immunosuppressant, whereas ω-3 fatty acids contribute to the formation of $PGE_1$ and $PGE_3$, which do not have an immunosuppressive effect. A 1:1 ratio of ω-6 to ω-3 fatty acids seems to be ideal, based on experimental data from animals that survived burns.[63] No data are available on the ideal ratio in neonates or children.

Essential fatty acid deficiency shows an elevated triene-to-tetraene ratio of greater than 0.2, where trienes consist of 5,8,11-eicosatrienoic acid and tetraenes consist of linoleic and arachidonic acids and an eicosatrienoic/arachidonic acid, and low plasma levels of one or more of the essential fatty acids. Overall, any infant not receiving the full amount of lipids should be monitored at least once a month for essential fatty acid deficiency. Absolute values of linoleic and 1-linolenic acid can be ordered, and actually may yield a better perspective for the clinical development of EFA deficiency.

## MINERALS, TRACE ELEMENTS, AND VITAMINS

The normal daily requirement of vitamins has been recently revised by the Food and Drug Administration.[64] Vitamins are essential components or cofactors of various metabolic reactions. Most commercial infant formulas contain adequate amounts of vitamins to meet known daily requirements. Such requirements were established by the American Medical Association (AMA) in the 1970s.[65] Infants who receive other types of formula or human milk may require additional vitamin supplementation.

### Fat-Soluble Vitamins

***Vitamin A*** Vitamin A is principally stored in the liver and is involved in formation of retinoic acid for vision and the coordination of cell cycles. Deficiencies of vitamin A may lead to night blindness, xerophthalmia, poor growth, and impaired resistance to infection. It is also clear, however, that low levels of vitamin A predispose infants to long-term pulmonary disease, and vitamin A levels are low in such infants.[66] In a recent Cochrane review, eight studies were reviewed, and it was found that vitamin A supplementation was associated with a prevention in the development of bronchopulmonary dysplasia (BPD).[67] Neurodevelopment at 18 to 22 months of age was not different between those treated with and without vitamin A. Excessive amounts of vitamin A can be quite deleterious to infants. As little as 6000 μg of retinol daily can produce anorexia, desquamation of the skin, and increased intracranial pressure.[68]

***Vitamin D*** Vitamin D is essential for bone formation and mineral homeostasis. A deficiency may occur with fat malabsorption; however, overuse of vitamin D may lead to hypercalcemia.[69] Most formulas contain adequate amounts of vitamin D (approximately 60 IU/100 kcal). No evidence to support the supplementation of vitamin D to infants for better bone growth beyond that provided by standard formulas exists. During the past decade, a greater appreciation of the link between deficient immune status and low vitamin D levels has been examined in pediatric children. In fact, this association may account for an increased risk of pediatric asthma and food allergies.[70]

***Vitamin E*** Vitamin E seems to have significant antioxidant affects. Vitamin E may prevent the neuropathy seen in infants with biliary atresia as well as muscle weakness in children with cystic fibrosis.[71] The dose of vitamin E required for full-term infants is approximately 0.7 IU/100 kcal of energy intake. Because of its antioxidant action, vitamin E has been used to decrease lung injury in neonates with bronchopulmonary dysplasia. It does appear that usage of vitamin E is beneficial in this regard.[72] It also appears that vitamin E is beneficial in the prevention of retinopathy in premature infants[73]; and it may have a benefit in reducing the incidence of intraventricular hemorrhage.[74]

***Vitamin K*** Vitamin K is required at birth to prevent coagulopathy in newborns and should be administered soon after delivery.[75] Vitamin K is included in most formulas; however, larger amounts may be needed in infants with prolonged episodes of diarrhea. Assessment of deficiencies is most readily done by attaining a prothrombin time.

### Water-Soluble Vitamins

Deficiencies of water-soluble vitamins are rare in formula-fed and breast-fed babies. B vitamins are needed for carbohydrate, protein, and fat metabolism as well as oxidation and reduction reactions. Deficiencies may be seen with short-bowel syndrome and manifest as chelosis and lethargy. Abnormal levels of vitamin $B_1$ (thiamine) are generally the first signs of vitamin B deficiency and can be detected with an erythrocyte transketolase enzyme assay. Vitamin C is required for optimizing several enzyme reactions and has direct antioxidant effects. Excessive amounts of vitamin C may lead to nephrolithiasis and interference with vitamin $B_{12}$ absorption.

### Trace Elements

Trace elements comprise less than 0.01% of the total body weight in humans.[76] They often function as metalloenzymes, which maximize enzymatic reactions, but may also act as soluble ionic cofactors or nonprotein organic molecules. Without supplementation, specific deficiencies of many of these factors have been manifested clinically in patients maintained on long-term PN as well as those with short-bowel syndrome or malabsorptive conditions. Table 12-4 lists the recommended doses of trace elements.

***Zinc*** Zinc has several biochemical functions, including formation of metalloenzymes, ribonucleic acid (RNA) conformation, and membrane stabilization.[77] In addition, zinc seems to play a critical role in the maintenance of a normal immunologic system. Deficiencies in zinc can arise from various sources that are common in pediatric surgical patients; such sources include the short-bowel syndrome, thermal burns, peritoneal dialysis, inflammatory bowel disease, and other causes of diarrhea. Clinical manifestations of zinc deficiency include growth retardation, alopecia, skin lesions (acrodermatitis enteropathica), impaired lymphocyte function, impaired wound healing, and zinc deficiency can actually lead to diarrhea.[78] Supplementation in infants should be a minimum of 400 μg/kg/day. Because gastrointestinal losses can be higher during episodes of diarrhea and sepsis, higher doses are indicated in these instances. In addition, zinc deficiency may impair recovery of the intestines after massive resection.[79]

***Copper*** Copper is a critical trace element for metalloenzyme function. The main site of copper storage, distribution, and excretion is the liver. Copper deficiency has been reported in patients receiving PN formulas that are not supplemented with copper.[80] Manifestations of copper deficiency include microcytic, hypochromic anemia; neutropenia; hypothermia; mental status changes; and, in children, growth retardation and skeletal demineralization. Removal of copper from infants and children may lead to an aplastic anemic condition, which can be fatal.[81]

***Selenium*** During the past decade, selenium has been acknowledged as an essential trace element. Selenium is a component of a selenoenzyme that helps catalyze glutathione peroxidase, an enzyme system that is necessary to reduce free radicals. The most practical way of measuring selenium levels is by assaying glutathione peroxidase activity in erythrocytes. Selenium levels dramatically decline after as few as 6 weeks of PN.[82] Without the addition of selenium, deficiencies are generally manifested by cardiomyopathy as well as by peripheral myositis with associated muscle tenderness.

***Manganese, Chromium, and Molybdenum*** Although no clear-cut cases of manganese deficiency have been documented in the literature, manganese is an essential element for many organisms and is believed to also be essential for humans. Animals that are deficient in manganese show growth retardation and ataxia in the newborn period.[83] Excess deposition of manganese has been shown to occur in both the liver and brain of infants on prolonged PN, and clinicians should have a very low threshold of eliminating Mn from the trace element package of infants who have developed PN-associated liver disease (PNALD).[84] Chromium seems to have its predominant action as a potentiator of insulin action. Deficiencies of chromium can lead to poor glucose tolerance.[85] Molybdenum is important in the oxidative metabolism of purines and sulfur-containing compounds[86] but is not typically supplemented in PN. Deficiencies of molybdenum are associated with increases in serum uric acid levels.

## Enteral Nutrition

Enteral nutrition (EN) includes oral nutritional supplementation and tube feedings. EN should be the primary source of nutrients if the gastrointestinal tract is functional. Even when full feedings are not tolerated enterally, the provision of small volumes of "trophic" feedings may prevent further deterioration of intestinal function.

### INDICATIONS

Infants in a state of good health before surgery or trauma can sustain 5 to 7 days without significant energy intake and without serious systemic consequences, provided that adequate nutritional support is initiated thereafter. Premature infants less than 32 to 34 weeks' gestation do not generally have a maturely coordinated suck and swallow. Feedings must therefore be provided enterally either by bolus every 2 to 3 hours or by continuous feedings. The overall growth patterns are exceedingly poor for premature infants. In addition, the younger an infant's gestational age, the greater the percentage who are discharged with growth restriction. In fact, almost 100% of infants born at 24 weeks' gestational age will be discharged with a diagnosis of growth restriction. Therefore aggressive feeding even within the first 24 hours of life is generally considered advisable. Enteral feedings are begun after the resolution of the postoperative ileus. There are many high-calorie formulas available to address variable needs (Tables 12-5 (infant) and 12-6 (pediatric). Children who have specific

LCHAD, long-chain hydroxyacyl-CoA dehydrogenase deficiency; MCT; medium-chain triglyceride.

Composition of infant and pediatric formulas is summarized in Tables 12-5 and 12-6, respectively. Enfamil (Mead Johnson) and Similac (Ross, Columbus, Ohio) both have milk-based proteins and contain lactose as the carbohydrate source. There are only limited reasons to use soy formulas. The soy-based products include Prosobee (Mead Johnson) and Isomil (Ross). Both contain corn syrup solids as a carbohydrate source. Isomil also contains sucrose. Soy formulas are indicated to manage galactosemia and primary or secondary lactase deficiency. Soy formulas should not be used in patients with a documented allergy or intolerance to milk protein, because one third of infants who have an allergen-induced reaction to cow's milk are also intolerant of soy. Therefore a protein hydrolysate or elemental formula is recommended in infants who have milk-protein intolerance. Protein hydrolysates include Nutramigen (Mead Johnson), Alimentum (Ross), and Pregestimil (Mead Johnson). Alimentum and Pregestamil also provide 50% to 55% of fat as medium-chain triglycerides (MCT). If infants have continued symptoms of protein intolerance when ingesting a protein hydrolysate, then an amino acid–based formula may be provided. For the infant population, Neocate (Scientific Hospital Supplies, Gaithersburg, Md.) is the only amino acid–based formula available. Children older than 12 months of age who continue to be intolerant of milk protein may respond well to Peptamen, Jr (Clintec, Chicago, Ill.), which is a whey protein hydrolysate. If an amino acid–based formula is needed in children older than 12 months of age, options include Neocate 1+ (Scientific Hospital Supplies), L-emental (Gala/Gen/Nutrition Medical, Arden Hills, Minn.), and Elecare (Ross). Neocate 1+ and Elecare both have long-chain triglycerides. Sixty-eight percent of the fat in L-emental is derived from MCT. The authors thank Megan Perkowski, RD, for her contribution and editing of this table.

underlying diseases associated with malabsorption may benefit from specialized formulas. Once oral feeds are clinically possible they should begin. Delay in initiating oral nutrient swallowing will result in long-term oral aversion.

## DELIVERY MODALITIES

Aside from oral intake, a number of modalities are available for enteral delivery. These include nasogastric and nasojejunal feedings. Children receiving gastric feedings tolerate a higher osmolarity and volume than those being fed into the small bowel. Furthermore, gastric acid may benefit digestion, has a bactericidal effect, and is associated with less-frequent gastrointestinal complications.[7] Auscultation of air insufflated into the tube is inadequate. Confirmation must be obtained by aspiration of gastrointestinal contents or radiographic confirmation.[87] For patients requiring feedings for more than 8 weeks, a more permanent feeding access (e.g., gastrostomy tube) should be considered. The preoperative assessment usually consists of an upper gastrointestinal series followed by a 24-hour pH probe study if the results of the upper gastrointestinal study are abnormal. If either of these studies reveals reflux, a fundoplication should be done at the time the gastrostomy tube is placed. Assessment of gastric emptying should also be done before surgery, with a nuclear gastric-emptying study.[88,89] The most common procedure for gastrostomy placement is a percutaneous endoscopic gastrostomy (PEG) tube.[90] An improvement in gastrostomy tubes is the gastrostomy "button." The button is made of nonreactive Silastic components. It has a valve placed into a low-profile device that lies almost flush with the abdominal wall, and it can be capped between uses.[91] These buttons may now be placed at the same time as the percutaneous endoscopic procedure.[92] It has been reported that the incidence of complications is less with a PEG technique compared with other approaches; however, several complications have been described, including improper placement (i.e., close to the pylorus), inadvertent placement through an adjacent loop of bowel, necrosis of the tract of the gastrostomy tube, and technical failures that require laparotomy.[93]

Use of jejunal tubes is plagued with problems, including involuntary dislodgement of transpylorically placed tubes and catheter obstruction because of inspissation of feedings or instillation of medications. Short-term complications of surgically-placed J-tubes include intra-abdominal abscess and volvulus with bowel infarction. Long-term complications include intestinal obstruction and peritonitis. When using tubes passed distal to the pylorus, continuous drip feedings are recommended to prevent the development of diarrhea and other symptoms of dumping. Verification of the location of the tube is mandatory before beginning enteral tube feedings. This requires either aspiration of enteric contents or radiologic confirmation.

## ENTERAL FORMULAS

The choice of formula depends on the age of the patient and the condition of the gastrointestinal tract. In general, term infants should be maintained on human milk (see later) or a standard 20 kcal/oz formula (see Tables 12-5 and 12-6). Cow milk–based formulas for term infants contain nutrients that closely approximate the nutritional profile of human milk. Some formulas have added arachidonic acid (ARA) and docosahexaenoic acid (DHA), the two fatty acids that are found in human milk and believed to be essential for brain and eye development; however, no strong evidence-based literature supports the need for this. A lactose-based formula is generally the first choice, because it is the most physiologically

Btaiche I, Khalidi N, Kovacevich D (eds): The Parenteral and Enteral Nutrition Manual, ed 9. Ann Arbor, Mich, 2010, University of Michigan, University of Michigan Hospitals and Health Centers.

similar to human milk and is the least expensive. Soy formulas are indicated to manage galactosemia and primary or secondary lactase deficiency. Soy formulas should not be used in patients with a documented allergy or intolerance to milk protein, because one third of infants who have an allergen-induced reaction to cow's milk are also intolerant of soy. Therefore a protein hydrolysate or elemental formula is recommended in infants who have milk-protein intolerance. Further, soy formulas are not recommended for premature infants, because of their high aluminum content, which may contribute to osteopenia.

Calories from enteral nutrition can be added by increasing the volume delivered, increasing the concentration of the formula, or by supplementing the feedings. Formula concentrations may be increased to 30 kcal/oz; however, highly concentrated formulas may be difficult for some infants to digest, because they have a higher renal solute load and it may take time for them to build up tolerance. Higher concentrations have also been associated with a necrotizing enterocolitis–type process.[94] Formula supplementation can be done by the addition of a glucose polymer or fats (as medium-chain triglycerides or vegetable oil). Each 0.5 g of glucose polymer added to an ounce of standard formula increases calories by 0.06 kcal/mL, therefore creating a total caloric delivery of 0.73 kcal/mL. The addition of 0.5 g of oil to formula increases calories by 0.13 kcal/mL or a total of 0.8 kcal/mL. Caution must be taken when supplementing calories in this fashion, because it may compromise the ability of the infant to consume sufficient amounts of protein or minerals if the amount of formula is limited. However, up to 2 g of glucose polymer or 1 g of oil per ounce of formula can be added safely.

Standard premature infant formulas are milk-based formulas that provide 22 to 24 calories/ounce, and are optimized for required vitamins, minerals, and trace element needs. A portion of fat is provided as medium-chain triglycerides (MCT) to compensate for the limited bile salt pool in young infants. MCTs can be absorbed directly through the basolateral surface of the epithelial cell without the need for bile salts. MCTs, however, cannot be used to prevent essential fatty acid deficiency (all of which are long-chain triglycerides). The carbohydrate is composed of glucose polymers, as well as lactose, to optimize carbohydrate absorption in the presence of limited lactase activity. Premature infants are at increased risk for necrotizing enterocolitis. This risk is not increased with gastrointestinal (GI) priming feeds; however, excessive advancements in the rates of these feedings have been shown to put neonates at increased risk. In general, feeding advancements should not exceed 20 mL/kg/day.[61] Whether feedings are given through a bolus or continuous methods does not appear to influence hospital outcomes or days to reach full feeding.[95,96]

### Administration of Enteral Nutrition

For preterm infants, a feeding protocol is typically followed to maintain consistency of practice and reduce the incidence of necrotizing enterocolitis, and these guidelines are now well established.[97,98] For term infants, intermittent enteral feeding can be initiated at 2 to 5 mL/kg every 3 to 4 hours. Feeding is advanced in increments of 2 to 5 mL/kg every two feedings to a goal rate as tolerated. Guidelines have been revamped for safe delivery of enteral nutrition, and are given in Table 12-7 for term and premature infants. Feeding residuals are checked before each intermittent feeding, and enteral nutrition is held if the residual volume is greater than twice the administered volume.

## HUMAN MILK

Human milk has a variety of advantages compared with commercial formulas. The American Academy of Pediatrics advocates nursing until 1 year of age; yet, the majority of mothers in the United States stop nursing by the infant's second month of life.[99] Breast-feeding provides both nutrition as well as passive immunologic protection to the neonate. Breast milk contains 87% water and provides 0.64 to 0.67 kcal/mL. The fat content of breast milk is fairly high, at 3.4 g/dL. The protein content of human milk (0.9%) is lower than that of bovine milk or commercial formulas but appears much better absorbed because of the higher amounts of whey content. Casein, which predominates in bovine milk, is a complex of protein and calcium. The whey fraction contains primarily lactalbumin and, as well, lactoferrin, an iron-binding protein that is bacteriostatic to *Staphylococcus aureus* and *Escherichia coli* by restricting iron availability.[100] Additionally, ingestion of human milk allows for the acquisition of passive immunity by the transfer of both immunoglobulins and lymphocytes from the mother.[101] Breast milk also contains elevated levels of cysteine, which is potentially essential for a neonate, and taurine, which is needed for bile salt excretion and neurologic and retinal development. Despite similar amounts of trace elements, human milk allows for a more efficient absorption of these elements compared with commercial formulas. The immunologic advantages of breast milk include the transmission of both humoral as well as cellular factors to the neonate.[101] Although human milk has many advantages, high demands for calcium, phosphorus, electrolytes, vitamins, and trace elements cannot be achieved with human milk alone. Because of this, human milk fortifiers (one pack per ounce) should be added to breast milk fed to preterm infants. Supplementation should continue until the child achieves the weight of a term infant. When human milk fortifier is added to human milk, the hang time of the final reconstituted formula is 2 hours. Because of reports of vitamin D

deficiency and rickets in breast-fed infants, the American Academy of Pediatrics recommends beginning, within the first few days of life, a daily supplementation of vitamin D 400 IU to all breast-fed and non–breast-fed infants who do not receive at least 1000 mL of daily vitamin D-fortified formula or milk.[102]

## COMPLICATIONS OF ENTERAL FEEDING

The gastrointestinal tract generally tolerates feedings quite well once the postoperative ileus has resolved. Not uncommonly, the critically ill child will sustain a loss of a significant portion of the absorptive function, often because of a lactase deficiency. Symptoms are generally manifested by cramping, diarrhea, or emesis. Symptoms will often improve with the initiation of a lactose-free diet. Enteral nutrition is the preferred route of feeding when oral nutrition is not possible or adequate. In the critically ill child, frequent interruptions of enteral feeding for procedures, feeding intolerances, fluid restriction, or gastrointestinal dysmotility result in suboptimal enteral nutrition delivery.[103,104] The gastrointestinal tract generally tolerates increased volume more readily than increased osmolarity. Therefore in situations of gastrointestinal dysfunction, such adverse symptoms can be avoided by initiating ¼-strength formula and slowly advancing the formula concentration. Second, administration of formula by continuous drip may be better tolerated than bolus feedings. The risk of gastroesophageal reflux and dumping symptoms are thereby greatly reduced. Aspiration is a major risk of enteral feedings. Rapid-bolus nasogastric feedings may lead to a high incidence of reflux. Complications can be decreased with the use of a slow, continuous infusion or, preferably, with jejunal feedings.[105] However, this latter method has become controversial. Although patients with delayed gastric emptying (e.g., infants with sepsis, recent trauma, electrolyte imbalance, or receipt of opiates) or those who are comatose may be at risk for aspiration; in stable patients, a continuous infusion through a nasogastric tube is associated with no higher incidence of aspiration than is infusion through a nasoduodenal tube.[106] When the patient's clinical condition allows, raising the backrest or the head of the bed to 30 to 45 degrees during continuous feeding decreases the risk of aspiration.[107] Third, care must be taken to ensure that the enteral formula does not become contaminated, either during preparation or at the bedside. Expiration times should be observed. Finally, pectin, Metamucil, Lomotil, paregoric, or Imodium may be required for those who have lost a significant amount of their bowel length (see Short-Bowel Syndrome section). Assessment of adequate absorption can be carried out most readily by the testing of the stool for the absorption of carbohydrates, by measuring stool pH, and detecting for reducing substances. The presence of a stool pH less than 5.5 or a reducing substance of greater than one-half percent indicates the passage of unabsorbed carbohydrates into the stool, and once detected, should lead to a decrease in the formula concentration of carbohydrate.

# Parenteral Nutrition

Parenteral nutrition (PN) is the intravenous administration of balanced and complete nutrition to support anabolism, prevent weight loss, or promote weight gain. Because acute illness causes mobilization of energy and protein stores, appropriate and timely nutrition should be provided to prevent malnutrition and promote speedy recovery.[108] PN is indicated when oral or enteral feeding is not possible, or as a supplemental nutrition when enteral feeding fails to meet nutritional needs. PN should be used for the shortest time possible, and oral or enteral feeding should be initiated as soon as clinically feasible. Although enteral feeding can prevent gut atrophy and reduce the risk of PN-associated hepatobiliary complications,[109–111] a recent meta-analysis showed that the incidence of complications resulting from enteral and parenteral nutrition are essentially the same.[112]

## INDICATIONS FOR PARENTERAL NUTRITION

Parenteral nutrition is ideal for maintaining nutrition in infants and children who are unable to tolerate enteral feedings. Clinical conditions in children likely requiring PN include gastrointestinal disorders (short-bowel syndrome, malabsorption, intractable diarrhea, bowel obstruction, protracted vomiting, inflammatory bowel disease, enterocutaneous fistulas), congenital anomalies (gastroschisis, bowel atresia, volvulus, meconium ileus), radiation therapy to the gastrointestinal tract, chemotherapy resulting in gastrointestinal dysfunction, and severe respiratory distress syndrome in premature infants. Very-low-birth-weight infants are generally intolerant of enteral feeding and require PN during the first 24 hours following birth. Signs of starvation may be seen in underfed premature infants in as soon as 1 to 2 days. Although older children and adults generally do not require PN unless periods of starvation extend beyond 7 to 10 days, young infants require PN if periods of starvation extend beyond 4 to 5 days.

Protein and calories are essential for growth but must be provided in appropriate proportions for their optimal utilization. Very-low-birth-weight infants are born with limited nutritional reserves, loose protein in desquamated epidermal cells and urine, and quickly use their somatic protein reserves for energy if inadequate nutrition is provided early after birth. Providing early nutrition within 24 hours after birth is essential for the transition from fetal to extrauterine life to prevent growth failure and neurodevelopmental delays. Therefore prompt initiation of PN within a few hours after birth is essential. Further, because very-low-birth-weight infants have shown decreased plasma amino acid levels following birth, protein intake at about 3.8 to 4.0 g/kg/day improves nitrogen retention and stimulates weight gain.[113,114]

## VENOUS ACCESS

The type of venous access varies depending on the nutritional needs of the patient. Although peripheral PN may be used for a limited number of days, the high risk of using peripheral veins is extravasation of the solution with a subsequent inflammatory response and potential skin necrosis. Since the mid-1990s, a percutaneous intravenous catheter (or PIC-line) has been used. These catheters are relatively small in diameter (2-Fr or 22-gauge). They are placed through the child's peripheral veins, in the upper or lower limbs, and passed into the central venous system. These catheters are extremely well tolerated in adults and children; they can often be maintained for several weeks with reasonably low infection rates.[115,116] Unlike the placement of a Broviac-type catheter, which

requires local or general anesthesia, PIC-lines can generally be placed in the neonatal intensive care unit (NICU) with minimal sedation. Another advantage of these catheters is avoidance of pneumothorax, because access is through the extremities rather than the chest. The cost of the peripheral access devices is considerably less than that of Broviac-type catheters; however, PIC-lines have similar or higher incidences of venous thrombosis, and comparable rates of infection and complications.[117]

For infants and children who require longer durations of infusion, central venous PN may be administered through a tunneled Silastic catheter (e.g., Broviac, 2.7- or 4.0-Fr). Such a catheter often has a woven Dacron cuff. Although the tunneling of the catheter and cuff has not been shown to reduce catheter sepsis, the use of a cuff can prevent accidental dislodgement.[118] The catheter may be placed into the superior or inferior vena cava. The ideal position for the tip of the catheter is the junction of the right atrium and the superior vena cava. The child's facial, external jugular, subclavian, or saphenous veins are ideal locations for access. In children who weigh less than 750 g, the internal jugular or femoral vein may need to be used because of the small caliber of other vessels.

## PARENTERAL NUTRITION: COMPOSITION AND REQUIREMENTS

Parenteral nutrition is a source of macronutrients (amino acids, dextrose, lipid emulsions), micronutrients (multivitamins, trace minerals), fluids, and electrolytes.

### Amino Acids

Pediatric parenteral crystalline amino acid formulas provide essential and nonessential amino acids specifically balanced to meet the needs of the developing child. Neonatal-specific amino acid formulas are formulated to closely reproduce the plasma amino acid profile of breast-fed infants. These formulas have led to greater weight gain and improved nitrogen balance in infants compared with standard amino acid formulas.[119] Some amino acids, such as cysteine, tyrosine, glycine, and taurine, are considered conditionally essential for the child. Taurine supplementation for premature infants is essential to promote bile acid conjugation and to improve bile flow[120] and has been shown to decrease the degree of PN-associated cholestasis.[40] Premature infants are at risk for taurine deficiency as a result of elevated renal taurine losses and their low capacity for taurine synthesis resulting from low cystathionase enzyme activity.[49,121] Amino acids are a source of energy (4 kcal/g) and nitrogen for protein synthesis. Parenteral amino acids should provide approximately 10% to 15% of total calories. Amino acids are started at 1 g/kg/day and advanced to goal over 2 to 3 days. To simulate intrauterine protein accretion rates, low-birth-weight infants may need up to 3.85 g/kg/day of amino acids.[46,122] Amino acid requirements are 2.5 to 3 g/kg/day in term infants, 1.5 to 2 g/kg/day in older children, and 1 to 1.5 g/kg/day in adolescents. Amino acid doses should be adjusted based on the patient's clinical condition and nutritional status. For example, higher amino acid doses are required for wound healing. Patients with liver failure and hyperammonemia require lower amino acid doses. Higher amino acid doses are required in patients treated with dialysis or continuous renal replacement therapies to make up for losses through the dialysis membrane and filter.[123,124]

### Dextrose

Hydrous dextrose is the major source of energy and provides carbon skeletons for tissue accretion. Dextrose also acts as a protein-sparing substrate by preventing breakdown of somatic protein stores by suppression of gluconeogenesis.[125] In most children and adolescents receiving PN, parenteral dextrose usually provides 50% to 60% of total calories. The caloric value of hydrous dextrose is 3.4 kcal/g. In infants, PN should be initiated at a dextrose infusion rate of 4 to 8 mg/kg/min to maintain adequate serum glucose concentrations. Lower amounts of glucose in a young neonate will lead to hypoglycemia because of inadequate hepatic production of glucose. Dextrose infusion is thereafter advanced at a daily rate of 2 mg/kg/min until the nutritional goal is achieved. The maximum dextrose infusion rate should not exceed 10 to 14 mg/kg/min, which can usually be achieved when PN is administered through a central venous catheter.[126,127] Premature infants with hypoglycemia or failure to thrive may require higher dextrose infusion rates up to 20 mg/kg/min to maintain euglycemia and promote adequate growth.

### Lipid Emulsions

Intravenous lipid emulsions are a condensed source of energy and essential fatty acids, providing 9 kcal/g of energy. The caloric value of lipid emulsions varies with the lipid emulsion concentration. Lipid emulsions at 10%, 20%, and 30% concentrations yield 1.1 kcal/mL, 2 kcal/mL, and 3 kcal/mL, respectively. Currently marketed intravenous lipid emulsions in the United States are made of long-chain triglycerides (LCT). Lipids usually provide 30% to 50% of the non-nitrogen caloric needs or about 20% to 30% of total calories. Typically, lipid emulsions in infants and children are initiated at a dose of 1 g/kg/day and advanced by 1 g/kg/day to a maximum of 3 g/kg/day. Gradually increasing the daily lipid intake (0.5 or 1 g/kg/day) does not seem to improve lipid clearance. However, the lipid emulsion is cleared better[128,129] and lipid utilization is improved[130] when lipid is infused continuously over 24 hours rather than intermittently or for part of the day. Keeping the intravenous lipid infusion rate below 0.12 g/kg/hour improves lipid clearance.

There are also differences between the clearances of lipid emulsions. The 20% lipid emulsion is favored rather than the 10% emulsion because of its better clearance as a result of its lower phospholipid content.[131,132] Because lipid emulsions are derived from vegetable oils, they are also a natural source of variable amounts of vitamin K[133] and vitamin E isomers.[134,135]

### Multivitamins

Pediatric parenteral multivitamins contain a combination of water-soluble and fat-soluble vitamins that are added to the daily PN (Table 12-8). Several pediatric multivitamin formulas are available in the United States. No parenteral multivitamin products are currently available to specifically meet the needs of premature infants. Pediatric parenteral multivitamins provide low vitamin A and high water-soluble vitamins to premature infants. Higher vitamin A intake may be essential in

low-birth-weight infants who are at increased risk for lung disease.[136] Depletion of water-soluble vitamins occurs rapidly under stressful conditions. Thiamine is a cofactor for normal dextrose metabolism. Dextrose is normally metabolized to pyruvate, which is then converted to acetyl coenzyme A, which undergoes oxidation through the citric acid cycle. If thiamine deficiency occurs, pyruvate is instead converted to lactate, which can result in lactic acidosis.[137] Lactic acidosis has been reported in patients who received dextrose infusions without thiamine supplementation,[138,139] and fatalities from lactic acidosis resulting from thiamine deficiency were also reported during periodic multivitamin shortages in the United States.

## Trace Elements

Standard pediatric trace mineral formulas contain zinc, copper, manganese, and chromium, and some formulas have added selenium. Trace element formulas are designed to meet the recommendations of the American Gastroenterological Association (AGA)-AMA and the Society of Clinical Nutrition for daily intravenous supplements of trace minerals in the absence of deficiencies.[65] The Safe Practice Guidelines by the American Society for Parenteral and Enteral Nutrition (ASPEN) recently issued different guidelines with lower daily parenteral trace element requirements and supplementation (see Table 12-4).[140] Trace element status varies with the patient's underlying clinical conditions, and are mentioned in a preceding section of this chapter. Whenever trace elements are restricted or supplemental doses are given, blood trace element concentrations should be periodically measured to avoid deficiencies or toxicities.

## Fluids and Electrolytes

A parenteral nutrition solution should be not be used to manage acute fluid and electrolyte losses. Instead, patients should receive a separate intravenous solution for fluid and electrolyte supplementation (Table 12-9). In the home setting, fluid and electrolyte requirements are incorporated into the PN admixture for convenience of administration. Maintenance fluid and electrolyte requirements in children are shown in the respective chapters. Electrolyte adjustments in PN are based on serum electrolyte concentrations. Adjustments should account for all electrolyte sources and losses, acid-base status, clinical conditions, and medications that affect electrolyte balance.

***Sodium*** Sodium can be provided in PN solutions in the form of chloride, acetate, or phosphate salts. Neonates and especially premature infants develop a natruresis during the first 1 to 2 weeks following birth, resulting from their immature kidney function. Because adequate sodium intake is essential for protein synthesis and tissue development, adequate sodium supplementation is necessary and is guided by serum and urine sodium levels.[141] Premature infants may require as much as 8 mEq/kg/day of sodium, and this decreases with age such that in older children needs range from 1 to 2 mEq/kg/day. Maximum sodium concentration in PN solutions should not exceed normal saline solution equivalent (154 mEq of sodium/L).

***Potassium*** Potassium can be provided in PN solutions in the form of chloride, acetate, or phosphate salts. Higher potassium requirements are needed during anabolism[142] and to correct any gastrointestinal or renal potassium losses. Potassium concentrations in the PN solution should not exceed 120 mEq/L, and potassium infusion rates in infants and children should not exceed 0.5 mEq/kg/hour[143]; in adolescents dosage should be at 0.7 mEq/kg/hour. With higher potassium infusion rates, the patient should be placed in the intensive care unit on a cardiac monitor.

***Chloride and Acetate*** The chloride to acetate ratio in the PN solution can be adjusted based on the patient's acid-base status. Acetate is converted in vivo to bicarbonate at a 1:1 molar ratio. A high acetate-to-low chloride ratio is indicated to help correct the metabolic acidosis, such as resulting from lower intestinal bicarbonate losses. High acetate may also be used to help a child compensate for a respiratory acidosis. Premature infants are

especially at risk for acid-base changes because of their inadequate response resulting from inefficient hydrogen ion excretion and bicarbonate reabsorption by the kidneys.[141,144] A low acetate-to-high chloride ratio minimizes the bicarbonate load in patients with metabolic alkalosis such as resulting from excessive gastric fluid and electrolyte losses. Great caution should be used when adjusting the chloride-to-acetate ratio because dramatic acid-base changes may rapidly occur.

***Calcium and Phosphate*** Calcium and phosphate requirements in infants and children are greater compared with adults because of increased demands for growth. Corticosteroids and loop diuretics that are commonly used in neonatal and pediatric intensive care patients can further increase calcium requirements by increasing calcium losses. Following birth, hypophosphatemia is commonly observed in premature infants, resulting from high urinary phosphate excretion.[145] Because phosphates dissociate into monobasic and dibasic forms, depending on solution pH, they should be dosed in millimoles (mmol) instead of mEq to avoid dosing errors. Calcium and phosphate should be provided in adequate ratio and amounts to optimize bone mineralization and prevent metabolic bone disease.[146] Bone mineralization is optimized at an intake ratio of 2.6 mEq of calcium:1 mmol of phosphorus (1.7 mg calcium:1 mg phosphorus).[147] Inadequate calcium and phosphorus supplementation is problematic because of a solubility limitation. As such, enteral calcium and phosphorus supplementation may be required. Also, cysteine hydrochloride, an acidic compound that can be added to the PN solution, can be used to lower the solution pH and allow higher calcium and phosphate amounts in PN. An acidic medium favors the formation of monovalent phosphates instead of the divalent phosphates that otherwise would bind to calcium. Cysteine hydrochloride is added to the neonatal PN solution at a dose of 40 mg/g of amino acids.[148] Calcium and phosphorus can safely be added to PN when the concentrations provided satisfy the following equation:

$$\text{Calcium (mEq)} + \text{Phosphorus (mmol)} < 30 \text{ (per 1000 mL of PN)}$$

Because of these solubility issues, the full needs for optimal tissue and bone growth may not be met unless calcium and phosphorus are also provided enterally.

## ADDITIVES TO PARENTERAL NUTRITION

### Heparin

The addition of heparin to the PN solution at a concentration of 0.5 to 1 units/mL[149] maintains the patency of the venous catheter,[150] and reduces vein irritation.[151] Further, heparin is a cofactor of lipoprotein lipase, an enzyme released from the vascular endothelium, which enhances the clearance of lipid particles and thus enhances lipid clearance.[152] Heparin should not be used in patients with bleeding or at risk for bleeding, or in patients with thrombocytopenia.

### Histamine-2 Receptor Antagonists

Histamine-2 receptor antagonists, such as ranitidine, famotidine, and cimetidine, are compatible with PN and may be added to the PN solution for stress ulcer prophylaxis or to decrease gastric secretions.

### Regular Insulin

Regular insulin is compatible with the PN solution. However, insulin therapy is difficult to regulate in infants, and intravenous insulin should be administered as a separate intravenous infusion to allow safe titration of the insulin dose.

### Iron Dextran

Iron deficiency anemia may occur in PN-dependent patients. Iron is not routinely added to PN. Iron dextran is the most common parenteral iron available for use when oral iron absorption is unreliable or results in gastrointestinal intolerance and is the only parenteral iron formulation that can be added to PN solutions. Because iron can be used as a substrate for bacterial proliferation, iron dextran should be avoided in infected patients. Because severe anaphylactic side effects may occur with iron dextran, an intravenous test dose must be first administered before the total dose is given. Although not recommend by manufacturers, its use during the first 4 months of life has been safely done by many qualified groups. Daily iron dextran doses up to 1 mg/kg have been added to neonatal PN to prevent iron deficiency anemia. Iron replacement calculations can be found in Table 12-10. The estimated total iron dextran dose can be equally divided into incremental doses and added to the daily supply of non–lipid-containing PN solution until the total replacement dosage is given. Iron dextran at therapeutic doses is incompatible with lipid emulsions.[153] Other potentially safer intravenous iron preparations are iron sucrose and sodium ferric gluconate; however, a test dose of these other iron preparations must also be given to determine the potential for an adverse reaction. Their use has been predominately in renal failure patients but also appears effective in children.[154]

### Carnitine

Carnitine is a quaternary amine required for the transport of long-chain fatty acids into the mitochondria, where they undergo oxidation.[155] Premature infants are at risk for carnitine deficiency because of their limited carnitine reserves and reduced ability for carnitine synthesis.[156] Reduced fatty acid oxidation and elevated serum triglyceride concentrations have been correlated with low plasma carnitine concentrations.[157] Although many enteral formulations contain carnitine, PN solutions are carnitine-free. Supplementation of L-carnitine to PN normalized plasma carnitine concentrations[158] and improved fatty acid oxidation. Premature infants who develop

**TABLE 12-10**

| Infants weighing < 5 kg: 25 mg |
| Children weighing 5-10 kg: 50 mg |
| Children > 10 kg: 100 mg |

unexplained hypertriglyceridemia during lipid infusion may benefit from L-carnitine supplementation at a dose of about 10 mg/kg/day.[159] In neonates, L-carnitine 20 mg/kg/day for 8 weeks resulted in higher-than-normal plasma total carnitine concentrations. Doses of L-carnitine exceeding 20 mg/kg/day in infants are unlikely of clinical benefit. Larger oral L-carnitine doses have caused seizures, diarrhea, nausea, abdominal cramps, and may negatively affect growth by possibly increasing the infant's metabolic rate. Parenteral L-carnitine doses of 48 mg/kg/day in low-birth-weight infants increased protein oxidation, decreased nitrogen balance, and increased the time to regain birth weight.[160]

## COMPLICATIONS OF PARENTERAL NUTRITION

Despite more than 40 years of experience with PN, complications continue to be a major obstacle in the care of pediatric patients. Complications of PN can be classified into metabolic, respiratory, hepatobiliary, and infectious.

### Metabolic Complications

***Hyperglycemia*** Hyperglycemia in patients receiving PN is primarily the result of excessive dextrose infusion. Factors that exacerbate glucose intolerance include sepsis, surgery, diabetes, pancreatitis, prematurity, and corticosteroid therapy. Elevated blood glucose may coincide with PN initiation, but endogenous insulin secretion usually adjusts within 48 to 72 hours. Untreated hyperglycemia causes osmotic diuresis that can lead to hyperosmolar, hyperglycemic, nonketotic dehydration with electrolyte disturbances,[127] impaired phagocytosis,[161] and liver steatosis.[162] Intensive insulin therapy to maintain tight glucose control in critically ill patients has variably affected patient outcomes and was associated with increased incidence of hypoglycemia. Although an earlier study in critically ill surgical adult patients showed decreased patient morbidity and mortality with continuous insulin infusion to maintain blood glucose levels between 80 to 110 mg/dL,[163] a recent large multicenter study reported that a more permissive glycemic target range of 140 to 180 mg/dL is desirable, because tight glycemic control was associated with increased patient mortality.[164] Data in pediatric intensive care unit patients showed that intensive insulin therapy targeting age-adjusted blood glucose levels was associated with decreased inflammatory response, reduced secondary infections, a shorter length of intensive care unit stay, and increased incidence of hypoglycemia.[165] Although uncontrolled hyperglycemia is unacceptable, there is disparity in practice of glycemic control in pediatric intensive care units, and the long-term outcomes and optimal blood glucose targets in these children remain unknown.[166]

The first attempt in managing hyperglycemia is to decrease the dextrose load or reduce the infusion rate. However, this may compromise nutritional intake, because dextrose is the major source of calories in PN. If reducing dextrose does not improve hyperglycemia, insulin therapy is then indicated. Because infants have a variable response to insulin therapy,[167] adding insulin to the PN solution should be avoided. Instead, a regular insulin drip should be initiated and titrated based on serial glucose checks.

***Hypoglycemia*** Hypoglycemia with PN is usually the result of a sudden reduction of the PN infusion rate. In patients who receive PN during a portion of the day ("cycled"), hypoglycemia may be avoided by gradually reducing the rate during the 1 to 2 hours prior to discontinuation. Capillary glucose levels (chemsticks) should be monitored 15 to 60 minutes (typically 30 minutes) after PN is discontinued to check for any reactive hypoglycemia. Premature infants are at very increased risk for hypoglycemia because of their underdeveloped metabolic response[168]; cycling of PN in this group of patients is typically not safely performed until the child is more mature. If PN is unavoidably to be discontinued, intravenous administration of 10% dextrose in water, following PN discontinuation, will prevent symptomatic hypoglycemia.[9] Iatrogenic hypoglycemia can result from insulin therapy. If insulin is added in PN, adjustments to the insulin dose, guided by regular capillary glucose level checks, are necessary when metabolic stress decreases, pancreatitis resolves, or when corticosteroid therapy is tapered or discontinued.

***Hypertriglyceridemia*** High dextrose infusion is the primary cause of hypertriglyceridemia in PN patients. Excessive carbohydrate intake enhances hepatic and adipose tissue lipogenesis.[169] Other factors that predispose to hypertriglyceridemia in pediatric patients receiving PN include prematurity,[170] lipid overfeeding,[171,172] critical illness, and sepsis.[173] Although the tendency would be to reduce lipid infusion, a reduction in dextrose would be far more effective. However, the dextrose infusion rate should not be decreased to less than 4 mg/kg/minute in infants, a minimum rate required for protein-sparing effect. If hypertriglyceridemia persists despite reducing glucose intake, the lipid emulsion dose and rate should be decreased to keep triglyceride levels less than 275 mg/dL. A lipid dose of 0.5 to 1 g/kg/day in children would prevent essential fatty acid deficiency. If the 10% lipid emulsion is used, switching to the 20% lipid emulsion is recommended because of its better clearance.[174] Carnitine deficiency should be ruled out, especially in premature infants and those with renal insufficiency, because it may also be a cause of hypertriglyceridemia (see previous).

***Metabolic Acidosis*** Metabolic acidosis may result from excessive chloride (hyperchloremic acidosis may occur with serum chloride levels >130 mEq/L) or high amino acid load in PN. The addition of cysteine hydrochloride to the PN solution to improve calcium and phosphate solubility may also cause acidemia,[48] which may also lead to just the opposite effect—a leaching of calcium from the infant's bones. Premature infants and patients with liver or renal disease are at increased risk for metabolic acidosis and should be closely monitored for acid-base changes.

***Electrolyte Disturbances*** Hypokalemia, hypomagnesemia, and hypophosphatemia may result from increased requirements during anabolism and protein synthesis (refeeding syndrome), which is particularly common in the severely malnourished patient. Slow advancement of feeding with electrolyte repletion is recommended.[142] Phosphate is required intracellularly for generation of high-energy phosphate bonds and bone formation, and intracellular shift of phosphate occurs with carbohydrate infusion.[175] Severe hypophosphatemia may lead to hypoventilation, neurologic and cardiac

disturbances, and coma.[176] Apparent hypocalcemia in malnourished patients is often secondary to a reduced serum albumin concentration with proportionally low total serum calcium. Hyperkalemia, hypermagnesemia, and hyperphosphatemia may result from increased intake in combination with decreased renal function and hypercatabolism.

***Metabolic Bone Disease*** Metabolic bone disease, including osteopenia, osteomalacia, and rickets, is a complication in PN-dependent patients. Diagnosis is often difficult and may not be evident until a pathologic fracture is observed. Biochemical markers may reveal elevated serum alkaline phosphatase concentrations, hypercalciuria, low to normal plasma parathyroid hormone (PTH), and low 1,25 dihydroxyvitamin D.[177,178] Several factors predispose to PN-associated metabolic bone disease, including calcium and phosphorus deficiency, excessive losses of calcium resulting from diuretics, excessive vitamin D intake,[179] and aluminum toxicity.[180] Maximizing calcium and phosphorus intake is most important to improve bone mineralization. Calcium deficit is the result of limitations on the amount of calcium supplementation and the resultant hypercalciuria from amino acids,[181] with secondary metabolic acidosis.[182] Aluminum, a contaminant of the PN solution, is another possible cause of metabolic bone disease. Aluminum causes bone remodeling by impairing calcium fixation in bones,[183] impairing PTH secretion, or reducing the formation of active vitamin D.[184] Premature infants and patients with renal failure are at highest risk for aluminum toxicity resulting from their reduced ability for aluminum elimination. Additional vitamin D administration may actually be dangerous, because vitamin D may also play a role in the pathogenesis of metabolic bone disease; however, the exact mechanism is unknown. Withdrawing vitamin D from these patients leads to improvement in bone demineralization, resolution of bone pain, positive calcium balance,[179] and normalization of plasma active vitamin D and PTH concentrations.[185]

### Hepatobiliary Complications

Hepatobiliary complications associated with PN include cholestasis, steatosis, and cholelithiasis. Multiple factors may predispose to PN-associated hepatobiliary complications, including prematurity, overfeeding, PN dependence, absence of enteral stimulation for gall bladder contraction, short-bowel syndrome, and recurrent sepsis.[186,187] Cholestasis is the most common hepatobiliary complication in children receiving PN. Jaundice may occur as early as 2 to 3 weeks after PN initiation. A serum conjugated bilirubin concentration greater than or equal to 2 mg/dL is commonly used as a biochemical marker of cholestasis.[187] A rapid rise in direct bilirubin is a strong predictor of impending hepatic failure. Use of a taurine-supplemented PN solution has been shown to decrease the degree of cholestasis in premature infants and those with necrotizing enterocolitis.[40] In infants with short-bowel syndrome, a direct bilirubin greater than 2.5 mg/dL for more than 4 months was associated with an 80% mortality[189] and suggests a potential criteria for referring patients for transplant evaluation.[190] Strategies to prevent or reduce PN-associated liver disease (PNALD) include initiation of enteral feeding, weaning PN, avoiding overfeeding,[191] balancing calories,[192] "cycling" PN,[193,194] and avoiding and promptly treating sepsis.[192] Pharmacologic interventions include improving bile flow with the administration of bile acids or use of cholecystokinin, both have been studied in controlled prospective trials without any proven benefit.[195,196] Oral antibiotics, such as oral gentamicin and metronidazole have been used to decrease intestinal bacterial overgrowth and reduce bacterial translocation.[197] During the past decade, it has become apparent that soybean-based intravenous fat emulsions are a causative agent of PNALD. Strategies to either reduce the amount of these fats[198] or replace them with a fish-oil–based intravenous fat[199–201] have proven successful in reversing PNALD, thus making soybean fats a potential contributing factor to this disease process.

### Infectious Complications

Sepsis is one of the most frequent and serious complications of centrally infused PN in infants and children.[202] Fever and sudden glucose intolerance are suggestive of sepsis. Persistent hyperglycemia has been shown to increase infection rates, and intensive control is recommended.[203] Microbial culturing of PN should be performed if PN is suspected as a source of microbial contamination, though this is a rare occurrence with the use of strict sterile compounding techniques. Catheter-related infections remain the main cause of sepsis in patients receiving PN. Although not specific for children, guidelines for the diagnosis and treatment of central venous access infections have recently been established by the Infectious Disease Society of America[204] and the European Society of Parenteral and Enteral Nutrition.[205] Microorganisms may enter the bloodstream (1) along the catheter tract, starting at the skin exit site; (2) through a contaminated intravenous solution; (3) by breaks in sterility at the catheter hub–blood drawing or cleaning intravenous tubing; or (4) from a distant septic site or the GI tract. The catheter in this case, acts as a foreign body focus for bacterial growth. The most important factors in reducing the incidence of septic complications are placement of catheters under strict aseptic conditions and meticulous care of the catheter sites. Factors that correlate with catheter-related infections include prolonged catheterization, use of the catheter for multiple purposes, manipulation of the catheter hub, and chronic PN therapy. Most series report an incidence of 0.5 to 2.0 infections per 1000 catheters-days for a nonimmunosuppressed patient with a central venous catheter.[206,207] For immunosuppressed patients (e.g., hematology or oncology patients), a rate of 2 to 3 infections per 1000 catheter-days is generally reported.[208,209] A considerably higher rate of infection is found in children with the short-bowel syndrome; this rate ranges from 7 to 9 infections per 1000 catheter-days.[210–213] Several measures have proven effective in preventing catheter-related infections, including the use of sterile barriers and topical disinfectants during catheter insertion, use of antimicrobial-coated catheters, and regular catheter flushing. Although some individual studies have shown benefit with chlorhexidine-impregnated catheters, a recent review found no benefit but did suggest beneficial reduction of infections when catheters were either heparin-coated or antibiotic-impregnated.[214] Use of chlorhexidine-impregnated dressings has been shown to reduce pediatric catheter infections.[215] Guidelines for the prevention and management of catheter-related infections have been published elsewhere.[216,217] In general, nonpermanent polyvinyl chloride lines should be removed with catheter sepsis; however, more than 80% of patients with a Silastic catheter (e.g., Broviac or Hickman) will be able to have the infection cleared with intravenous antibiotics. Another technique to treat such

infections is the antibiotic-lock technique. This technique allows delivery of markedly higher doses of antibiotics into the catheter with allowance of the antibiotic to remain in the lumen while it is not in use.[218,219] This allows use of antibiotics that would normally have such high minimal inhibitory concentrations (MIC) that systemic use would result in renal failure (e.g., nafcillin for a staphylococcal line infection). Antibiotic lock methods are used routinely in some centers but are probably most useful in patients who may not tolerate an aminoglycoside or vancomycin. Because of this problem, as well as the risk of developing resistant organisms in the patient, ethanol-lock therapy has become commonly used to both treat as well as prevent the development of pediatric central venous-line infections.[220–222] Overall, the use of ethanol lock can reduce infections by almost 10-fold. However, complications may occur because of the risk of precipitation of heparin or citrate with ethanol, which requires that these two agents *not* be used when patients are receiving ethanol lock.[221] Additionally, ethanol may weaken plastics in the catheter and should *not* be used if the device is composed of polyurethane.[223] Because of the high failure rate of antibiotics, most patients with a *track* infection should have the line removed. Most children with fungal infections should also have the catheter removed, because of reports of fatalities and high failure rates with attempts at trying to salvage the line with antifungal therapy.[224] Attempting to maintain a catheter with a *Candida* infection is associated with a mortality of up to 25% and the low chance of clearing the infection with the line in place (13%).[225] Only a relatively short course of antifungal agents needs to be given after the catheter is removed (7 to 14 days); however, the results of blood cultures must be negative.[226] For unusual cases in which central venous access has been lost because of previous placement of several catheters, a trial of antifungal agents with the line in place may be attempted. An uncommon fungal organism associated with PN is *Malassezia furfur.* This organism thrives in a lipid-rich environment, but as long as lipids are withheld, it generally responds to antifungal treatment without catheter removal.

### Complications from Overfeeding

Overfeeding can lead to a number of adverse consequences. The administration of excessive dextrose may lead to osmotic diuresis and subsequent dehydration resulting from serum glucose levels exceeding renal tubular reabsorption threshold. Immunologic suppression has also been associated with overfeeding and is believed to be due to an inactivation of the complement system, as well as a depression of natural killer activation (see previous section on hyperglycemia). Overfeeding may also adversely affect the liver, because excessive glucose, which is not oxidized, is converted into fat (lipogenesis). These changes may lead to elevated serum triglyceride levels and hepatic steatosis that may be injurious to the liver. Additionally, overfeeding from carbohydrates associated with lipogenesis will lead to high carbon dioxide production, as reflected by an elevated respiratory quotient (RQ).[227] A RQ value exceeding 1 may represent overfeeding, and this high level may exacerbate ventilatory impairment in a critically ill child, because it represents excessive carbon dioxide production. Overfeeding should be avoided and caloric needs are best assessed in the critically ill child using indirect calorimetry. Overfeeding critically ill patients may also lead to fluid retention that may further compromise respiratory function.

### Technical Complications

In recent years, the incidence of technical complications caused by the placement of central venous lines in infants and children has been greatly reduced by careful attention to technique and by radiologic confirmation of catheter position. The incidence of cardiac arrhythmias caused by catheter irritation has been greatly reduced by placing the tip of the catheter at the junction of the superior vena cava and right atrium. Another important point is to ensure that a subclavian catheter is not inserted too medially, because this could lead to a pinching of the catheter between the first rib and clavicle, with the potential shearing off of the distal catheter into the heart.[228] Even with the proper positioning of a silicone catheter, thrombosis of the vein in which the catheter resides can occur, especially in the critically ill patient with sepsis and reduced circulation. Thrombosis of the great vessels will require anticoagulation and catheter removal. Pulmonary embolism and infection of these thrombi have been reported in infants and small children.[229] Thrombolytic therapy has proven effective in clearing the catheter of clots and avoiding the need for catheter replacement.[230] This procedure may be repeated at least twice to ensure removal of thrombus. Patients with long-term indwelling lines may have occlusion from either lipids or calcium deposits. These patients should also receive a trial of ethanol and dilute hydrochloric acid.[231] Since 1996, use of percutaneous intravenous central catheters (PICCs) has become the dominant mode of PN delivery in the United States.[232] This mode of insertion has the advantage of avoiding many of the complications associated with central venous catheters and can be often easily inserted on the floor with little or no sedation[233,234]; however, thrombotic events are more frequent than with centrally placed catheters. A reduction in these thrombotic events is seen if the catheters are placed in a central position, rather than in the juncture of the periphery and central venous system.

## ADMINISTRATION OF PARENTERAL NUTRITION

Neonates are generally started on PN within the first 12 hours after birth; and many centers now stock a pre-made 10% dextrose (D10%) solution for such use in their units. Neonates tend to be somewhat intolerant of large amounts of dextrose or amino acids for the first 2 to 3 days of life. Dextrose solution concentrations are generally initiated at 10% to 12.5%, and the concentration is slowly increased on a daily basis to between 20% and 25%. Monitoring of the patient's glucose levels and electrolyte balance and checking for glucosuria will confirm whether the child can tolerate this level of dextrose administration. PN may be administered through a peripheral or central venous catheter. The risk of developing phlebitis in peripheral veins is greater when the PN solution osmolarity exceeds 600 to 900 mOsm/L.[235] Intravenous solutions with higher osmolarities must be infused through a central vein. The maximum dextrose concentration in peripherally infused solutions in infants and children is 12.5%. Because lipid emulsions are isotonic solutions, coinfusion of lipids with peripheral PN protects the veins and prolongs the viability of peripheral intravenous catheters.[236] Because calcium phosphate precipitates are potentially life threatening in PN solutions, the Food and Drug Administration has recommended

that PN solutions be infused through an inline filter. A 0.22-μ filter is used for non–lipid-containing PN solutions, whereas a 1.2-μ filter is used for total nutrient admixtures to allow lipid particles (0.5μ in diameter) to pass through the filter. PN should be initiated as a continuous infusion spanning 24 hours. For patients receiving long-term PN, delivery may be given spanning a shortened period of time (e.g., 16 hours). Importantly, to avoid hypoglycemia or hyperglycemia, the rate of infusion needs to be reduced by half for 1 to 2 hours before terminating or starting up infusion each day. Additionally, neonates, particularly premature infants, have limited glycogen reserves and generally do not tolerate cycling of PN. A suggested guideline for writing orders for neonatal PN is given in Figure 12-1. Adequate maintenance of catheters and

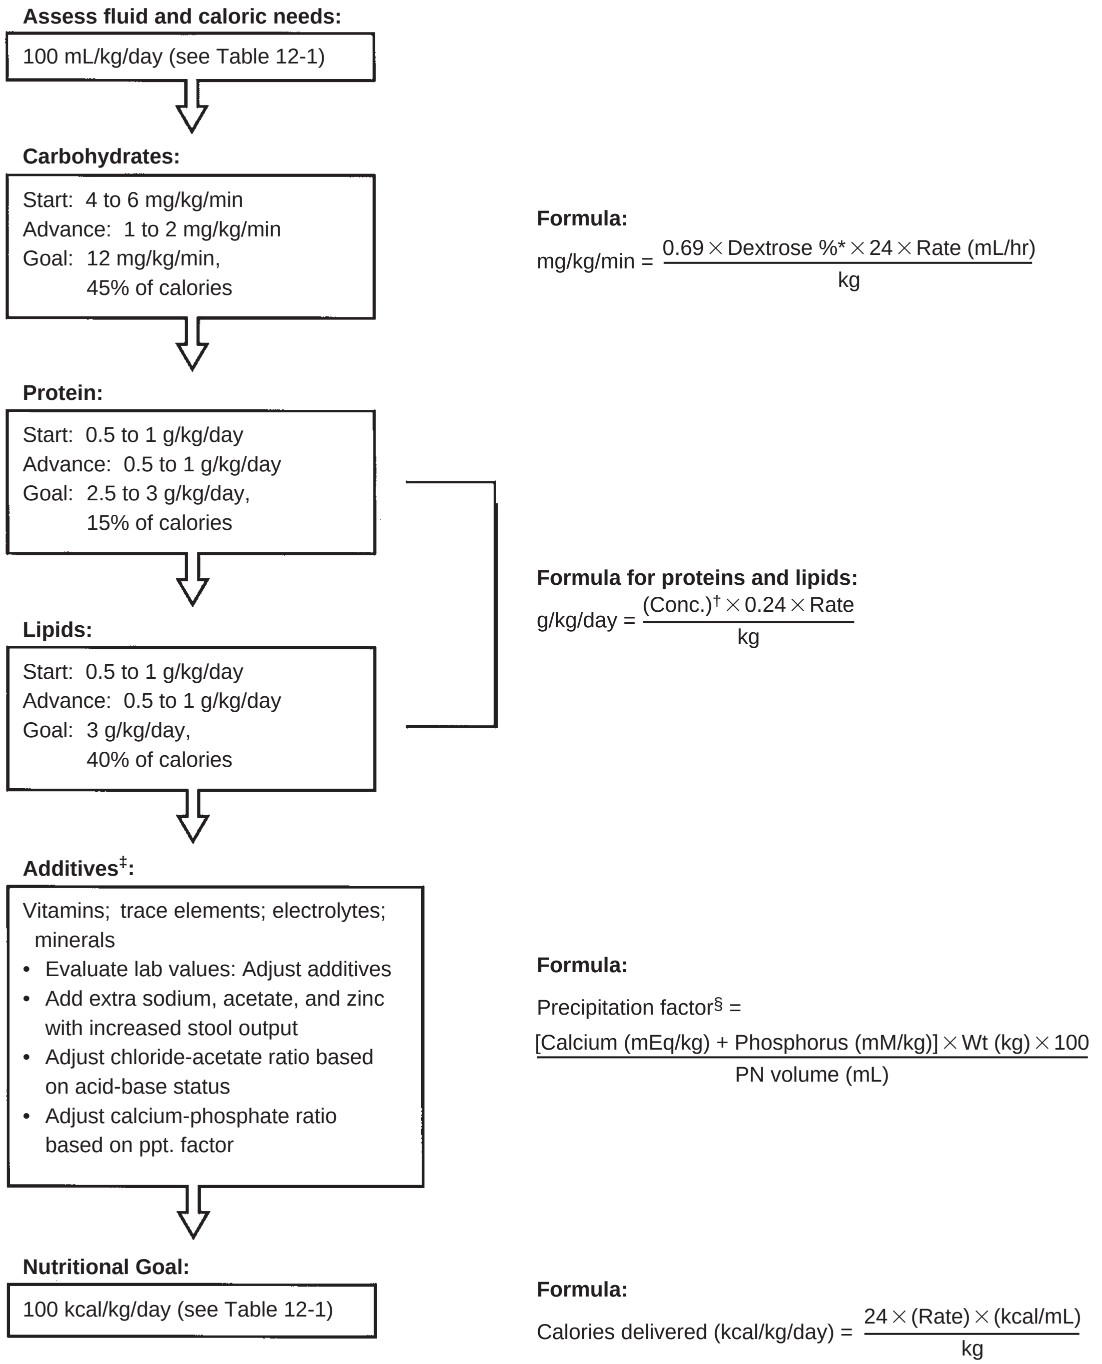

**FIGURE 12-1** Schematic diagram of how to begin to approach writing parenteral nutrition orders for a neonate or young infant. Fluids should be adjusted based on the infant's gestation age and body weight.

*Dextrose concentration should be used as the percent number (i.e., 20 for 20%). Conc, concentration; PN, parenteral nutrition; ppt, precipitation.

†The concentration in this formula should be written as the percent number (i.e., 4.25 for 4.25%).

‡See relevant tables for each of these additives.

§If the amino acid concentration is greater than 1.5%, the precipitation factor should be less than 3. If the final amino acid concentration is greater than 1% and less than 1.5%, a precipitation factor should be less than 2. Also, for an amino acid concentration less than 1%, calcium and phosphate should not be added. Adjustments to this formulation need to be done if additives (e.g., cysteine) are placed in the parenteral nutrition.

prevention of infection demands meticulous care, because catheters are a common source of sepsis in neonates.[211] Maintenance of all of these catheters requires that the skin site be cleansed with an antiseptic solution and dressed in a dry fashion every other day.[237] Tubing and infusion bags are changed every 72 hours, along with a new inline filter. Tubing used to deliver lipids must be changed every 24 hours.

### Monitoring of Laboratory Values

Monitoring of laboratory values is essential, because aberrations in these values are common in pediatric patients, particularly at the initiation of PN. Table 12-11 gives a suggested guide for such monitoring. A complete blood count, glucose, blood urea nitrogen, creatinine, and electrolytes (sodium, potassium, chloride, carbon dioxide) levels should be measured at initiation and on a biweekly basis. Liver function tests (alanine aminotransferase, aspartate aminotransferase, lactate dehydrogenase, alkaline phosphatase, and total direct bilirubin) should be done, and magnesium, albumin, calcium, and phosphorus levels should be checked at initiation and weekly. Triglyceride levels should be maintained until the desired level of fat intake is reached.

**TABLE 12-11**
**Guidelines for Blood Laboratory Monitoring of Nutrition Support in Parenteral Nutrition–Dependent Pediatric Patients**

| | *Initial* | *Daily* | *2 to 3 Times/ Week* | *Weekly* | *As Indicated* |
|---|---|---|---|---|---|
| Glucose | X | X | X | | |
| BUN, creatinine | X | X | X | | |
| Sodium, potassium, chloride, carbon dioxide | X | X | X | | |
| AST, ALT, LDH, alkaline phosphatase, total and direct bilirubin, GGTP | X | | | X | |
| Magnesium, calcium, phosphorus | X | | X | | |
| Albumin, total protein | X | | | X | |
| Triglycerides | X* | | | X | |
| Hb, Hct, CBC, platelets, PT | X | | | | X |
| Copper, zinc, selenium, chromium, manganese, iron | | | | | X |
| TIBC, ferritin | | | | | X |
| Vitamin concentrations | | | | | X |
| Chemsticks | | | | | X |
| Ammonia | | | | | X |
| Blood cultures | | | | | X |

*Measured once goal lipid infusion reached.
ALT, alanine transaminase; AST, aspartate transaminase; BUN, blood urea nitrogen; CBC, complete blood count; GGTP, gamma-glutamyl transpeptidase; Hb, hemoglobin; Hct, hematocrit; LDH, lactate dehydrogenase; PT, prothrombin time; TIBC, total iron-binding capacity.

# Special Problems in the Nutritional Support of the Pediatric Surgical Patient

## NUTRITION IN THE PEDIATRIC SURGICAL PATIENT

The surgical patient responds to the stress of surgery quite differently than older children or adults.[238] The metabolism of children is markedly affected by operative stress. The time period of increased energy expenditure, however, is much shorter than in adults.[239] Induction of anesthesia has profound effects on body metabolism, with agents such as fentanyl having a beneficial effect in reducing the catabolic effect.[240] Moreover, protein turnover and catabolism seems not to be affected by major operative procedures in neonates. PN, however, in surgical neonates is associated with increased production of oxygen-free radicals, and this may contribute to suppression of the immune status. Thus utilization must be tempered with any potential benefit. A discussion of the use of nutrition support both preoperatively and postoperatively follows.

## INDICATIONS FOR PREOPERATIVE NUTRITION

In malnourished adults, provision of enteral feedings preoperatively for 2 to 3 weeks may reduce postoperative wound infections, anastomotic leakage, hepatic and renal failure, and length of hospital stay.[241,242] Data for PN support are less clear. A meta-analysis demonstrated only a marginal benefit of preoperative PN. Little benefit, and possible increase in complications, was noted in mildly or moderately malnourished patients.[243] The most significant benefit has been documented in severely malnourished patients who have developed fewer noninfectious complications if receiving perioperative PN (PN presurgery for 7 to 15 days, and postsurgery for 3 days).[244] However, PN patients were noted to have an increased infection rate that could not totally be explained by the use of central venous catheters. This suggests that the use of PN may actually predispose patients to increased infectious complications. Thus unless there are clear indications of severe malnutrition (see Subjective Global Assessment in the previous section on nutritional assessment), a delay in operative management in order to provide preoperative PN is *not* indicated.[9] An extrapolation of these findings to neonatal patients is difficult because of their limited nutritional stores. However, because of similarities in the metabolic response to surgery, it seems reasonable to apply these same conclusions to the pediatric population.

## INDICATIONS FOR POSTOPERATIVE NUTRITION

Use of aggressive postoperative nutritional support is even more controversial. In critically ill adult patients, early enteral nutrition within 24 to 48 hours of admission to the intensive care unit has been shown to reduce infectious complications.[245,246] However, gastrointestinal complications and feeding intolerance can be a considerable limitation to the adequate delivery of enteral nutrition.[247] These data suggest that, when used, postoperative nutrition should be started

early, using a combination of PN and EN until the gastrointestinal tract fully recovers. A recent controlled study examining the effect of postoperative PN in children demonstrated a positive effect on nitrogen balance and levels of insulin growth factor-1 (IGF-I); however, no clinical benefit was noted.[248] The effect of PN on postoperative healing has been negligible. In the postoperative period, there are higher infection rates in patients on PN. Meta-analysis studies show that there is an actual adverse effect to postoperative PN.[243] Although prolonged starvation postoperatively places patients at adverse risk,[249] postoperative PN should be restricted to infants who will not tolerate even a short period of starvation or to older children who will probably not start enteral nutrition for at least 5 to 7 days. In well-nourished adolescents, this period of time should increase to 7 to 10 days.[9]

## NUTRITIONAL SUPPORT IN THE CRITICALLY ILL SURGICAL PATIENT

Nutritional care of the critically ill or septic postoperative patient represents a much greater challenge. Clinically, a critically ill child manifests poor enteral feeding, anorexia, and often a paralytic ileus. Insulin resistance results in hyperglycemia and hypertriglyceridemia. Control of this hyperglycemia has been shown to have a significantly beneficial effect in preventing sepsis.[203] Visceral protein stores become progressively reduced with time. Although measurements of albumin may change slowly because of its long half-life ($t_{1/2} > 18$ days), other measures of visceral protein status, such as prealbumin levels ($t_{1/2} = 2$ days), will better reflect these metabolic derangements. Estimates of energy needs during this time are important. Energy needs of postoperative or septic critically ill infants have not uncommonly been overestimated. Almost one third of an infant's energy needs is provided to support growth (30 to 35 kcal/kg/day). Because a cessation of growth occurs during periods of sepsis and critical illness, a marked decrease in energy needs may ensue. In a study of critically ill, postoperative infants, the mean measured basal energy expenditure was only 43 kcal/kg/day.[36] However, results are extraordinarily variable, further emphasizing the utility of performing indirect calorimetry. The use of indirect calorimetry can also yield information on the respiratory quotient (see previous) and aid in the prevention of overfeeding. Combined enteral and PN feedings in critically ill adult patients on ventilator support is controversial and may not be recommended.[250] Although not as well studied in neonates, data from meta-analyses in adult patients suggest that PN has little proven benefit to most critically ill surgical patients, and thus supplementation should be used sparingly in the initial few days of support until it is determined that the length of starvation will exceed 5 to 7 days.[251]

## BILIARY ATRESIA

The infant with biliary atresia, even after a clinically successful hepatic portoenterostomy, will typically have lower than normal amounts of bile flow into the intestine. This subsequently leads to a profound defect in fat digestion and absorption. Such a deficit may leave the infant with an essential fatty acid deficiency and inadequate absorption of fat-soluble vitamins.[252] Consequently, this will lead to a lack of bone mineralization as well as failure to thrive. The essential goals for such an infant are to provide adequate calories using a formula that maximizes fat intake. A commonly used formula in these patients is Pregestimil (Mead Johnson & Company, Evansville, Ind.). This formula has a large amount of medium-chain triglycerides and sufficient linoleic acid to prevent fatty acid deficiency in the face of decreased absorption. Use of this formula has been shown to increase growth in such patients.[253] Portagen (Mead Johnson & Company) should not be used in cholestatic infants, because it does not provide sufficient essential fatty acids to prevent deficiency. When PN is needed, a standard crystalline amino acid solution should be used; there is no proven benefit to hepatic formulas. Breastfeeding, although generally ideal in infancy, should be used cautiously in patients with biliary atresia. Breast milk has a much higher fat content than commercially available formulas and may not be well tolerated in these children. Vitamin supplementation is critical in patients with biliary atresia (Table 12-12). Unfortunately, supplemental vitamins are rarely covered by medical insurance payers despite the fact that they are medically necessary. Frequent monitoring of vitamin levels is essential to ensure sufficient supplementation is being achieved. The addition of water-soluble vitamins to levels greater than those provided in standard infant formulas should be carried out by the administration of a multivitamin preparation. Iron, zinc, and calcium deficiencies should be ruled out. From a practical perspective, it may be difficult and expensive to administer so many vitamins to a small infant. Many have used a combination form of fat-soluble vitamins (vitamins A, D, E, and K [ADEK] 0.5 mL/kg); however, vitamin K may be inadequate in this formulation, and additional supplementation (2.5 mg/day) should be given. Vitamin levels should be followed and deficiencies corrected with individual vitamins. Protein metabolism is impaired in children with biliary atresia, increasing from 4% to 9% of energy expenditure in healthy infants to 17% in patients with biliary atresia.[254] Pierro and colleagues[255] have shown that resting energy expenditure was about 29% higher than expected in infants with biliary atresia and that only 35% of the metabolizable energy intake was retained for growth in these children. Optimal growth and nutrition in infants with biliary atresia has recently been associated with improved outcomes and should be a major goal for pediatric surgeons.[256]

**TABLE 12-12**
**Vitamin Therapy in Cholestasis**

| *Name* | *Dose* | *Supplied As* |
|---|---|---|
| Vitamin A | 10,000-15,000 IU/day | 3-mg tablets |
| (Aquasol A; Centeon) | (50,000 IU = 15 mg) | 3-mg, 7.5-mg, or 15-mg capsules |
| | | 50,000 IU/mL drops |
| Vitamin D: 1,25(OH)$_2$D$_3$ | 0.01-0.05 μg/kg/day | 0.25 and 0.5 μg capsules |
| (Rolcaltrol; Roche Laboratories) | | 0.1 μg/mL/liquid |
| Vitamin E TPGS | 25 IU/kg/day | 26.7 IU/mL liquid |
| (Liqui-E; Twinlab) | | |
| Vitamin K | 2.5-5 mg/day | 5-mg tablets |

## SHORT-BOWEL SYNDROME

The nutritional support of a child with the short-bowel syndrome (SBS) is complex and requires a multidisciplinary approach with the pediatric surgeon, pediatric gastroenterologist, pharmacist, and dietitian working together. Although initially the child's main or sole caloric source will be through PN, enteral feedings should be initiated as soon as possible after the onset of the short-bowel syndrome. Enteral feedings will both stimulate small-bowel adaptation and prevent the development of PN-associated cholestasis. The ideal enteral solution should be isotonic. The protein source should be predominately elemental. Dipeptides and tripeptides have often been advocated, because this source of protein is most easily and efficiently absorbed.[257] Although data are limited, others have found better feeding tolerance with the use of an elemental (pure amino acid) enteral nutrition formula.[258] The formula should have at least 50% of medium-chain triglycerides because this type of fat is well absorbed through the basolateral wall of the intestinal enterocytes and into the portal venous circulation. However, medium-chain triglycerides contain no essential fatty acids; thus these fats cannot be the sole source of lipids in these patients, and supplemental long-chain triglycerides should be provided to prevent essential fatty acid deficiency. Tables 12-5 and 12-6 give recommended formulas for children of different ages. Despite the use of these elemental formulas early in the initiation of feedings, more complex diets, particularly human milk, appear to have the greatest benefit in achieving intestinal adaptation, and a modified regular diet should eventually be initiated.[259]

High stool output is associated with excessive losses of zinc, magnesium, sodium, bicarbonate, and potassium.[260] These losses must be monitored. Total-body sodium depletion has been shown to be associated with failure to thrive, despite the administration of adequate amounts of calories.[261] A simple way to detect such a deficit is to measure a spot urine sodium. A urine sodium of less than 10 mEq/L may well indicate total-body sodium depletion, and supplementation (sodium chloride or sodium bicarbonate, as indicated) by the oral route should be given on a daily basis.[262] A major obstacle to feeding advances may be high stool output. The etiology of this high output may include infections, malabsorption, rapid transit, as well as bile acid irritation of the colonic epithelium.[263] The child's stool should intermittently be assessed for infections. Additionally, measurement of stool pH, reducing substances, and qualitative fecal fats should be checked. Stool pH less than 5.5 and an elevated reducing substance level (greater than 0.5%) indicate carbohydrate malabsorption. Formulas with sucrose as the carbohydrate will not yield a positive reducing substance test despite carbohydrate malabsorption. Elevation in fecal fats will suggest fat malabsorption, which may require modification of the child's enteral diet (i.e., increase the percentage of medium-chain triglycerides). An increase in stool alpha-1 antitrypsin would indicate a protein malabsorption, although much less commonly encountered. Use of a resin binder (e.g., cholestyramine) will markedly reduce bile acid irritation and has proven extremely effective in many infants who have their small bowel in continuity with a portion of the colon. However, excessive use of bile acid binders, such as cholestyramine, may result in depletion of the circulating bile acid pool and thereby further limit fatty acid absorption. Because many infants with short-bowel syndrome have dysmotility, it is only after all other etiologies have been eliminated (i.e., infectious, bacterial overgrowth, bile acid irritation, and potentially correctable malabsorption) that an agent to reduce motility (e.g., Imodium) should be considered.

## OBESITY

Obesity has become a worldwide issue, with a striking increase in obesity rates being reported in North America as well as Europe and Asia.[264,265] Rates in the United States demonstrate a greater than threefold increase in obesity during the past 30 years. The implications of this rise in obesity are dramatic. First, more than 50% of children who are diagnosed with obesity will carry this excess weight into adulthood. Second, a number of secondary complications have been manifested in these children, including the prediabetic condition of syndrome X, type 2 diabetes mellitus, coronary artery disease, and obstructive sleep apnea.[266,267] Additional problems include bone and joint disease and cholelithiasis. The difficulty in the diagnosis of obesity has hampered the identification and treatment of many of these children. Although a National Institutes of Health (NIH) consensus has established a BMI of greater than 40 as morbid obesity,[268] BMIs change dramatically during adolescence and do not follow a linear curve. A more consistent diagnosis is based on the number of standard deviations from the mean using Centers for Disease Controls (CDC) standardized growth curves.[269] In this regard, at risk for overweight is defined as being at the 85th percentile, and overweight is defined as being at the 95th percentile.[264] Factors influencing the development of obesity are environmental as well as genetic.[270] The risk of obesity increases to 80% if one parent is also obese.[271]

Treatment of this condition is complex, and no ideal approach has been advanced. For the pediatric surgeon, use of surgery may be appropriate; however, it is essential that a team approach be applied to these children.[272] This approach includes pediatricians, nurses, nutritionists, psychiatric support, as well as the surgeon. The key issues when contemplating surgical intervention for obese adolescents include a careful patient evaluation and selection based on sufficient maturity to understand the implications of this lifelong decision, as well as the willingness to participate in follow-up for the rest of their lives. Vitamin and nutrient deficiencies are very common in such patients and require monitoring on an every-6-month basis.[273] Levels that are commonly deficient include protein, vitamin $B_{12}$, folate, iron, calcium, vitamin D, and thiamine.

## FAILURE TO THRIVE

Malnutrition in childhood is associated with poor growth and development. The diagnosis of failure to thrive is based on a weight more than two standard deviations less than the mean weight percentile (Z score of 2.0) resulting in a child falling at 2.1%.[274] Failure to thrive is symmetric, in which height, length, and development of other body organs fall below the fifth percentile, or asymmetric, in which the weight is below the fifth percentile but length and head circumference are within normal limits. In general, patients with symmetric failure to thrive have more profound malnutrition and suffer from greater neurologic underdevelopment than those with asymmetric failure to thrive; the latter patients have relatively

normal cognitive development. Recent investigations have shown that abnormal cognitive development in patients with failure to thrive probably results from a poor social environment and is often reversible.[275,276]

The approach to feeding a patient with failure to thrive should include a multidisciplinary assessment of medical, social, and psychological factors. A systematic evaluation to rule out neurologic pathology, swallowing disorders, feeding aversion, malabsorption, and metabolic disorders should be done. A trial of feeding the child in a hospital setting can often identify a problem with the child's home and social environment. Nutritional support for an infant should begin at approximately 50 kcal/kg/day and be increased by 20 to 25 kcal/kg/day as long as gastrointestinal tolerance to the feeding is adequate. Stool weight should be less than 150 g/day in young infants. Feedings may increase to 150 to 240 kcal/kg/day to achieve adequate catch-up growth,[277] but overshooting is not uncommon, and such high energy delivery states demands close clinical observation.

Supplementing the formula with additional potassium (up to 5 mEq/kg/day) may also be required during the first week of nutritional rehabilitation. Levels of potassium, magnesium, and phosphate need to be closely monitored, because they often drop rapidly after the initiation of feedings. One simple method to calculate caloric needs is that for each gram of weight gain desired per day, 5 additional calories should be provided.

## CHILDREN WITH SPECIAL CARE NEEDS

Between 10% and 20% of children in the United States have special health care needs because of chronic illness and developmental disorders.[278] For several of these disorders, pediatric surgeons take an active part in the nutritional care of the patients. Some of the disorders include several neurologic impairments; developmental delay; cerebral palsy; and such genetic syndromes as trisomies 13, 18, and 21 and Cornelia de Lange and Rett syndromes. Pediatric surgeons are often responsible for providing nutritional access in many of these patients as well as for maintaining nutritional care before and after surgery. Potential factors that may contribute to poor nutrition in these patients include feeding disorders, uncoordinated tongue movements, poorly coordinated swallowing reflexes, gastroesophageal reflux with associated nutrient loss, and increased energy expenditure caused by muscle spasticity or athetosis (a mixed pattern of too much and too little muscle tone). Because measuring energy expenditure in these children may be impractical, estimates of energy needs can be based on previous studies of resting energy expenditure. Children with spastic-type (hypertonia) cerebral palsy may have lower energy needs than normal; adolescents require a total of approximately 1200 to 1300 kcal/day.[279,280] Children with athetosis may require a higher-than-normal calorie intake, sometimes more than twice the RDA. Children with myelomeningocele are far less active than their peers; for that reason, their energy needs are approximately only 50% to 60% that of normal children (Table 12-13).

**TABLE 12-13**
**Guidelines for Estimating Caloric Requirements Based on Height in Children with Developmental Disabilities**

| *Condition* | *Caloric Recommendation* |
|---|---|
| Ambulatory, ages 5 to 12 years | 13.9 kcal/cm height |
| Nonambulatory, ages 5 to 12 years | 11.1 kcal/cm height |
| Cerebral palsy with severely restricted activity | 10 kcal/cm height |
| Cerebral palsy with mild to moderate activity | 15 kcal/cm height |
| Athetoid cerebral palsy, adolescence | Up to 6000 kcal/day |
| Down syndrome, boys, ages 1 to 14 years | 16.1 kcal/cm height |
| Down syndrome, girls, ages 1 to 14 years | 14.3 kcal/cm height |
| Myelomeningocele | Approximately 50% of RDA for age after infancy; may need as little as 7 kcal/cm height to maintain normal weight |
| Prader-Willi syndrome | 10-11 kcal/cm height (maintenance)<br>9 kcal/cm height (to promote weight loss) |

RDA, recommended daily allowance.

If the child's body habitus is markedly abnormal, a more appropriate estimate of energy needs should be based on surface area rather than weight. Repeated assessments of the child's growth during nutritional supplementation are essential, because obesity in these children is common. Obesity can cause a considerable burden on the family and caregivers because of the increased difficulty in moving an overweight child.

CHAPTER 13

# Pediatric Anesthesia

Ira S. Landsman, Stephen R. Hays,
Christopher J. Karsanac, and Andrew Franklin

Dr. Marc Rowe, a leader in pediatric surgery, noted, "no matter how skilled and experienced the pediatric surgeon, safe conduct of the newborn patients through the perioperative period requires an equally competent pediatric anesthesiologist."[1] Anesthetic management of both neonates and older children must take into account the process of rapid growth and development. The child's variable anatomic, physiologic, pharmacologic, and psychological characteristics, as well as the magnitude of the surgical problem, influence anesthetic care. This chapter provides an overview of important issues in pediatric anesthesia and pain management that are directly related to clinical management.

## Physiologic Considerations

During the first 3 months of life, circulatory and ventilatory adaptation is completed, thermoregulation processes change, the sizes of body fluid compartments shift toward adult values, skeletal muscle mass increases, and hepatic enzyme systems and renal function mature. Over the next 2 years, the child approaches adult physiologic but not psychological maturity. Between the ages of 18 months and 5 years, children demonstrate sufficient awareness of their surroundings so that psychological aspects of care become an issue. Anxiolytic agents may be useful in the child's preoperative preparation. Healthy preschool-aged children (2 to 6 years) present relatively few technical problems to the anesthesiologist, but the child's fear, apprehension, and lack of cooperation are of concern. Anxiety treatment before surgery in school-aged children (6 to 18 years) may also be necessary.

Newborns can feel acute pain and process established pain (postoperative pain). At birth peripheral nociceptors function similarly to mature receptors.[2] However, the nerves responsible for transmitting the immediate chemical, thermal, and mechanical painful stimuli to the central nervous system (CNS) are not fully mature, nor are the inhibitory pathways from the CNS mature.[3] In the past, because of their inconsistent response to pain, neonates did not receive adequate analgesia for procedures known to cause pain in adults.[4–6] However, neonates of various gestational ages clearly respond to painful stimuli by measurable physiologic, metabolic, and clinical changes, and analgesia and anesthesia attenuate these changes.[7]

Neonates are sensitive to anesthetic agents and have inefficient mechanisms of drug metabolism and elimination.[8] Until infants are 1 month old, there is a marked interpatient difference in the volume of distribution, sensitivity of the CNS, and quality and quantity of transport proteins such as albumin and $\alpha_1$-acid glycoprotein. These interpatient differences contribute to neonates' varied and often unpredictable responses to anesthetic agents.

After the first several weeks of life, drug metabolism gradually becomes so efficient that many of the opioid agents, such as fentanyl and morphine, have a shorter half-life in infants and young children than in older children and adults. The doses per body weight of intravenous (IV) anesthetic agents (e.g., thiopental and propofol) are higher in the first 6 months of life than during any other period (Fig. 13-1).[9] During the first year of life, the concentration of inhalation agent needed to maintain anesthesia is greater than during any other period (Table 13-1 and Fig. 13-2). However, the infant's heart is more sensitive to these higher concentrations.

## Anesthetic Risk and Common Complications

Recent animal studies have stimulated debate and concern that anesthetic gases and drugs may be toxic to the immature developing brain.[10,11] Jevtovic-Todorovic and associates[10] began this recent controversy after publishing the results from a study in which 7-day-old rats were exposed to commonly used anesthetics for a total of 6 hours. The authors found that these rats exhibited learning/memory deficits, and histologic specimens of the brain revealed widespread apoptotic neurodegeneration and deficits in hippocampal synaptic function. The results of this study caused concern throughout the pediatric anesthesia community and was the subject of a Federal Drug Administration (FDA) advisory committee meeting.[12–15]

The FDA committee found that at present practice changes would be ill advised. On the one hand there is no doubt that animals varying from rats to primates have exhibited signs of neurotoxicity when exposed to higher levels of anesthetic

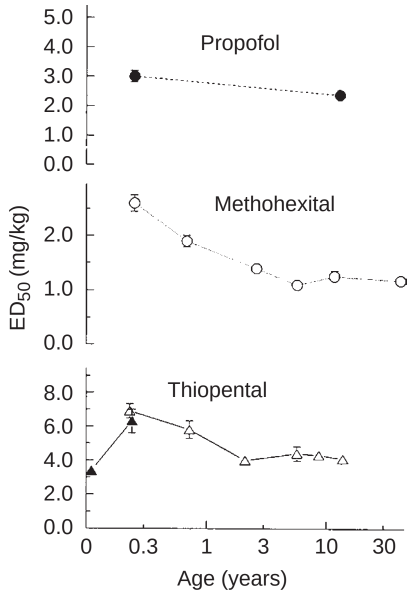

**FIGURE 13-1** Estimated $ED_{50}$ (dose of a drug that will induce anesthesia in 50% of patients) plus or minus the standard error in various age groups. Methohexital is indicated by open circles, thiopental by open or filled triangles, and propofol by filled circles. The vertical scales were adapted to yield the same height at $ED_{50}$ for children 7 to 16 years of age. §Data from Lerman J, et al: The pharmacology of sevoflurane in infants and children. Anesthesiology 1994;80:814.

agent than is normally experienced by human infants and children. On the other hand 4 million children are exposed to anesthesia, and predictable patterns of brain injury have yet to be identified.[14] More animal studies are needed with doses and duration of exposure that reflect human exposure to these agents.[16] More important, clinical studies evaluating neurodevelopment in children exposed to anesthetic drugs are critical to better understand the effect of general anesthesia on neurologic development. Two multicenter clinical protocols for studying these issues have been developed and implemented.[11,13]

The American Society of Anesthesiologists (ASA) risk classification system is used by anesthesiologists to estimate the severity of their patients' medical conditions and to determine the relative risk for morbidity and mortality secondary to the anesthetic agent, not the surgery.[17,18] The ASA classification system does not predict surgical risk, because the type of operative procedure is not taken into consideration.[19] The ASA classification allows the anesthesiologist to tailor the plan for anesthesia based on the patient's underlying condition. The six ASA classes are as follows:

ASA 1: normal healthy patient
ASA 2: patient with mild systemic disease
ASA 3: patient with severe systemic disease
ASA 4: patient with severe systemic disease that is a constant threat to life
ASA 5: moribund patient who is not expected to survive without the operation
ASA 6: A declared brain-dead patient whose organs are removed for donor purposes
E: Any patient in whom an emergency operation is required

Because of their medical complexity, patients in ASA classifications 3 and 4 should have a consultation with an anesthesiologist before the day of surgery. The Vanderbilt Children's Hospital recommendations for preoperative visit are shown in Table 13-2.

Death caused by anesthesia alone is uncommon. Mortality related to anesthesia varies from 1 in several hundreds of thousands for healthy children undergoing routine procedures to greater than 1:10,000 in neonates and infants with congenital or neurologic diseases.[20,21] Keenan and colleagues suggested that the use of pediatric anesthesiologists for all infants younger than 1 year might decrease anesthetic morbidity in this group.[23] Auroy and associates observed that a minimum of 200 pediatric cases per year per pediatric anesthesiologist is necessary to reduce the incidence of complications and improve the safety in pediatric practice.[24]

**TABLE 13-2**
**Summary of Fasting Recommendations to Reduce the Risk of Pulmonary Aspiration***

| *Ingested Material* | *Minimum Fasting Period (hr)*† |
|---|---|
| Clear liquids‡ | 2 |
| Breast milk | 4 |
| Infant formula | 6 |
| Nonhuman milk§ | 6 |
| Light meal¶ | 6 |

*These recommendations apply to healthy patients who are undergoing elective procedures. They are not intended for women in labor. Following these guidelines does not guarantee that complete gastric emptying has occurred.
†Fasting periods apply to all ages.
‡Examples of clear liquids are water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee.
§Because nonhuman milk is similar to solids in terms of gastric emptying time, the amount ingested must be considered when determining an appropriate fasting period.
¶A light meal typically consists of toast and clear liquids. Meals that include fried or fatty foods or meat may prolong gastric emptying time. Both the amount and the type of food ingested must be considered when determining an appropriate fasting period.
Data from ASA Practice Guidelines for Preoperative Fasting and the Use of Pharmacologic Agents to Reduce the Risk of Pulmonary Aspiration: Application to Healthy Patients Undergoing Elective Procedures, A Report by the American Society of Anesthesiologists. 1999.

The Pediatric Perioperative Cardiac Arrest Registry (POCA) was created in 1994 in an attempt to determine the clinical factors and outcomes associated with cardiac arrest in anesthetized children.[25] Through this registry, it was determined that anesthesia-related cardiac arrest occurred most often in patients younger than 1 year and in patients with severe underlying disease. Cardiac arrest during emergency surgery, especially in children with severe underlying disease, was associated with increased mortality. In this study, medication-related problems accounted for 37% of all cardiac arrests and 64% of arrests in ASA 1 and ASA 2 patients. A POCA update published in 2007 revealed that the decreased use of halothane (a potent cardiac depressant) in favor of sevoflurane decreased the number of cardiac arrests due to medications from 37% to 15%.[26] The most common causes of cardiac arrest in the POCA update were hypovolemia from blood loss and metabolic complications from blood transfusion.

## LARYNGOSPASM

Laryngospasm is a common complication of inhalation anesthesia in children. Laryngospasm is defined as glottic closure caused by reflex constriction of the intrinsic laryngeal muscles.[27] If not treated quickly laryngospasm makes ventilation of a patient's lungs difficult and can lead to hypercarbia, hypoxia, cardiac collapse, and death. Although the majority of laryngospasm episodes are self-limited or responsive to conservative maneuvers, the anesthesiologist must be prepared to treat laryngospasm to restore normal ventilation.

The incidence of laryngospasm is higher in children than in adults. Olsson and Hallen studied the incidence of laryngospasm in 136,929 patients of all ages over an 11-year period (1967 to 1978) and found an incidence of 8.7 per 1000 patients.[28] They reported that the laryngospasm incidence during general anesthesia correlated inversely with age, with higher rates in children between birth and 9 years (17.4 per 1000 patients) and the highest incidence in infants between birth and 3 months (28.2 per 1000 patients). In adolescent patients, a significantly higher laryngospasm incidence was found in boys than in girls (12.1 versus 7.2 per 1000 patients). The study also showed that children with upper respiratory infections or bronchial asthma had a very high laryngospasm rate (95.8 per 1000 patients).

Treatment of incomplete airway obstruction includes removing the irritating surgical stimulus, removing debris from the larynx, and deepening anesthesia. Lung ventilation is facilitated by applying gentle continuous positive airway pressure as 100% oxygen is administered through a tight-fitting facemask. If airway maneuvers do not improve ventilation, a muscle relaxant is required. Intramuscular (IM) or IV succinylcholine will relax the vocal cords, allowing adequate lung ventilation.[29]

## POSTOPERATIVE APNEA

Former preterm infants receiving general anesthesia are at risk for postoperative apnea. Regardless of whether they have a history of apnea, premature infants and full-term infants less than 44 weeks' postconceptual age may develop apnea in the postoperative period.[30–32] Postoperative apnea is defined as cessation of breathing or no detectable air flow for 15 seconds or longer, or less than 15 seconds with bradycardia. The cause of this phenomenon is unknown. Recovery from general anesthesia may unmask immature central respiratory regulation or decrease upper airway tone; both factors are believed to be responsible for postoperative apnea.[33] Although postoperative apnea usually develops in the first 2 hours after the anesthesia, it may present as long as 12 hours after anesthesia.

Several investigators have tried to establish a postconceptual age after which healthy premature infants with no history of neonatal apnea can be discharged on the day of surgery. Unfortunately, the recommendations vary from 44 weeks to 60 weeks.[32,34–36] The variance of recommendations are based in part on the sophistication of monitoring. The more sophisticated the monitoring, the higher the rate of identified apneic spells. Because considerable controversy exists, each hospital must develop its own policy. It is reasonable to monitor former premature infants for 24 hours if their postconceptual age is 55 weeks or less. Obviously, children with serious medical or neurologic problems or a history of significant and recurrent neonatal apnea are exceptions to this recommendation.

So far, anemia is the only independent risk factor identified that increases the likelihood of postoperative apnea in this at-risk population.[33,37] It has been recommended that anemic preterm infants with hematocrit values less than 30% have elective surgery delayed and receive iron supplementation until the hematocrit is greater than 30%. If surgery cannot be deferred, anemic infants must be observed and monitored very carefully for postoperative apnea.

## OBSTRUCTIVE SLEEP APNEA SYNDROME

Obstructive sleep apnea syndrome (OSAS) is a disorder of breathing during sleep that is characterized by prolonged partial upper airway obstruction (obstructive hypopnea) or intermittent complete obstruction (obstructive sleep apnea, OSA)

with or without snoring. OSAS is also associated with moderate to severe oxygen desaturation that disrupts normal sleep-time breathing and normal sleep patterns.[38] The most common cause of OSAS among children is upper airway narrowing with adenotonsillar hypertrophy. OSAS also occurs in infants and children with upper airway narrowing due to craniofacial anomalies and in those with neuromuscular diseases, including cerebral palsy and muscular dystrophy.[39,40]

In recent years, the epidemic increase in the prevalence of obesity during childhood seems to be contributing to substantial changes in the cross-sectional demographic and anthropometric characteristics of the children being referred for evaluation of OSAS. Although less than 15% of all symptomatic habitually snoring children were obese (i.e., >95% for age and gender) in the early 1990s, more than 50% fulfilled the criteria for obesity among all referrals to a Kentucky sleep center.[40,41]

Symptoms of OSAS include nocturnal snoring, breathing pauses, gasping, use of accessory muscles of respiration, enuresis, and excessive sweating.[42] In addition, children with OSAS have a host of sequelae, which are usually reversible after adenotonsillectomy but can lead to perioperative complications during and after surgery. Children with OSAS have a higher incidence of postoperative respiratory complications, including prolonged oxygen requirements, airway obstruction requiring a nasal airway, and major respiratory compromise requiring airway instrumentation.[43]

To date, the subpopulation of children with OSAS that must be monitored in the hospital is still unknown. Children who are most likely to experience postoperative respiratory complications and have a higher postoperative respiratory disturbance index on their postoperative polysomnogram include children younger than 3 years of age, children with severe OSAS diagnosed by preoperative polysomnography, and those with associated medical conditions such as hypotonia, morbid obesity, failure to thrive, or severe structural airway abnormalities.[44,45] These children are not candidates for outpatient surgery and should receive medical care in centers with pediatric inpatient facilities and pediatric intensive care unit support. High-risk patients should be monitored overnight with continuous pulse oximetry because standard apnea monitoring is unable to detect obstructive apnea and hypopnea. Patients can be discharged when significant oxygen desaturation during sleep has resolved.

# Preanesthesia Evaluation and Preparation

The primary purpose of a preoperative visit is to obtain information about the surgical problem and medical history and to assess the child's ability to tolerate anesthesia. The preoperative evaluation permits the identification of abnormalities that should be corrected before administration of an anesthetic; these disorders include severe anemia, sickle cell abnormalities, acute systemic infections, and active lower respiratory processes such as asthma, bronchopulmonary dysplasia, and cystic fibrosis.

In addition, the preoperative visit should be used to address the child's and parent's anxiety about the scheduled surgery and anesthesia. Preoperative behavioral evaluation programs are common in major pediatric hospitals. These preparation programs may provide narrative information, hospital tours, role rehearsal, and child life counseling.[46,47] Outpatient surgery programs may minimize a young child's separation anxiety. Ordinarily, a simple explanation of what the patient can expect before induction of anesthesia reduces the element of surprise and can be used to reinforce preoperative teaching materials. In older children, the preoperative visit allows the anesthesiologist to establish rapport, which fosters trust and may enhance cooperation. In some clinics, parents actively participate in the anesthesia induction process.[47,48] For some but not all parents and preschool-aged children, this joint experience minimizes fear and anxiety.

## PREOPERATIVE FASTING

The patient's stomach must be empty to prevent aspiration of stomach contents into the lungs during anesthesia induction. However, the patient should also be optimally hydrated. These two goals are compatible and are not difficult to achieve. Patients who are fed at the usual mealtimes and sleep through the night present no particular problems if procedures are scheduled for the early morning hours.

Numerous studies have failed to document an increased pulmonary aspiration risk when fasting guidelines are relaxed.[49,50] The perioperative fasting guidelines developed by the ASA are listed in Table 13-2.[51] These guidelines allow children to ingest clear liquids up to 2 hours before scheduled surgery. Infants and toddlers can be fed breast milk up until 4 hours before surgery, and infants and young children can be fed formula up until 6 hours before surgery.

If these details are not clearly stated in an itemized fashion with specific times, fluids may inadvertently be withheld from some children, particularly infants, for excessively long periods. Procedures should be scheduled according to age, with the youngest patient being the first on the operating schedule. Both the surgeon and the anesthesiologist must be alert to delays and ensure that the infant's fluid restriction is revised accordingly.

## PREANESTHESIA MEDICATIONS

Various drugs and routes of administration have been described as parts of premedication regimens. In the past, many anesthesiology departments created their own unique mixtures of sedative-hypnotic, narcotic, and antisialagogue medications, which were usually administered by the IM route. The goal of this premedication was to allay anxiety, provide analgesia, decrease autonomic (vagal) reflexes, decrease airway secretions, and reduce the volume and acidity of gastric fluid. The oral or nasal route is now preferred.

Premedication should provide a rapid level of short-term sedation that allows easy separation of the child from the parents and a smooth induction of anesthesia. Because children are usually not in pain before elective surgery, the use of opioids as part of standard premedication is not required. Antisialagogues were useful when diethyl ether and cyclopropane were the commonly used inhalation anesthetics. The newer inhalation agents do not significantly increase the quantity of oral secretions, thereby eliminating the need for anticholinergic premedication.

Midazolam is a popular, short-acting benzodiazepine that is now used frequently for preoperative sedation. It is an anxiolytic, hypnotic, and anticonvulsant agent, with antegrade but not retrograde amnestic properties.[52,53] At physiologic pH, midazolam becomes lipophilic, allowing quick absorption by the gastrointestinal tract and rapid entry into the CNS.[52] Sedative doses of IV midazolam can depress the hypoxic ventilatory drive and attenuate reflex cardiorespiratory responses to hypoxemia.[54] When combined with opioids, IV midazolam is likely to place unmonitored patients at significant risk for apnea and hypoxemia.[55]

In children, sedation with midazolam can be delivered by the intranasal, oral, rectal, IV, or IM route. The bioavailability of intranasal midazolam is 51% of the IV dose, and the speed of onset is 45% faster than with the rectal route.[56] Wilton and colleagues reported that intranasal midazolam given to children between 18 months and 5 years of age at a dose of 0.2 mg/kg calmed the patient within 5 to 10 minutes of administration.[57] Davis et al. found that intranasal midazolam at a dose of 0.2 to 0.3 mg/kg produced excellent sedation without prolonging recovery from anesthesia or time to hospital discharge in infants and small children undergoing very short ambulatory surgical procedures.[58] Cardiorespiratory depression has not been encountered when recommended doses of intranasal midazolam (0.2 to 0.3 mg/kg) or oral midazolam (0.5 to 0.75 mg/kg) are administered to otherwise healthy children for preoperative sedation.[57,59] Commercially prepared oral midazolam produces satisfactory sedation and anxiolysis within 10 to 20 minutes of consumption.[60] Oral midazolam prepared from the IV product has an onset time between 20 and 30 minutes.

Intranasal midazolam can cause mild, transient burning of the nasal mucosa, and amounts greater than 1 mL of a 0.5% solution (5 mg/mL) may produce choking and coughing. If more than 1 mL of 0.5% midazolam is necessary, the oral route is usually better tolerated. Oral midazolam prepared from the IV product should be flavored with sweetened clear liquids or syrup to mask the bitter taste. It has been demonstrated that commercially prepared oral midazolam has a more consistent bioavailability and pH characteristics. This stability allows doses as low as 0.25 mg/kg while still producing adequate sedation.[60]

Preoperative medication given to increase the pH of gastric fluid or to promote gastric emptying is not needed in healthy children, because pediatric pulmonary aspiration is rare.[61,62] Clear liquids administered to infants, children, and adults up to 2 hours before surgery do not alter residual gastric volume.[63] In fact, some children who have consumed liquids have a lower residual gastric volume and a higher gastric pH than controls who have had nothing by mouth (NPO).

# Fluid Requirements

## MAINTENANCE FLUID REQUIREMENTS

Various calculations involving body weight, surface area, and calorie expenditure have been used to determine fluid therapy for full-term infants and children.[64–66] Body weight and calorie expenditure, as well as estimates of insensible water loss, renal water requirement, stool water loss, and water needed for growth, determine the amount of fluid needed for maintenance. Calorie expenditure is related to size: infants weighing 1 to 10 kg require 100 calories/kg; small children weighing 10 to 20 kg require 1000 calories/day plus 50 calories/day for each kilogram greater than 10 kg; older children weighing more than 20 kg require 1500 calories/day plus 25 calories/day for each kilogram greater than 20 kg. For every 100 calories that the patient consumes, 67 mL of water is required for solute excretion; an additional 50 mL per 100 calories is associated with insensible loss, but 17 mL per 100 calories is produced by oxidation. Thus, infants and children need 100 mL of water for each 100 calories expended. Assuming that there are 25 hours in a day, a simple formula can be used to calculate the hourly maintenance fluid needed by healthy full-term infants and children. For children weighing 1 to 10 kg, the hourly maintenance fluid requirement (MFR) is 4 mL/kg per hour. For patients weighing 10 to 20 kg, the hourly MFR is 4 mL/kg per hour for the first 10 kg, plus 2 mL/kg per hour for each kilogram between 10 and 20 kg. For patients weighing more than 20 kg, the MFR is calculated as 4 mL/kg per hour for the first 10 kg, plus 2 mL/kg per hour for the next 10 kg, plus 1 mL/kg per hour for each additional kilogram greater than 20 kg. For example, a 28-kg child requires 68 mL of maintenance fluid per hour.

For every 100 mL of water given to an infant or child, 3 mEq $Na^+$, 2 mEq $K^+$, 2 mEq $Cl^-$, and 5 g glucose (to prevent ketosis) are required. It is more convenient to equalize the sodium and chloride requirements at 3 mEq. For routine IV fluid therapy, 5% dextrose in 0.25% normal saline meets these requirements. However, this is not an ideal fluid for intraoperative use, as noted later.

### Premature or Critically Ill Infants

Many factors influence water and electrolyte balance in premature or critically ill infants. The infant's gestational age, postnatal age, weight, renal solute load, and maximum renal concentrating ability are variables. Tissue destruction and catabolism that result from disease, stress, infection, reduced bowel activity, phototherapy, and gastric or intestinal drainage affect fluid therapy. These issues are reviewed by Bell,[65] Rowe,[67] and Hammarlund.[68]

## INTRAOPERATIVE FLUID REPLACEMENT

Intraoperative fluid replacement involves the initiation of fluid management or, alternatively, a continuation of ongoing therapy. Fluid replacement can simply consist of replacing the deficit from preoperative fasting and providing maintenance fluids. Fluid therapy can also be complex when preoperative deficits, translocated fluids, and variable blood loss are part of the equation.

### Estimated Fluid Deficit

The fluid deficit incurred during fasting should be replaced during anesthesia. Assuming a child is healthy at the time of fasting, the fluid deficit is estimated by multiplying the hourly MFR by the number of hours the patient has had nothing by mouth. This deficit can be replaced during surgery and if necessary in the recovery room. Maintenance fluids should continue in conjunction with replacement fluids.

### Role of Glucose

Surgery may cause the release of stress hormones that decrease insulin sensitivity, so serum glucose levels are usually elevated during surgery. If serum glucose concentrations become too

high, glycosuria and osmotic diuresis ensue. Hyperglycemia may contribute to neurologic damage subsequent to episodes of severe ischemia and hypoxia.[69–71] Several studies have shown that healthy infants and children remain euglycemic for up to 17 hours after the start of a fast. These studies suggest that healthy infants and children do not require glucose-containing solutions during surgery.[72,73] Frequent monitoring of blood sugar should accompany fluid and glucose therapy in patients who are at high risk for hypoglycemia (e.g., premature infants and those who are small for gestational age, children on total parenteral nutrition, and patients with diabetes).

### Choice of Intraoperative Fluid

For most patients, lactated Ringer solution can be used to provide maintenance and replacement fluids for intraoperative losses. The electrolyte composition of lactated Ringer is similar to that of serum. Hyponatremia with associated neurologic complications can occur if hypotonic solutions are used for fluid maintenance and replacement of third space fluid losses.

Surgical trauma is associated with isotonic transfer of fluids from the extracellular fluid compartment to the interstitial compartment.[74] This acute sequestration of edematous fluid to the interstitial compartment is called third-space loss. The greater the third-space volume losses, the greater the loss of intravascular volume. The magnitude of third-space loss varies with the surgical procedure and is usually highest in infants having intraabdominal surgery. In pediatric patients, estimated third-space loss is 6 to 10 mL/kg per hour during intraabdominal surgery, 4 to 7 mL/kg per hour during intrathoracic surgery, and 1 to 2 mL/kg per hour during superficial surgery or neurosurgery. Generally, lactated Ringer solution is used to restore third-space losses. In cases of massive volume replacement, some advocate using 5% albumin to restore one third to one fourth of the loss. The end point of third-space replacement therapy is maintenance of adequate blood pressure, tissue perfusion, and urine output.

## BLOOD REPLACEMENT

Blood replacement depends on the patient's needs, and clear communication between the surgeon and the anesthesiologist is crucial. Accurately measuring blood loss and assessing the limit of safe blood loss in infants are vital parts of any replacement regimen. Weighing sponges and using calibrated miniaturized suction bottles and visual estimates define the magnitude of blood loss. Allowable blood loss is determined by calculating the starting blood volume and measuring the hemoglobin or hematocrit of the patient.[75,76] Other factors used to determine allowable blood loss include the patient's age, cardiopulmonary status, and general medical condition. These factors are also used to determine the risk versus benefit of blood transfusion.

### Estimating Allowable Blood Loss

Several methods have been proposed for estimating allowable blood loss. The formulas range from simple to complex, but all involve an estimate of blood volume. Allowable blood loss can be calculated using the following equation:

$$\text{ABL} = \text{Weight (kg)} \times \text{EBV} \times [\text{Ho} - \text{Hl}]/\text{H},$$

where ABL is allowable blood loss, EBV is estimated blood volume, Ho is the original hematocrit, Hl is the lowest acceptable hematocrit, and H is the average hematocrit ([Ho + Hl] / 2).

This equation assumes that blood loss and replacement are gradual and exponential. Estimated blood volume is approximately 90 mL/kg for neonates, 80 mL/kg for infants and children, and 65 to 78 mL/kg for adolescents. This equation has general applicability for all age groups.

The ideal fluid to replace blood loss until the lowest acceptable hematocrit value is reached is a matter of controversy.[77–79] Generally, lactated Ringer solution is given in an amount equal to 2 to 3 times the estimated amount of lost blood except in situations of massive transfusion when massive transfusion protocols are followed (see later).

### Blood Products

Blood component therapy depends on the clinical setting and the availability of various blood products. Fresh whole blood (i.e., blood that was obtained less than 4 hours previously) has limited availability. Thus treatment with component therapy rather than fresh whole blood is the rule rather than the exception.[80,81] Packed red blood cells (RBCs) have a hematocrit value between 55% and 75% and are relatively hyperkalemic (K ± 15 to 20 mEq/L) and acidotic (pH <7.0). The estimated rise in hematocrit for every 10 mL/kg of packed RBCs (assuming a hematocrit of 70%) depends on the patient's age, size, and estimated blood volume (Table 13-3).

The need for platelets during surgery can be predicted from the preoperative platelet count. Platelets are mobilized from the spleen and bone marrow as bleeding occurs. An infant with a high preoperative platelet count (>250,000/mm$^3$) may not need a platelet transfusion until two to three blood volumes are lost, whereas an infant who has a low count (<150,000/mm$^3$) may need platelets after only one blood volume is lost. Two platelet packs/10 kg increases the platelet count by 50,000 to 100,000/mm$^3$.

Fresh frozen plasma (FFP) is indicated for emergency reversal of warfarin, for correction of microvascular bleeding in the presence of elevated prothrombin time and partial thromboplastin time, and as part of a massive transfusion protocol.[81] Ten to 20 ml/kg of FFP usually raises the level of coagulation factors by 20%. FFP contains the highest concentration of citrate per unit volume of any blood product; thus rapid FFP

**TABLE 13-3**
**Estimated Rise in Hematocrit with Increasing Blood Volume**

| | *Blood Volume (mL/kg)* | *Estimated Rise Age in Hematocrit** |
|---|---|---|
| Premature | 100 | 6.30 |
| Infants | | |
| Term infants | 90 | 7.00 |
| Preschool-aged children | 80 | 7.7 |
| School-aged children | 75 | 8.2 |
| Adults | 65 | 9.3 |

*The estimated rise in hematocrit for every 10 mL/kg of packed red blood cells (RBCs) (assuming a hematocrit of 70%) depends on the patient's age, size, and estimated blood volume.

causes the greatest change in ionized calcium. Under most circumstances, mobilization of calcium and hepatic metabolism of citrate are sufficiently rapid to prevent precipitous decreases in ionized calcium. However, because infants' calcium stores are small, rapid infusion of FFP can acutely decrease ionized calcium and cause significant decreases in arterial blood pressure.[82] Treatment of acute hypocalcemia includes IV calcium chloride (10 mg/kg) or calcium gluconate (30 to 60 mg/kg), which effectively increases ionized calcium and ameliorates hemodynamic changes.

When blood loss approaches one blood volume many centers have established massive transfusion protocols.[83] These protocols help prevent the acidosis, hypothermia, and coagulopathy seen when only packed RBCs are infused during massive hemorrhage.[79] The goals of these protocols are to improve communication between the surgeon, anesthesiologist, and blood bank to expedite delivery of appropriate quantities of blood products to the patient care team. Although the transfusion and coagulation management in children experiencing severe hemorrhage is not well studied, it is prudent to develop a massive transfusion protocol. The goal of transfusion is to deliver blood products that resemble whole blood. Current data support the use of plasma-to-RBC-to-platelet at 1:1:1.[84,85]

# Inhalation Anesthetic Agents

Several inhalation agents are available for induction and maintenance of anesthesia. The choice of agent depends on the age of the child and the disease process. Each agent has general and specific advantages and disadvantages (Table 13-4). None ensures hemodynamic stability. In patients with significant cardiac depression or hemodynamic instability, inhalation agents are generally avoided or used in markedly reduced concentrations. In healthy children, most inhalation agents can be used safely and successfully regardless of age.

To spare children an awake placement of an IV catheter, anesthesia is often induced by inhalation. However, inhalation anesthesia in children has some risk and is associated with an increased incidence of bradycardia, hypotension, and even cardiac arrest.[25,86] These risks have been reduced with the use of sevoflurane rather than halothane.[26] In premature or critically ill infants, the incidence of untoward effects from potent inhalation agents is attributed to age-related differences in uptake, anesthesia requirements, and cardiovascular system sensitivity. The uptake of inhalation anesthetics is more rapid in infants and small children than in adults because of major differences in blood-gas solubility coefficients,

**TABLE 13-4**
**Inhalation Anesthetics**

| *Agent* | *Advantages* | *Disadvantages and Precautions* |
|---|---|---|
| Nitrous oxide | Inexpensive<br>Odorless | Should be used as a supplement to other inhalation or intravenous anesthetics to provide complete general anesthesia |
| | Rapid onset and recovery of clinical effects | In critically ill patients, can be a potent vasodilator |
| | When combined with potent inhalation anesthetics, side effects of potent agents are reduced | Expands gas-containing spaces, such as the intestines or middle ear; increases the expansion of pneumothorax and pneumocephalus |
| | Activates the sympathetic nervous system, which attenuates cardiac depression or vasodilatation caused by potent inhalation agents | Exposure to operating room atmosphere contamination may cause neuropathies |
| Halothane | Nonpungent odor<br>Effective inhalation induction agent | Causes cardiac depression manifested as bradycardia and decreased myocardial contractility |
| | Bronchodilator (like all potent inhalation agents) | Causes halothane-associated hepatitis (rare in children) |
| | | Sensitizes the myocardium to the arrhythmogenic properties of epinephrine; however, infants and children require higher doses of epinephrine to stimulate ventricular arrhythmias than do adolescents and adults |
| Isoflurane | Maintains myocardial contractility and heart rate | Pungent odor |
| | Minimal sensitization of the myocardium to the arrhythmogenic properties of epinephrine | Not an effective inhalation induction agent |
| | | Can cause bradycardia in neonates and young infants |
| | | May cause hypotension by decreasing systemic vascular resistance |
| Sevoflurane | Nonpungent odor | More expensive than halothane |
| | Effective inhalation induction agent<br>Low blood-gas coefficient | Metabolized by liver, releasing free fluoride ions; theoretical risk for renal diabetes insipidus |
| | Maintains myocardial contractility and heart rate | Degradation in Baralyme and soda lime, forming potentially toxic metabolites |
| | Minimal sensitization of the myocardium to the arrhythmogenic properties of epinephrine | Increased incidence of postanesthesia delirium |
| Desflurane | Low blood-gas coefficient | Pungent odor |
| | Maintains myocardial contractility and heart rate | Poor inhalation induction agent |
| | Minimal sensitization of the myocardium to the arrhythmogenic properties of epinephrine | High incidence of laryngospasm |
| | | Expensive |
| | | Increased incidence of postanesthesia delirium |

blood-tissue solubility coefficients, body composition, ratio of alveolar ventilation to functional residual capacity, and distribution of cardiac output.[87–89] Thus, early in the course of anesthesia induction, infants have higher tissue concentrations of the drug in the brain, heart, and muscle than do adults.

## MINIMUM ALVEOLAR CONCENTRATION

The minimum alveolar concentration (MAC) is the minimum concentration of an inhaled anesthetic at 1 atm of pressure that prevents skeletal muscle movement in response to a surgical incision in 50% of patients. The MAC of a volatile anesthetic changes with the patient's age (see Table 13-1). LeDez and Lerman[91] showed that premature infants younger than 32 weeks' gestation have a lower MAC for isoflurane than do neonates of longer gestation. For all anesthetic agents, the MAC is highest at 6 to 12 months of age. The increased MAC requirement in conjunction with the rapid uptake of anesthetic makes infants and children very susceptible to anesthetic overdose.[92,93]

## NITROUS OXIDE

Because nitrous oxide is a nonpotent inhalation agent with a MAC of 105%, it is usually used as an adjunct to the more potent inhalation agents. Nitrous oxide reduces the side effects of these agents by reducing the amount required for effective analgesia. During the induction phase of anesthesia, nitrous oxide hastens the uptake of potent inhalation agents. Eger and Saidman[93a] noted that nitrous oxide is more soluble than nitrogen in blood and thus distends any air-containing space, such as the intestines, to which it is carried. As a result, nitrous oxide is usually avoided in patients with closed pneumothorax, intestinal obstruction, or air in the cerebral ventricles. Nitrous oxide has been implicated in lymphocyte depression, testicular damage, birth defects, and miscarriages with chronic exposure, so it is important to adequately scavenge this gas in the operating suite.

## HALOTHANE

Halothane was once the most commonly administered anesthetic agent in children because it was less likely than isoflurane and desflurane to cause airway irritability. However, halothane was not an ideal induction agent because of its potential to cause bradycardia, hypotension, and ventricular ectopy secondary to induced sensitivity to catecholamines. In the United States, sevoflurane (because of its cardiovascular safety profile) has replaced halothane as the induction agent of choice.[94]

## ISOFLURANE

Isoflurane has a lower solubility coefficient than that of halothane, so induction and recovery with isoflurane is faster than with halothane. However, isoflurane causes moderate to severe airway irritability if used as an induction agent.

The cardiovascular effects of isoflurane in children are well documented. Unlike adults, unpremedicated infants 5 to 26 weeks of age who were anesthetized with isoflurane showed a decrease in heart rate similar to that seen with halothane and a decrease in blood pressure half that seen with halothane.[95] In children older than 2 years who did not receive atropine, isoflurane preserved heart rate and cardiac function better than did halothane.[96] Halothane and isoflurane both reduced blood pressure. Isoflurane reduced peripheral vascular resistance but preserved cardiac output. Gallagher and colleagues[97] compared the anesthetic effects of halothane and isoflurane on cardiac function in 15 older children using pulsed Doppler echocardiography.[97] Cardiac output, heart rate, and myocardial contractility were preserved with isoflurane, but contractility was decreased with halothane. Kotrly and associates[98] found that isoflurane preserved the baroreceptor response in adults more than halothane did.

## DESFLURANE

Desflurane is a potent inhalation agent. The blood-gas solubility is low and similar to nitrous oxide.[99] Because it is a pungent airway irritant, desflurane results in an unacceptably high incidence of laryngospasm, coughing, and hypoxia when used as an induction agent in children.[100–102] Patients anesthetized with desflurane have a faster emergence from general anesthesia.

The cardiovascular profile of desflurane is age dependent.[100] When desflurane was given at a MAC of 1 before incision, the arterial blood pressure decreased approximately 30% compared with awake values, and the heart rate decreased significantly or remained the same. Thus at a MAC of 1, desflurane, like isoflurane and halothane, seems to attenuate the baroreceptor response in children. Weiskopf and colleagues[103] also demonstrated that in adults, rapid increases in desflurane from a MAC of 0.55 to 1.66 can transiently increase arterial blood pressure and heart rate; this excitation is associated with an increase in sympathetic and renin-angiotensin system activity.

## SEVOFLURANE

Sevoflurane is a potent inhalation agent with a low blood-gas solubility coefficient. It does not have a pungent odor and has replaced halothane as the inhalation anesthetic of choice for infants and children.[104,105] Clinical studies with sevoflurane inpediatric patients have found shorter times to emergence than with halothane.[94] This may be related to the low blood-gas solubility. Sevoflurane has fewer cardiovascular side effects than halothane.[94,108–112] Wodey and colleagues[111] compared cardiovascular changes at equipotent concentrations of sevoflurane and halothane in infants. They concluded that in infants, sevoflurane decreases cardiac output less than does halothane, and a minor decrease in contractibility is compensated by a greater decrease in systemic vascular resistance (SVR) without a change in heart rate.[111] Unlike halothane, sevoflurane does not increase the sensitivity of the myocardium to the arrhythmogenic effects of epinephrine.[113] Sevoflurane causes a significant decrease in respiratory resistance, and it is an effective bronchodilating agent.[114]

One theoretical concern surrounding the use of sevoflurane is that it is metabolized in the liver by the cytochrome system, with the subsequent release of fluoride and the potential for renal diabetes insipidus. However, renal concentrating ability and normal creatinine clearance have been demonstrated in adult volunteers subjected to prolonged sevoflurane exposure. In addition to in vivo metabolism, sevoflurane

undergoes degradation by soda lime and barium hydroxide lime (Baralyme) to produce two potentially toxic olefins, compound A and compound B. Although human exposure to sevoflurane administered by circle absorption systems has not demonstrated toxicity, animal studies have yielded conflicting histologic evidence of chemical-induced toxicity.[97,115,116] Frink and associates[117] concluded that the concentrations of compound A measured in pediatric patients during sevoflurane anesthesia using a 2-L flow circle system were low, and there was no evidence of abnormal renal or hepatic function up to 24 hours after anesthesia.

## Emergence Delirium

The advent of the use of volatile anesthetics in children brought with it the new entity of emergence delirium (ED). ED is a dissociated state of consciousness in which children are inconsolable, irritable, uncompromising, or uncooperative, or a combination of these behaviors.[118] It occurs in 2% to 80% of children, depending on the age of the patients, anesthetics used, and the type of surgery. It usually occurs within 30 minutes after the conclusion of the anesthesia procedure and is typically self-resolving within 30 minutes.[119] Children experiencing ED are disruptive to the postanesthesia care unit (PACU) and increase the risk of injury to themselves and others; ED is also associated with parent dissatisfaction with the hospital care. The current theories on the causes of ED involve the direct interaction of volatile agents on neurons. The two most prominent theories are an uneven susceptibility of neurons to volatile anesthetics or direct, low-level activation of excitatory neurons by volatile anesthetics.[120,121]

The main risk factors are age, perioperative anxiety, and the anesthetics used, with volatile agents causing the most ED.[119] Preventive measures include preoperative anxiolysis, avoidance of volatile anesthetics, and preemptive treatment. Multiple agents have been used for preemptive treatment, and most are given 10 minutes before the patient wakes up. They include fentanyl, propofol, ketamine, nalbuphine, and dexmedetomidine. Once a child is in ED, fentanyl, midazolam, propofol, or dexmedetomidine can be used for treatment.

Dexmedetomidine, a highly specific and selective $\alpha_2$-adrenergic agonist, is becoming an important drug in the treatment of ED. It can be given either preoperatively as an anxiolytic agent, intraoperatively for ED avoidance, or postoperatively for the treatment of ED. Currently, there are six prospective clinical trials that have shown that dexmedetomidine significantly reduces the incidence of ED when given to children before recovery from volatile anesthetics.[122] Doses range from 0.15 to 1 μg/kg given either as a bolus or infusion before completion of surgery. Once a child is in ED, a single bolus dose of 0.5 μg/kg can be used as treatment. Side effects are minimal and usually consist of bradycardia with a concomitant decrease in blood pressure.

## Neuromuscular Blocking Agents

Neuromuscular blocking agents (i.e., muscle relaxants) are used to facilitate endotracheal intubation, to provide surgical relaxation, and to facilitate controlled mechanical ventilation. This is accomplished through blockade of the nicotinic acetylcholine receptor site on the neuromuscular junction. The use of neuromuscular blocking agents reduces the need for potent inhaled anesthetics or IV sedative-hypnotics. Throughout infancy, the neuromuscular junction matures physically and biochemically. The contractile properties of skeletal muscle change, and the amount of muscle in proportion to body weight increases. As a result, the neuromuscular junction is variably sensitive to relaxants.[123] In addition, age-related changes in the volume of distribution of relaxants, their redistribution and clearance, and possibly their rate of metabolism occur. These factors influence the dose-response relationships of relaxants and the duration of neuromuscular blockade.[124–126]

When allowances are made for differences in the volume of distribution and for the type and concentration of anesthetic, infants seem to be relatively resistant to succinylcholine and relatively sensitive to nondepolarizing relaxants (Table 13-5). The degree of neuromuscular blockade should be monitored with a nerve stimulator during the course of the operation, and the patient should be treated with a dose of the selected agent sufficient to achieve the desired degree of block. The paralysis caused by nondepolarizing relaxants should be reversed at the end of each operation unless postoperative mechanical ventilation is planned. Anticholinesterase drugs, such as neostigmine and edrophonium, combined with anticholinergics are given to prevent muscarinic side effects. The effectiveness of reversal is judged by muscle strength, adequacy of ventilation, and response to nerve stimulation. Minimum criteria for withdrawing assisted ventilation should include good muscle tone, flexing of the arms and legs, and adequate respiratory effort.

Neuromuscular blocking agents have no sedative, hypnotic, or analgesic effects, but they may indirectly decrease metabolic demand, prevent shivering, decrease nonsynchronous ventilation, decrease intracranial pressure, and improve chest wall compliance. Major organ failure, up-regulation of acetylcholine receptors, malnutrition, electrolyte and acid-base abnormalities, drug interactions, and muscle atrophy can also have a profound influence on the kinetics and dynamics of relaxants. In addition, repeated doses of relaxants over relatively long periods without monitoring of neuromuscular transmission may lead to prolonged muscle weakness despite discontinuation of therapy. Knowledge of neuromuscular pharmacology and its modification by age, concurrent medications, and concurrent disease processes permits a more rational use of neuromuscular blocking agents in patients in intensive care.

### COMPLICATING CONDITIONS OF DEPOLARIZING BLOCKING AGENTS

The use of succinylcholine for elective pediatric procedures has been abandoned secondary to multiple case reports of cardiac arrest from hyperkalemia due to undiagnosed muscular dystrophy. Life-threatening hyperkalemia can also be caused by succinylcholine in all of the following situations: burns on greater than 8% of the body, upper motor neuron lesions, lower motor neuron lesions, crush injuries, neuromuscular diseases, and chronic ongoing sepsis. It is also a known triggering agent of malignant hyperthermia (MH). The FDA issued the following "Black Box" warning in 1993 because of previous listed potential complications:

> Since there may be no signs or symptoms to alert the practitioner to which patients are at risk, it is recommended that the use of succinylcholine should be reserved for emergency intubation or

**TABLE 13-5**
**Muscle Relaxants**

| *Agent* | *Type* | *Dose* | *Metabolism and Excretion* | *Advantages* | *Disadvantages and Precautions* |
|---|---|---|---|---|---|
| Succinylcholine | Short acting; depolarizing | IV: 1.0-2.0 mg/kg IM: younger than 6 mo, 4.0-5.0 mg/kg; older than 6 mo, 3.0-4.0 mg/kg | Pseudocholinesterase | Rapid onset; rapid recovery; may be delivered through intravascular or intramuscular routes | Masseter muscle spasm; trigger for malignant hyperthermia; bradycardia; hyperkalemia leading to life-threatening arrhythmias; myoglobinemia (muscle injury); muscle fasciculations; increased intraocular pressure; prolonged neuromuscular blockade with pseudocholinesterase deficiency<br>Avoid in patients with muscular dystrophy; multiple trauma >24 hr; burns >24 hr; spinal cord injury >24 hr; malignant hyperthermia–susceptible |
| Mivacurium | Short acting; nondepolarizing | Intubation: 0.2 mg/kg Maintenance: 0.1 mg/kg | Plasma cholinesterase | Recovery time 10 min; infusion possible | Histamine release; unpredictable intubating conditions |
| Atracurium | Intermediate acting; nondepolarizing | Intubation: 0.5 mg/kg Maintenance: 0.15 mg/kg | Ester hydrolysis; Hoffman degradation | Recovery time 30 min regardless of age; can be used in renal and kidney disease; infusion possible | Histamine release; (metabolite of Hoffman degradation); epileptogenic in high doses |
| Cisatracurium | Intermediate acting; nondepolarizing | Intubation: 0.1 mg/kg Maintenance: 0.03 mg/kg or 1-2 mcg/kg/min continuous | Ester hydrolysis; Hoffman degradation | Recovery time 30 min; no cardiovascular effects; infusion possible | |
| Rocuronium | Intermediate acting; nondepolarizing | Intubation: 0.6 mg/kg (onset 50-80 sec) or 1.2 mg/kg (onset 30 sec) Maintenance: 0.1 mg/kg | Liver and renal | Recovery time 15-40 min (dose dependent); can be used for rapid-sequence intubation; infusion possible | Slight vagolytic effect |
| Vecuronium | Intermediate acting; nondepolarizing | Intubation: 0.1 mg/kg Maintenance: 0.02 mg/kg | Kidney and liver | Recovery time approx 30 min in children; no histamine release at up to 0.4 mg/kg; no effect on cardiovascular system | Long-acting muscle relaxant in infants; recovery time approx 70 min. |
| Pancuronium | Long acting; nondepolarizing | Intubation: 0.1 mg/kg Relaxation: 0.02 mg/kg | Kidney and liver | Recovery time approximately 50 min; inexpensive | Vagolytic effect; tachycardia; hypertension; histamine release |

IV, intravenous.

in instances where immediate securing of the airway is necessary (e.g., laryngospasm, difficult airway, full stomach, or for IM route when a suitable vein is inaccessible).

Succinylcholine is broken down by plasma cholinesterase and is the reason for the short period of paralyzation (3 to 5 minutes). However, 1 in 3000 to 1 in 10,000 patients may be homozygous for an alternative version of the plasma cholinesterase enzyme. This enzyme has limited ability to bind and break down succinylcholine. In this patient population, muscle paralysis from succinylcholine can last up to 8 hours.[127]

## Malignant Hyperthermia

MH is a life-threatening condition characterized by hyperthermia, hypermetabolism, and muscle injury that occurs in response to a triggering agent. Potent inhalation agents (not nitrous oxide) and the depolarizing muscle relaxant succinylcholine are two potent triggers in children. Triggers that stimulate MH cause excessive release of $Ca^{2+}$ from the sarcoplasmic reticulum of skeletal muscle into the myoplasm, resulting in a chain of metabolic events that culminates in heat production, cell injury, hyperkalemia, and myoglobinemia.[128] The mortality rate for untreated MH is greater than 60%; rapid treatment with dantrolene reduces mortality to almost zero.

The incidence of fulminant MH is approximately 1 in 50,000 to 1 in 100,000 in adults and 1 in 3,000 to 1 in 15,000 in children. Most cases of MH occur in patients thought to be healthy. Predisposition to MH is a familial condition of multigenetic inheritance. First-degree relatives are at high risk; second-degree relatives have a lower but significant risk of MH developing in response to the appropriate triggering agents. Patients with Duchenne muscular dystrophy are thought to be at high risk for the development of MH. Other

diseases associated with the development of MH are central core disease and King-Denborough syndrome.

The classic signs of MH include tachycardia, ventricular dysrhythmias, tachypnea, a rapid increase in temperature to greater than 39.5° C, rigidity of the jaw or generalized rigidity, metabolic and respiratory acidosis, and decreased mixed venous oxygen saturation. Associated laboratory values include hyperkalemia, hypercarbia, respiratory and metabolic acidosis, increased creatine phosphokinase and lactate levels, blood clotting abnormalities, and myoglobinuria.

The clinical diagnosis of MH should be considered before signs of hypermetabolism and elevated temperature reach extremes. The early signs of the disorder include tachypnea, tachycardia, increased end tidal carbon dioxide ($ET_{CO_2}$), and ventricular dysrhythmias. These signs must be evaluated quickly because they can have many causes, such as iatrogenic hyperthermia, sepsis, pheochromocytoma, hyperthyroidism, ventilator valve malfunction with rebreathing of carbon dioxide, inadequate levels of anesthesia, and faulty temperature and $ET_{CO_2}$ monitors.

Management of an acute episode of MH is outlined in Table 13-6. The cornerstone of treatment is IV dantrolene, which must be diluted with sterile, preservative-free, distilled water. The initial IV dose is 2.5 mg/kg, although much higher doses may be required. The usual dose limit of 10 mg/kg may be exceeded if necessary.[129] Dosing of dantrolene should be guided by clinical and laboratory signs and carried out every 5 minutes until metabolic acidosis has resolved. Dantrolene decreases the release of calcium from the sarcoplasmic reticulum by decreasing the mobility of calcium ions or the protein that transports calcium across membranes and is specific for skeletal muscle.[130,131] Dantrolene attenuates muscle hypermetabolism, reducing muscle rigidity and restoring normal muscle function. As skeletal muscle function normalizes, serum potassium levels decrease and abnormal lactic acid production slows.[132] Patients respond to dantrolene within 20 minutes. The $ET_{CO_2}$ begins to decrease in 6 minutes, and arterial blood gas analysis demonstrates significant resolution of metabolic and respiratory acidosis within 20 minutes.[132] By 45 minutes, metabolic and respiratory acidosis and hyperthermia should be resolved. Dantrolene treatment at higher doses is necessary if metabolic dysfunction persists.[129]

Parents of an affected child may wish to have a muscle biopsy and contracture testing because negative findings mean that other relatives have no increased risk of MH.

In patients with a personal history or a strong family history of MH, surgery can be safely performed under regional or local anesthesia. General anesthesia with nontriggering agents can also be used. All nondepolarizing muscle relaxants and IV anesthetic agents are safe to use in patients who are susceptible to MH. Monitoring for the early signs of MH and initiating quick treatment are the most important aspects of caring for these patients.

**TABLE 13-6**

**Management of Acute Episodes of Malignant Hyperthermia**

| |
|---|
| Stop inhalation anesthetics immediately |
| Cancel or conclude surgery as soon as possible |
| Hyperventilate with high-flow 100% oxygen |
| Administer IV dantrolene (2.5 mg/kg) and repeat as needed |
| Give more dantrolene if signs of the condition reappear |
| Initiate cooling with hypothermia blanket, IV cold saline solution (15 mL/kg for 10 min), ice packs in the axillary region and groin, and lavage of body cavities with cold saline solution if core temperature is >37° C. Stop cooling when core temperature falls to 38° C |
| Correct metabolic acidosis with 1.0 to 2.0 mEq/kg sodium bicarbonate as an initial dose |
| Administer calcium (10 mg/kg calcium chloride) or insulin (0.2 U/kg) in 50% dextrose in water (1 mg/kg) to treat the effects of hyperkalemia |
| Administer lidocaine (1 mg/kg) to treat ventricular arrhythmias |
| Maintain urine output at 2 mL/kg/hr with furosemide (1 mg/kg) and additional mannitol if needed. |
| Insert arterial and central venous catheters |
| Repeat venous blood gas and electrolyte analysis every 15 min until signs of the disorder resolve and vital signs normalize |

# Intravenous Anesthetic Agents

## PROPOFOL

Propofol is a sedative-hypnotic, lipophilic IV agent used for induction and maintenance of anesthesia. It has become the IV agent of choice because of its favorable pharmacokinetic profile. The pharmacokinetics of propofol are characterized by rapid distribution, metabolism, and clearance. After termination of an infusion, redistribution to the peripheral tissues results in a prompt decrease in plasma concentration. Propofol is eliminated by hepatic conjugation to inactive metabolites, and excretion is by the renal route.[133]

Multiple studies have shown that the dose of propofol needed for induction is indirectly related to age. A typical induction dose is between 2.5 and 3.5 mg/kg.[134–137] Although the mechanisms that contribute to different dose requirements in younger children compared with older children have not been delineated, Westrin[137] hypothesized that because infants have a greater cardiac output in relation to body weight and a larger vessel-rich component, arterial peak concentration reaching the brain may be lower than that achieved in adults.

Propofol can induce hypotension, but the mechanism through which this occurs has not been clearly established.[135,138,139] Aun and associates[138] compared the hemodynamic responses to an induction dose of thiopental (5 mg/kg) or propofol (2.5 mg/kg) in 41 healthy children aged 8 months to 12 years. Heart rate, blood pressure, and velocity of flow were measured. The 28% to 31% reduction in mean arterial pressure after propofol administration was significantly greater than that after thiopental administration (14% and 21%, respectively). The 10% to 15% reduction in cardiac index was similar for both drugs. The children studied tolerated the hypotensive episodes without requiring pharmacologic intervention. Hannallah and associates[135] noted that like adults, children anesthetized with propofol have a slower heart rate than those given a volatile agent. Atropine may be useful to attenuate the bradycardia that can develop in young children when propofol and an IV opioid are used to maintain anesthesia. Keyl and colleagues[140] concluded that the vagally mediated heart rate response to cyclic peripheral baroreflex stimulation was markedly depressed during propofol anesthesia; there was also an impaired blood pressure response to cyclic baroreceptor stimulation.

Pain at the site of injection occurs in up to 50% of patients receiving propofol through a vein in the dorsum of the hand.[141] Pain on injection of propofol can be attenuated or eliminated by injection through a large antecubital vein or by adding 0.1 mg/kg of lidocaine to every 2 to 3 mg/kg of propofol drawn into the syringe.[142]

Long-term sedation with propofol in the pediatric population is not recommended. Five deaths of infants and children (4 weeks to 6 years old) involving propofol infusions were reported in 1992.[143] These deaths involved lipemia, metabolic acidosis, hyperkalemia, and rhabdomyolysis. Further case reports have delineated what is now called propofol infusion syndrome (PIS). Risk factors for PIS include young age and propofol infusion rates of 70 μg/kg/min or greater for longer than 48 hours. However, there are reports of PIS in cases in which infusions were continued for less than 48 hours at lower levels.[144]

## THIOPENTAL

Thiopental is a barbiturate induction agent that can be administered by the IV or rectal route. The dose required for IV induction varies with age. Several studies[145,146] confirmed previous findings by Cote and colleagues[147] and Brett and Fisher,[148] who showed that thiopental requirements are higher in children (Fig. 13-3). Barbiturates decrease cerebral blood flow and intracranial pressure. The direct myocardial depression and venodilatation caused by thiopental are well tolerated by healthy children.[145] In patients who are hemodynamically compromised, however, these cardiovascular effects can result in significant hypotension. Thiopental should be avoided in children who are dehydrated, have heart failure, or have lost a significant amount of blood. Side effects seen with an induction dose of thiopental include hiccups, cough, and laryngospasm. Valtonen and associates[149] reported these side effects in 20% of children aged 1 to 6 years. Extravasation can cause tissue injury caused by thiopental's alkalinity. Barbiturates also cause histamine release, which is why they are often avoided in patients with a history of asthma.[150,151]

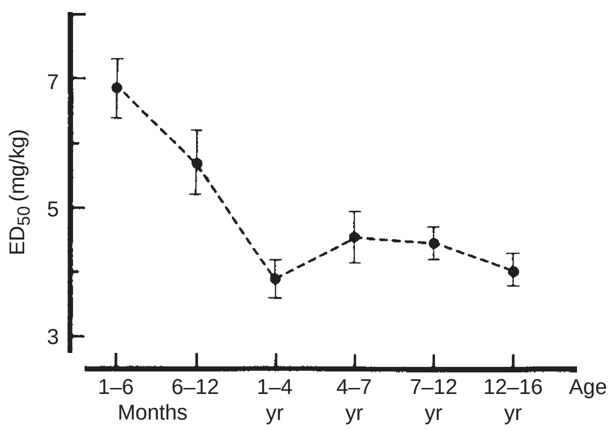

**FIGURE 13-3** Estimated $ED_{50}$ (the dose of a drug that will induce anesthesia in 50% of patients) plus or minus the standard error for thiopental in various age groups. (From Jonmarker C, Westrin P, Larsson S, Werner O. Thiopental requirements for induction of anesthesia in children. Anesthesiology 1987;67:104.)

## KETAMINE

Ketamine is a derivative of phencyclidine that antagonizes *N*-methyl-D-aspartate (NMDA) receptors. It causes a central dissociation of the cerebral cortex along with causing cerebral excitation. It is an excellent analgesic and amnestic, with recommended doses of 1 to 3 mg/kg IV, 5 to 10 mg/kg IM, or 5 to 10 mg/kg PO. The IV dose has a duration of 5 to 8 minutes. Glycopyrrolate or similar antisialagogue should be given for the copious secretions associated with ketamine use.

Ketamine increases heart rate, cardiac index, and systemic blood pressure. It also causes bronchodilation with minimal effects on respiration.[152,153] There is no direct effect on pediatric pulmonary artery pressure as long as ventilation is controlled. Its systemic effects are sympathetically mediated. However, ketamine will cause bradycardia and a decrease in systemic vascular resistance in patients who are depleted of catecholamine. Also, it is the only IV anesthetic to increase both intracranial pressure and intraocular pressure. Therefore, it is relatively contraindicated in patients in whom these increases could be detrimental.

## ETOMIDATE

Etomidate is a steroid-based hypnotic that has minimal effects on the hemodynamics or cardiac function of a patient at clinical doses. It also has minimal effects on respiratory parameters. Therefore, it is useful in pediatric patients with known or anticipated hemodynamic instability. The main drawbacks to its routine use are pain with injection and adrenal suppression even after one dose. Typical dosages for induction are 0.2 to 0.3 mg/kg IV.

# Monitoring

## NONINVASIVE MONITORING

The ASA has established standards for basic anesthesia monitoring, which include continuous evaluation of the patient's oxygenation, ventilation, circulation, and temperature during the use of all anesthetics. Delivery of an adequate oxygen concentration is ensured by measuring the inspired concentration of oxygen in the patient's breathing system using an oxygen analyzer on the anesthesia machine. Blood oxygenation is measured by pulse oximetry. Ventilation is ensured by qualitative clinical signs such as chest excursion, observation of the reservoir breathing bag, and auscultation of breath sounds as well as continual monitoring for the presence of end-tidal carbon dioxide. When ventilation is controlled by a mechanical ventilator, a continuous device that is capable of detecting the disconnection of system components is used. Circulation is monitored by a continuously displayed electrocardiogram, arterial blood pressure reading, and heart rate, which is determined and evaluated at least every 5 minutes. In addition, adequate circulation is ensured by auscultation of heart sounds, palpation of a pulse, monitoring of a tracing of intraarterial pressure, ultrasonographic pulse monitoring, or pulse plethysmography or oximetry. Temperature monitoring is required to aid in the maintenance of appropriate body temperature during all anesthesia.[154]

### Temperature Monitoring

The oral or nasal cavity is the most common site for temperature measurement in the pediatric population. Midesophageal or nasopharyngeal temperature better reflects core temperature compared with rectal or tympanic measurements. However, tympanic temperature theoretically provides ideal information because it most closely reflects the temperature of the brain. Rectal temperature is also a common site for temperature measurement, despite the following disadvantages: (1) potential for perforation of the bowel wall with a stiff thermistor probe wire, (2) potential dislodging of the probe, and (3) excessive warming of the thin tissues of the perianal and coccygeal area by the circulating warm water mattress. A more fundamental objection is that rectal temperatures, in general, do not promptly track rapid temperature changes, such as those that occur during deliberate hypothermia or rewarming.

### Pulse Oximetry

Continuous, noninvasive monitoring of arterial oxygen saturation ($Sao_2$) can be accomplished by pulse oximetry. The oximeter is usually placed on a finger or toe, but any site is acceptable as long as a pulsating vascular bed can be interposed between the two elements. Two wavelengths of light chosen for their relative reflectance with oxygenated versus deoxygenated hemoglobin illuminate the tissue under the probe. Through expansion and relaxation, the pulsating vascular bed changes the length of the light path, thereby modifying the amount of light detected. The result is a characteristic plethysmographic waveform, and artifacts from blood, skin, connective tissue, or bone are eliminated. This technique is accurate with oxygen saturation values from 70% to 100%. Reduction in vascular pulsation—for example, with hypothermia, hypotension, or the use of vasoconstrictive drugs—diminishes the instrument's ability to calculate saturation. In addition to a continuous indication of $Sao_2$, the pulse oximeter usually provides a continuous readout of pulse rate and amplitude.

### Capnography

The presence of end tidal $CO_2$ ($ETco_2$) is the gold standard in confirming proper endotracheal tube placement and measuring the adequacy of ventilation. Plotting $ETco_2$ versus time produces the classic time-capnograph curve. In Figure 13-4, *A,* the curve represents an ideal time-capnograph tracing during quiet respiration with no rebreathing of exhaled gas. The maximum value of $ETco_2$ at number 4 represents alveolar gas, which is in equilibrium with arterial $CO_2$ ($Paco_2$). In the absence of any ventilation-perfusion (V/Q) mismatch, the value at 4 should be within 2 to 4 mm Hg of $Paco_2$. Any discrepancy that is larger points to an increase in V/Q mismatch due to larger dead-space ventilation.

An ideal capnographic tracing cannot always be obtained, but the abnormal curve may be diagnostic or highly suggestive of certain types of problems involving the patient, the anesthesia circuit, or the ventilation technique. In Figure 13-4, B, several capnographic tracings are presented that represent changes or pathologic features in ventilation. In all of these, the maximum obtained $ETco_2$ is no longer indicative of $Paco_2$.

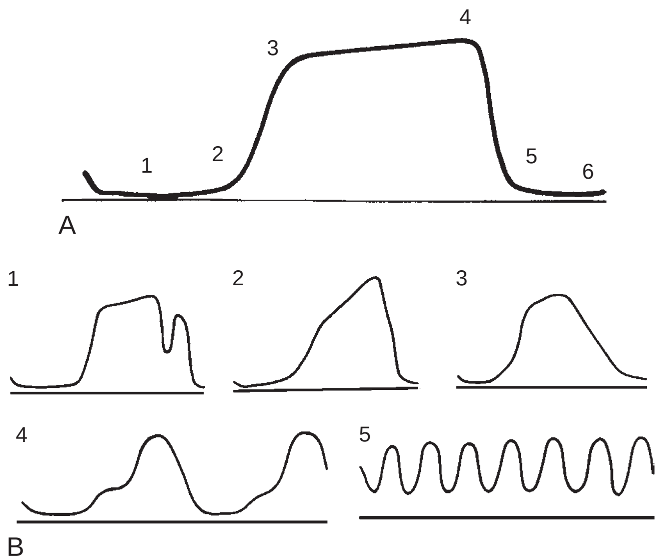

**FIGURE 13-4** **A,** Ideal capnographic tracing. Exhalation begins *(1)*. Anatomic dead space is cleared *(1-2)*. Dead-space air mixes with alveolar gas *(2-3)*. Alveolar plateau *(3-4)*. End-tidal maximum value; inspiration begins *(4)*. Dead-space air is cleared *(4-5)*. Inspiratory gas is devoid of carbon dioxide *(5-6)*. **B,** Types of capnographic tracings: Efforts at spontaneous breathing with incomplete neuromuscular blockade *(1)*. Respiratory obstruction *(2)*. Lack of sustained pressure resulting from a large leak in the breathing system *(3)*. In the Mapleson D system, when large amounts of fresh gas flow at small tidal volumes, the expired carbon dioxide is diluted and achievement of a stable alveolar plateau is prevented *(4)*. The effect of partial rebreathing of carbon dioxide from the expiratory limb of the Mapleson D system, when fresh gas flows at small amounts, is excessively rapid ventilation and small tidal breaths *(5)*.

### Monitoring Neuromuscular Function

The only satisfactory method of monitoring neuromuscular function is stimulation of an accessible peripheral motor nerve and observation or measurement of the response of the skeletal muscle supplied by this nerve. Various nerve stimulators are commercially available. Usually, the ulnar nerve is stimulated at the wrist with surface electrodes, and the response of the adductor pollicis brevis is noted. Supramaximal electrical stimuli are necessary to ensure full activation of the nerve. The evoked response to single repeated nerve stimuli at 0.1 Hz or train-of-four stimulation at a low frequency (2 Hz for 2 seconds) allows continuous monitoring of neuromuscular transmission after the administration of muscle relaxants. Tetanic rates of stimulation (50 Hz), train-of-four ratios, or double-burst stimulation allow the assessment of neurotransmission after reversal.

In adults clinical signs of adequate neuromuscular transmission include the ability to sustain a head lift for 5 seconds in conjunction with a vital capacity of at least 15 to 20 mL/kg or a negative inspiratory force of 30 cm $H_2O$. Because an infant cannot lift the head for 5 seconds, the ability to flex its arms or legs is a reliable sign of adequate neuromuscular transmission. Because vital capacity cannot easily be determined in infants, inspiratory force is measured instead. The ability to sustain tetany of 30 to 50 Hz for 5 seconds or a near-normal train-of-four ratio (>0.7) is also a reliable sign of adequate neuromuscular transmission.

### INVASIVE MONITORING

The availability of sophisticated noninvasive monitoring devices has reduced the need for invasive monitoring. The need for invasive monitoring is driven more by patient condition than by surgical procedure.[155] Intraarterial and, to a lesser degree, central venous and pulmonary artery catheters are required for the continuous measurement of pulse, intravascular pressures, and serial arterial blood gas concentrations, blood chemistry values, and coagulation abnormalities intraoperatively and postoperatively for extended periods in critically ill patients.

The most desirable site for arterial sampling is the right radial artery, where the concentration of oxygen tension most closely resembles that of the carotid artery. Postductal arteries have lower oxygen tension in the presence of right-to-left shunting and may become occluded during procedures such as repair of coarctation of the aorta. When the radial artery is not available, the femoral, dorsalis pedis, or posterior tibial artery may be used. In infants, the brachial and axillary arteries are generally avoided because of the risk of loss of the limb. Femoral artery catheterization may be complicated by joint injury, and cannulation of the superficial temporal artery is associated with a risk of temporal lobe infarction resulting from retrograde perfusion of the vessel during flushing. Despite their accessibility during the first 10 days of life, umbilical arteries are a limited option because the incidence of infection is high. In addition, because of the risk for thrombosis and embolism, the catheter tip must be carefully positioned above the diaphragm or below the third or fourth lumbar vertebra away from the origins of the celiac, mesenteric, and renal arteries. Also, when blood is sampled from below a patent ductus arteriosus in a patient with right-to-left shunting, oxygen saturation in the umbilical arteries may be less than that of the carotid or right radial artery and thus lead to the administration of dangerously high oxygen concentrations.

The indications for central venous catheterization, and especially for flow-directed pulmonary artery (Swan-Ganz) catheters, are limited in infants and children. The procedure is probably indicated more often for patients in the intensive care unit than for those in the operating room. Central venous catheterization is indicated for patients having operations involving major blood loss, shock, and low-flow states. The preferred route of access for either catheter is the internal jugular vein, although the subclavian and femoral veins are alternatives. Placing the catheter and monitoring the pressure in a major vein returning blood to the heart allows proper maintenance or adjustment of the patient's circulating blood volume.[155] Possible complications include atrial or ventricular arrhythmias, thromboembolic phenomena, hemothorax, pneumothorax, and infection.

## Pain Management

Children of all ages feel pain. Although progress remains to be made, recent interest in and awareness of pain in pediatric patients, along with philosophical shifts and technical advances, have markedly improved pain management for children.[156,157]

Appropriate care of pediatric surgical patients entails pain management tailored to each child's age, emotional and developmental maturity, and surgical procedure. Children's ability to both experience pain and to tolerate potent analgesia has been questioned.[158,159] Many pediatric patients undergo surgery without adequate pain management. Historically, up to 40% of children undergoing surgical procedures have reported moderate to severe pain on the first postoperative day.[160] Although many children continue to receive inadequate perioperative analgesia, the evolution of integrated, multidisciplinary approaches has dramatically improved treatment strategies for pediatric surgical patients.[161] Preoperative, intraoperative, and postoperative strategies for minimizing pain should be based on the planned surgical procedure, anticipated severity of postoperative pain, anesthesia technique, and expected course of recovery.[162] Children must be reassessed at frequent intervals, with analgesic regimens modified accordingly.

Acute pain is a physiologic response to actual or impending tissue damage and may provide helpful information regarding the location and nature of injury or illness. Accordingly, there is often reluctance to provide potent analgesia to patients who will potentially undergo surgical procedures before obtaining a definitive diagnosis. It is now increasingly recognized that this dramatically undertreats pain in such patients, particularly children.[163] Appropriately titrated analgesia not only relieves pain and reduces distress but also often allows a more thorough and accurate evaluation, particularly in frightened or uncooperative pediatric patients. IV morphine, for example, provides significant analgesia to children with acute abdominal pain without masking focal tenderness or impairing the clinical diagnosis of appendicitis.[164] The traditional teaching that potent analgesia must be withheld from patients, including children, who may potentially have diagnoses requiring surgery is invalid and should be abandoned.

### PERIOPERATIVE PLANNING AND GENERAL APPROACH

The goal of perioperative pain management is to maximize patient comfort while minimizing side effects such as excessive sedation or respiratory depression. Multiple techniques are available and are chosen and titrated to effect based on each child's particular needs. Planning begins with the preoperative anesthesia evaluation and continues throughout the surgical procedure and postoperative period.

Nonpharmacologic techniques, such as distraction and guided imagery, may augment analgesia, enhance patient cooperation, and minimize pharmacologic therapy.[165] Nonopioid analgesics most commonly include acetaminophen, nonsteroidal antiinflammatory agents, and ketamine. Oral opioids are often adequate for the treatment of mild to moderate pain, whereas IV opioids are the mainstay of therapy for moderate to severe pain. Persistent requirement for IV opioids can be managed with continuous infusion or patient-controlled analgesia (PCA) modalities. Regional anesthesia may also be used as part of a comprehensive analgesia regimen. A useful paradigm that can be applied to pediatric pain management is the World Health Organization's analgesic ladder (Fig. 13-5).[166]

### DEVELOPMENT AND PHYSIOLOGY

Children of all ages feel pain, but the type and intensity may vary dramatically. Although peripheral nociceptors are fully functional at birth,[167–170] central modulation and pain

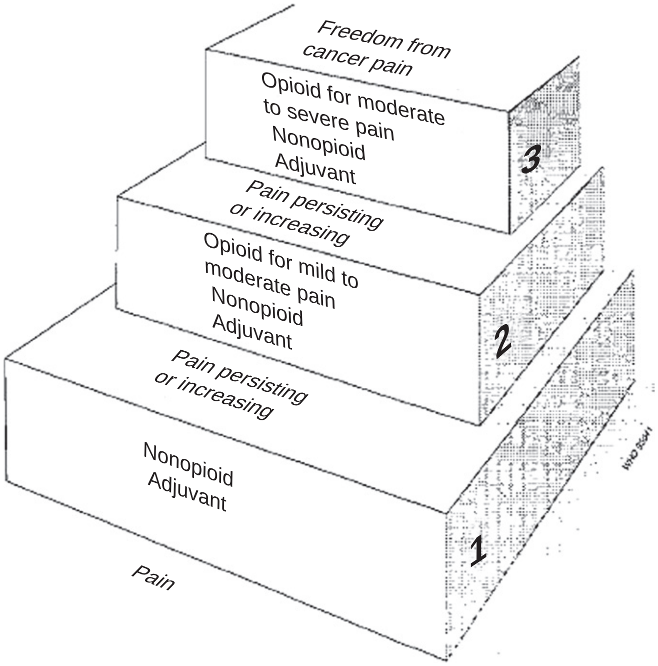

**FIGURE 13-5** First proposed in 1986 as a protocol for managing cancer pain, the analgesic ladder has become a popular and effective model for pain management in a variety of settings and can be applied to pediatric surgical patients. (From World Health Organization: Cancer Pain Relief: With a Guide to Opioid Availability, ed 2. Geneva, World Health Organization, 1996, p 15.)

perception in children are not well understood. Further, many reflex pathways allowing the expression of nociception are structurally and functionally immature in neonates and young infants.[171] Thus, although peripheral nociceptors register painful stimuli, central processing of pain in these young patients is more variable, and their ability to indicate pain perception is more limited. The response of infants and young children to pain is therefore unpredictable, particularly in premature neonates,[170] which often leads to inadequate pain management.

## HYPERSENSITIZATION AND PREEMPTIVE ANALGESIA

Acute pain is a physiologic response to actual or impending tissue damage. Untreated, persistent, or severe pain, however, may contribute to potentially detrimental pathophysiologic processes.[170,172] Tissue injury and inflammation enhance peripheral nociceptor activity, resulting in hypersensitivity to mechanical and chemical stimuli. In animal models, dorsal horn neurons respond to sustained afferent stimulation with neurophysiologic and morphologic changes consistent with increased excitability. The development of peripheral and central hypersensitization may alter normal sensory perception (dysesthesia), accentuate pain due to noxious stimuli (hyperalgesia), and produce pain in response to normally innocuous processes (allodynia), suggesting that hypersensitization at the cellular and neurophysiologic level correlates with clinical hypersensitivity to pain.

Preemptive analgesia before tissue injury may inhibit stimulation of nociceptive pathways, blunting the neuroendocrine stress response and preventing the development of peripheral and central hypersensitivity.[173] General anesthesia alone is ineffective for such purposes; nonsteroidal antiinflammatory drugs (NSAIDs), opioids, and a variety of local anesthesia techniques have been studied in animal models, with variable results.[173–175] Animal models generally suggest that preemptive analgesia, before noxious stimuli decreases dorsal horn neuron hyperexcitability, blunts observed pain behaviors and lowers clinical analgesic requirements. Human studies, however, have yielded conflicting and frequently negative results, particularly in children.[176–182] Subjective pain scores, objective assessments, and analgesic requirements are not dramatically affected in most patients by varying the timing of the analgesic technique before or after surgery. Preemptive analgesia as a strategy for blunting hypersensitization and reducing perioperative pain remains a subject of ongoing investigation and controversy.[183–187]

## PAIN ASSESSMENT

Pain assessment in pediatric patients can be challenging. Preverbal or developmentally delayed children may be unable to convey the severity or even the presence of pain to caregivers. In patients of any age, it may be difficult to distinguish pain from agitation. Nonetheless, pain in children should be recognized, assessed, and treated promptly.

Numerous tools have been developed and prospectively validated to allow ongoing quantitative assessment of pain in children of all ages and developmental skills.[188,189] In preverbal, young, or developmentally delayed patients, numerous tools allow the quantitative assessment of pain intensity by generating a pain score derived from the objective assessment of various pain-associated behaviors. The recently developed neonatal pain, agitation, and sedation scale (N-PASS) is a useful tool to assess pain in neonates 0 to 100 days of age and may also be applied to intubated or extremely premature children.[190–192] The face, legs, activity, cry, and consolability (FLACC) scoring system is valid and reliable for pain assessment in patients 5 to 16 years of age. Analog scales, useful for school-aged patients, use drawings or photographs of faces in varying degrees of distress, with colors, arrows, lines, or numbers (usually 0 to 10) for patients to indicate their level of pain.[193] Subjective, self-reported analog pain scores and objective, behavioral assessment pain scores in children are often discordant,[194] likely reflecting difficulties in distinguishing pain, agitation, and other causes of distress. The particular pain assessment tool chosen is less important than application of the tool to the appropriate population and consistent use of the tool in each patient over time.

## NONOPIOID ANALGESICS

Often overlooked, nonopioid analgesics are important adjunctive agents in pediatric pain management. They are often adequate for mild to moderate pain and may reduce opioid requirement in cases of moderate to severe pain.[195] Unlike opioids, nonopioid analgesics generally demonstrate a ceiling effect: exceeding recommended doses does not significantly improve analgesia but does increase the risk of side effects and toxicity.[196] Common nonopioid analgesics for children include acetaminophen, various NSAIDs, and in appropriate settings ketamine (Table 13-7).

**TABLE 13-7**
**Common Nonopioid Analgesics for Children**

| *Drug* | *Dose* | *Comments* |
|---|---|---|
| Acetaminophen | 20 mg/kg PO load (max 1000 mg), then<br>15 mg/kg PO (max 1000 mg) q4h<br>40 mg/kg PR load (max 1300 mg), then<br>20 mg/kg PR (max 1300 mg) q4h<br>Max 4 g/24 hr PO or PR | Good antipyretic<br>Hepatic toxicity with overdose |
| Selected nonsteroidal anti-inflammatory drugs (NSAIDs) | | |
| Choline magnesium trisalicylate | 10 mg/kg PO or PR (max 1000 mg) q6h<br>Max 4 g/24 hr | Good antipyretic<br>Only NSAID without platelet dysfunction<br>No association with Reye syndrome |
| Ibuprofen | 10 mg/kg PO or PR (max 800 mg) q6h<br>Max 4 g/24 hr | Good antipyretic |
| Ketorolac | 0.5 mg/kg IM or IV (max 30 mg) q6h<br>Total duration must be <5 days | Poor antipyretic<br>Potentially significant platelet dysfunction |
| Ketamine (requires appropriate personnel and monitoring) | 4.0-10.0 mg/kg PO (adult dose, 300-500 mg) | Anticholinergic agent; reduces sialorrhea |
| | 3.0-5.0 mg/kg IM (adult dose, 150-300 mg) | Benzodiazepine; may prevent agitation |
| | 0.5-1.0 mg/kg IV (adult dose, 50-100 mg) | Increases intracranial pressure; may precipitate seizures |

IM, intramuscular; PO, orally; IV, intravenous.

## Acetaminophen

Acetaminophen remains popular for the management of mild to moderate pain in children and as an antipyretic. Acetaminophen is a potent inhibitor of cyclooxygenase but has virtually no antiinflammatory activity and therefore few gastrointestinal, renal, or hematologic complications. The primary toxicity of acetaminophen is hepatic injury, seen with acute and chronic overdose. Acetaminophen may provide complete analgesia for mild to moderate pain and reduces opioid requirements in the treatment of moderate to severe pain, particularly when given on a scheduled basis. Procedural and perioperative analgesia with acetaminophen is enhanced by NSAIDs.[197]

Acetaminophen is available in a variety of oral and rectal preparations in the United States (see Table 13-7); IV preparations are available in other countries. The total dose should not exceed 4 g/day.

Rectal absorption of acetaminophen is slower and bioavailability is more variable than with oral administration, requiring higher doses for equivalent analgesia.[198] Although rectal acetaminophen has been shown to reduce pain scores and lower opioid requirements after surgical procedures, including myringotomy tube placement and inguinal hernia repair,[199] at least 40 mg/kg must be given.[200]

## Nonsteroidal Antiinflammatory Drugs

Like acetaminophen, NSAIDs may provide adequate analgesia for mild to moderate pain and are useful in conjunction with opioids in the management of moderate to severe pain.[202,201] NSAIDs are particularly effective for musculoskeletal pain. Unlike acetaminophen, NSAIDs have significant antiinflammatory activity. NSAIDs reduce mesenteric and renal perfusion and impair platelet function, potentially causing gastrointestinal ischemia, renal insufficiency, and bleeding. Risk is higher with elevated doses or prolonged administration.

Choline magnesium trisalicylate is the only NSAID that does not cause significant platelet dysfunction and may be useful in patients with coagulopathy or those who are at risk for bleeding during surgery. Pediatric aspirin use has declined dramatically since the described association with Reye syndrome in children with primary varicella.[196] Although choline magnesium trisalicylate is an aspirin derivative, it has no known association with Reye syndrome; nonetheless, it may be prudent to limit its use in children to patients who have previously had primary varicella or received varicella immunization. Choline magnesium trisalicylate is available in liquid and tablet preparations; the liquid preparation can be given rectally at the same dose to patients unwilling or unable to tolerate oral administration (see Table 13-7). The total dose should not exceed 4 g/day.

The most widely used oral NSAID in children in the United States is ibuprofen, available in a variety of liquid, tablet, and capsule preparations (see Table 13-7). An IV formulation is now available but is licensed only for medical closure of patent ductus arteriosus in infants. Ibuprofen is a moderate-potency analgesic and an excellent antipyretic with an impressive pediatric safety record, but it is still underused for procedural and perioperative pain management in children.[201] The liquid preparation can be given rectally at the same dose as choline magnesium trisalicylate. The total dose should not exceed 4 g/day.

Ketorolac is the only NSAID available for IV use as an analgesic (see Table 13-7). Indomethacin may be given IV but is approved only for medical closure of patent ductus arteriosus in infants. Ketorolac is a high-potency NSAID with an analgesic efficacy similar to that of many opioids and provides superior perioperative analgesia compared with other NSAIDs or acetaminophen.[203] Ketorolac may be particularly useful in patients who are intolerant of opioids, or in procedures that involve a high risk of postoperative nausea and emesis. Initially approved only for IM administration, ketorolac is safe and effective when given IV.[204] Oral ketorolac administration is approved for adults but not for children.

The volume of distribution and plasma clearance rate of ketorolac in children are roughly twice those in adults, but

the overall elimination half-life is similar.[205] As the most potent NSAID, ketorolac also has the highest incidence of side effects; total duration of therapy must not exceed 5 days to avoid potentially serious gastrointestinal and renal complications. Given its ability to compromise mesenteric perfusion, ketorolac should probably be avoided in infants at risk for necrotizing enterocolitis.

Significant platelet dysfunction may develop after a single dose of ketorolac, and its use in patients at high risk for bleeding is controversial. Initial experience indicated greater intraoperative blood loss during tonsillectomy in children receiving perioperative ketorolac,[198] and retrospective studies reported higher rates of postoperative hemorrhage.[206,207] Other retrospective studies suggested otherwise,[208] and prospective, randomized trials have shown only statistically insignificant trends toward increased bleeding.[209] The product literature warns against using ketorolac in patients at high risk of bleeding; it is probably prudent to avoid administering ketorolac to such patients until more definitive information is available.

### Ketamine

Ketamine can be used as an adjuvant analgesic in perioperative pain management. More recently, ketamine has been recommended for procedural analgesia and sedation in children in a variety of settings[210,211] and has become particularly popular in pediatric emergency departments, given its favorable safety profile.[212,213] Concomitant administration of anticholinergic agents to prevent sialorrhea, and benzodiazepines to decrease the likelihood of hallucinations and delirium, has traditionally been recommended. Recent data suggest these practices are of limited efficacy.[214] Adequate monitoring and immediate availability of appropriate resuscitation equipment and personnel are mandatory for children receiving Oketamine.[215]

## OPIOID ANALGESICS

Reluctance to use opioids in children is a common excuse for inadequate pain management in the pediatric population. Opioids are the mainstay of pharmacologic therapy for moderate to severe pain, however, and have established roles in procedural and perioperative pain management for children.[216] Acting on various subtypes of opioid receptors throughout the CNS, opioids cause dose-dependent pain relief and respiratory depression; other side effects include somnolence, miosis, decreased gastrointestinal motility, nausea, and urinary retention. Many opioids induce histamine release, causing urticaria, pruritus, nausea, bronchospasm, and occasionally hypotension. Pruritus is more common, and typically more intense, with neuraxial administration, likely owing to the CNS opioid effect rather than histamine release. Opioid side effects can be managed with a variety of agents (Table 13-8).

The opioid receptor antagonist naloxone rapidly reverses opioid effects. Mild respiratory depression or somnolence can be treated with IV naloxone 1.0 μg/kg titrated every 1 to 2 minutes as needed; doses of 10 to 100 μg/kg should be reserved for apnea or coma secondary to opioid overdose. Higher or repeated doses may be necessary. Naloxone may precipitate withdrawal in opioid-dependent patients, and pulmonary edema has been reported with higher doses. A low-dose naloxone infusion (0.25 μg/kg/min) may reduce the incidence of unwanted opioid side effects without significantly affecting analgesia for patients on patient-controlled opioid analgesic regimens.[217] Opioid analgesics do not generally have maximum effective doses. Recommended doses are for initial administration in opioid-naive patients; titration to clinical effect is required, and higher doses may be necessary. Increased dosage requirements (tolerance, tachyphylaxis) are often observed with prolonged administration or persistent pain. Opioid therapy longer than 7 to 10 days may result

**TABLE 13-8**
**Agents for Management of Opioid Side Effects**

| *Side Effect* | *Agent* | *Dose* | *Comments* |
|---|---|---|---|
| Apnea, coma | Naloxone | 10-100 μg/kg IV or IM q1-2 min PRN<br>Usual initial max: 400 μg<br>Higher or repeated doses may be required | Resedation may occur<br>Withdrawal in opioid-dependent patients<br>Higher doses may cause pulmonary edema |
| Mild respiratory depression, mild sedation | Naloxone | 1.0 μg/kg IV or IM q1-2 min PRN<br>Usual initial max: 400 μg<br>Higher or repeated doses may be required | Resedation may occur |
| Constipation | Docusate | 5.0 mg/kg PO (max 100 mg) bid | Stool softener |
| Nausea | Metoclopramide | 0.1 mg/kg IV (max 10 mg) q6h PRN | Extrapyramidal side effects |
| | Ondansetron | 0.1 mg/kg IV (max 4.0 mg) q6h PRN | Expensive |
| | Promethazine | 0.25-0.5 mg/kg PO, PR, or IV (max 25 mg) q6h PRN | May cause somnolence |
| Pruritus | Diphenhydramine | 0.5-1.0 mg/kg PO or IV (max 50 mg) q6h PRN | May cause somnolence |
| | Hydroxyzine | 0.5-1.0 mg/kg PO or IV (max 50 mg) q6h PRN | May cause somnolence |
| | Nalbuphine | 0.05 μg/kg IV (max 5.0 mg) q4h PRN | For pruritus from neuraxial opioid |
| | Naloxone | 1.0 μg/kg/hr IV infusion | For pruritus from neuraxial opioid |

IM, intramuscular; IV, intravenous; PO, orally; PRN, as needed;

in physical dependence, requiring weaning before discontinuation to avoid withdrawal.[218] Tolerance and dependence may occur independently. Addiction, a psychopathologic condition of volitional drug-seeking behavior, rarely develops in children receiving appropriately dosed opioids for analgesia and is not a valid reason to withhold therapy.[216] Opioids are commonly administered in conjunction with sedative-hypnotic agents, particularly benzodiazepines, increasing the risk of respiratory depression and desaturation.[219–221] Careful titration of doses, appropriate monitoring, and full capability to manage complications, including respiratory depression and apnea, are essential. Appropriate reversal agents should be available.

Opioid use in neonates and young infants has been the subject of much investigation and controversy. Historical studies in rats and humans suggested increased permeability of the neonatal blood-brain barrier to opioids, particularly morphine, and greater clinical respiratory depression.[222,223] It has more recently and more accurately been realized that the pharmacologic properties and clinical effects of morphine,[224–228] fentanyl,[229] and indeed all opioids in human neonates are subject to great individual variability. In general, opioid clearance is decreased and elimination is more prolonged in neonates than in older children, with values approaching adult levels by several months of age. There is no intrinsic reason to withhold opioid therapy from children of any age provided that doses are individualized to each patient and titrated to clinical effect.

## Oral Opioids

When pain needs allow and gastrointestinal function permits, oral opioids offer freedom from parenteral therapy. Onset of action is relatively slow, rendering oral opioid therapy unsuitable for the acute management of severe pain. Several lower-potency oral opioids are used commonly in children (Table 13-9), providing adequate analgesia for mild to moderate pain.

Codeine, available in liquid and tablet preparations, is commonly used in combination with acetaminophen. Codeine has a high rate of gastrointestinal upset. Hydrocodone, available in liquid and tablet preparations, is also usually used in combination with acetaminophen or an NSAID. Hydrocodone tends to cause less gastrointestinal upset than does codeine. Oxycodone is available in tablet preparations containing only oxycodone or in combination with acetaminophen or an NSAID; liquid preparations contain only oxycodone. This analgesic causes little gastrointestinal upset and is generally well tolerated. Sustained-release oxycodone is available for chronic therapy.

Although often given IV, higher-potency opioids may also be given orally (Table 13-10). The histamine release induced by morphine may cause urticaria, pruritus, bronchospasm, and even hypotension at higher doses, although these are less common with oral administration. Sustained-release oral morphine is available for chronic therapy. Hydromorphone causes less histamine release than does morphine. Methadone is particularly useful for chronic therapy in opioid-dependent patients.[230] Treatment of psychopathologic opioid addiction with methadone may be undertaken only in federally licensed facilities.

Oral transmucosal fentanyl citrate (OTFC) is a formulation of fentanyl in a lozenge attached to a stick. Oral transmucosal fentanyl citrate may provide effective preanesthetic sedation in children,[231,232] as well as analgesia and sedation for painful procedures,[233] although nausea and emesis are common. Appropriate monitoring is required.

**TABLE 13-9**
**Lower-Potency Oral Opioids for Children**

| *Drug* | *Dose* | *Comments* |
|---|---|---|
| Codeine | 1.0 mg/kg PO q4h (adult dose, 30-60 mg) | Tablet and liquid preparations |
| | | Usually in combination products with acetaminophen |
| | | High rate of GI side effects |
| Hydrocodone | 0.2 mg/kg PO q4h (adult dose, 10-15 mg) | Tablet and liquid preparations |
| | | Usually in combination products with acetaminophen or NSAID |
| | | Moderate rate of GI side effects |
| Oxycodone | 0.1 mg/kg PO q4h (adult dose, 5-10 mg) | Tablet preparations as oxycodone or in combination products with acetaminophen or NSAID |
| | | Liquid preparation as oxycodone |
| | | Low rate of GI side effects |
| | | Sustained-release product available for chronic therapy |

GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug; PO, orally.

## Intravenous Opioids

IV opioids are the mainstay of therapy for moderate to severe pain (see Table 13-10). Subcutaneous or IM administration, although pharmacologically reliable, causes additional pain and distress, particularly in children, and should be avoided.[234–236] Side effects are more common and potentially more serious with IV opioids, mandating appropriate monitoring and prompt management of complications. Neonates and young infants receiving IV opioids should be monitored particularly closely, and doses should be reduced by 25% to 50%. Equipotent doses of opioids entail a similar risk of side effects.[216]

Morphine is the traditional IV opioid analgesic but hydromorphone causes less histamine release. Although historically popular, meperidine offers no significant advantages over other opioids and causes no less hepatobiliary spasm at equipotent doses. Meperidine is useful at lower doses for the treatment of shivering but is no longer recommended as a primary analgesic.[216,218,237,238] A benefit of IV methadone is its longer duration of action with dosing regimens suggested at 6 to 12 hours. Pediatric surgical patients receiving intraoperative methadone require less subsequent analgesia than those receiving intraoperative morphine.[235] The risk of respiratory depression and other opioid side effects is also prolonged with methadone.

Fentanyl is commonly used for procedural and perioperative pain management in children because of its rapid onset and short duration of action. Fentanyl is highly lipophilic; high-dose, repeated, or sustained administration results in

**TABLE 13-10**
**Higher-Potency Opioids for Children**

| *Drug* | *Dose** | *Comments* |

*Recommended doses are for initial administration in opioid-naive patients; titration to clinical effect is required, and higher doses may be necessary. Doses should be reduced 25% to 50% in neonates and young infants.
IM, intramuscular; IV, intravenous; PO, orally; SC, subcutaneous.

significant tissue accumulation and a markedly prolonged duration of effect.[239] Fentanyl is also available as a transdermal patch that provides continuous transcutaneous absorption, mimicking IV infusion; one 25-μg fentanyl patch is roughly equivalent to 1.0 mg/hour IV morphine. Onset is slow, and absorption is somewhat variable. Although useful in some settings for the management of chronic pain, transdermal fentanyl is not indicated for acute pain management.[216,240]

Continuous infusion is an effective means of providing analgesia to infants and children requiring more than occasional doses of IV opioids. Respiratory depression is uncommon in healthy patients at suggested doses, which neither prevent spontaneous ventilation nor hamper weaning from mechanical ventilatory support.[241] Methadone infusion is generally neither necessary nor helpful in most children because of the drug's long half-life. Adequacy of analgesia, level of sedation, and degree of respiratory depression should be followed closely, and the infusion titrated as required. All patients receiving continuous opioid infusions should probably receive continuous pulse oximetry, with cardiorespiratory monitoring for neonates and young infants. Doses in opioid-naive neonates and young infants should generally be reduced by 25% to 50%.[242,243]

## Patient-Controlled Analgesia

Historically, it has been all too common to provide opioids only after patients feel pain. This can lead to a vicious circle of symptomatic pain followed by frequently delayed administration of medication, with the resultant risk of persistent pain or excessive sedation (Fig. 13-6).[244] This pattern exposes patients to potentially significant opioid side effects while providing only intermittent analgesia. Optimally, opioid levels should be maintained above the threshold for analgesia but below that for obtundation or apnea, preserving a balance between desired efficacy and undesired toxicity (Fig. 13-7).[245] Intermittent bolus dosing of opioids at appropriate intervals

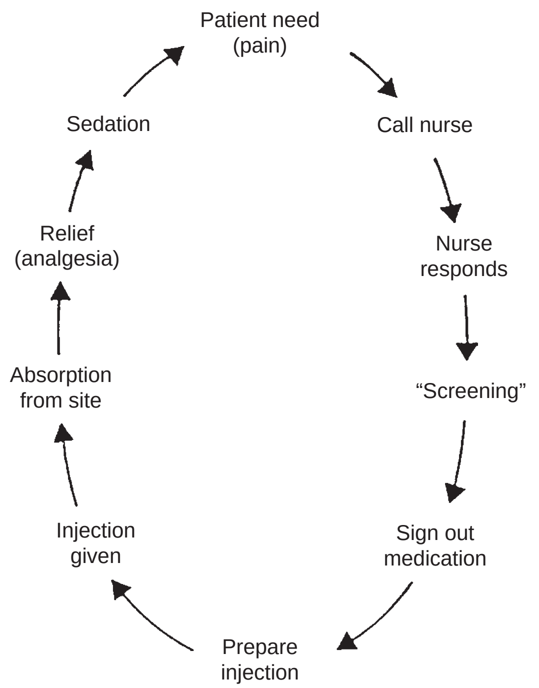

**FIGURE 13-6** Vicious circle of conventional opioid therapy. (From Graves DA, Foster TS, Batenhorst RL, et al: Patient-controlled analgesia. Ann Intern Med 1983;99:360-366.)

before patients experience pain may maintain opioid levels within this analgesic window, but this is time-consuming for staff and entails the risk of drug accumulation. Continuous opioid infusion eventually establishes a pharmacologic steady state but lacks easy short-term adjustment. A safe, effective, and readily titratable modality for IV opioid administration in children is PCA.[200,244,246]

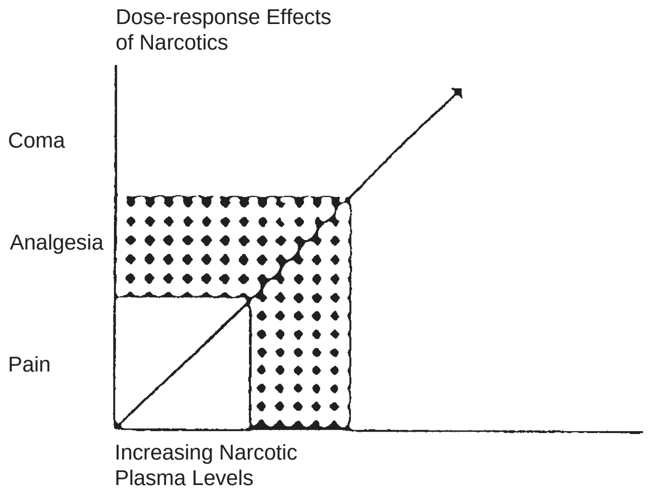

FIGURE 13-7 Analgesic window of opioid therapy. Idealized dose-response curve shows the continuum from pain to analgesia to coma associated with increasing plasma opioid levels. The shaded area depicts the analgesic window between inadequate pain relief and excessive sedation. (From Berde CB: Pediatric postoperative pain management. Pediatr Clin North Am 1989;36:921-940.)

**Patient-Controlled Analgesia Regimens for Children**

| *Drug* | *Demand Dose** | *Basal Infusion (if used)* |
|---|---|---|
| Fentanyl | 0.5-1.0 μg/kg IV (adult dose, 50-100 μg) | 0.5-1.0 μg/kg/hr IV (adult dose, 50-100 μg/hr) |
| Hydromorphone | 4 μg/kg IV (adult dose, 0.2-0.3 mg) | 4 μg/kg/hr IV (adult dose, 0.2-0.3 mg/hr) |
| Meperidine | Not recommended | |
| Methadone | Not generally used | |
| Morphine | 0.02 mg/kg IV (adult dose, 1.0-1.5 mg) | 0.02 mg/kg/hr IV (adult dose, 1.0-1.5 mg/hr) |

*Generally every 8-10 min for patient-controlled analgesia; every 15-60 min for nurse- or parent-controlled analgesia. Recommended opioid doses are for initial administration in opioid-naive patients; titration to clinical effect is required, and higher doses may be necessary. Doses should be reduced 25% to 50% in neonates and young infants.
IV, intravenous.

With PCA, opioid delivery is controlled by a device that allows administration of small doses of drug in response to patient request, usually by pressing a button; an appropriate lockout interval is programmed to prevent excessive administration. Analgesia is excellent, and with appropriate doses, serious complications are rare.[235] With proper instruction, most school-aged children can safely and effectively use PCA for opioid delivery.[235,247] Nurse- or parent-controlled analgesia can be used for children unable or unwilling to control their own pumps,[249,250] although the risk of respiratory depression increases if dosing intervals are not adequately adjusted, particularly in combination with basal infusions.[251] Overall risk of complications with so-called PCA by proxy in children is not elevated compared with the PCA, although risk of serious complications requiring intervention may be somewhat increased.[252] Morphine is the most common choice for PCA, but hydromorphone or fentanyl can be used (Table 13-11). Meperidine PCA is not recommended because of the increased risk of toxicity with sustained administration. Methadone PCA has been described in pediatric cancer patients with significant opioid requirements and tolerance to other agents,[253] but it is neither necessary nor helpful in most children because of the drug's long half-life. Routine PCA regimens provide a specified dose every 8 to 10 minutes for patient-controlled administration or every 15 to 60 minutes for nurse- or parent-controlled administration. Longer dosing intervals may be safer in younger or more medically fragile patients. Concomitant basal infusion to ensure ongoing analgesia and sustain drug levels during sleep has been advocated[254] but has not been shown to improve analgesia significantly.[255,256] PCA basal infusions in adults have been shown to increase the risk of respiratory complications,[257,258] but this has not been observed in children. PCA basal infusions in pediatric patients, although safe, appear to offer little analgesic benefit except in the setting of significant opioid tolerance. Patients receiving PCA should be assessed frequently, and doses and intervals should be adjusted appropriately. Continuous pulse oximetry is recommended for children receiving any opioid infusion. Cardiorespiratory monitoring may be appropriate in very young or medically fragile patients. Instruction of patients, families, and caregivers regarding appropriate PCA use is essential.

## Regional Anesthesia

Regional anesthesia with a local anesthetic can be provided by topical application or direct infiltration at desired sites or by myriad peripheral nerve, plexus, or neuraxial blocks. An advantage of regional anesthesia is that pain relief is often provided without reliance on opioids or other systemic agents, although these may be needed in some children despite apparently successful block.[259] Greater apprehension and variability in developmental and emotional maturity in pediatric patients may explain this unpredictable requirement for supplemental analgesia. Regional anesthesia in children entails a lower risk of adverse effects, including nausea, sedation, and respiratory depression, than does systemic opioid therapy.[245,259,260,261] Regional anesthesia may be particularly advantageous in patients with potentially increased sensitivity to opioids, including neonates and children with chronic respiratory disease. In some settings, regional anesthesia in children has been shown to improve surgical outcomes.[255] Topical anesthesia can be applied to children without sedation or anesthesia. Infiltration anesthesia can be accomplished in cooperative or older children, or it can be performed during surgical procedures. In contrast to adult practice, peripheral nerve, plexus, and neuraxial blocks in children are most commonly performed after induction of general anesthesia.[263,264] Theoretically, this prevents the detection of complications, including paresthesias, failed block, or injection into undesired sites or structures; fortunately, serious complications of regional techniques in anesthetized children are rare.[234,265,266] Performance of regional anesthesia after induction but before surgical incision offers the advantages of lighter intraoperative anesthesia and more rapid emergence and recovery.[267] The use of ultrasonographic imaging to visualize anatomic structures and facilitate placement of peripheral and neuraxial blocks has grown in popularity over the past few years.

**TABLE 13-12**
**Maximum Recommended Doses of Local Anesthetics**

| Local Anesthetic | Maximum Recommended Dose (mg/kg)* |
|---|---|
| Bupivacaine | 3.0 |
| Levobupivacaine | 3.0 |
| Lidocaine | 5.0 |
| Prilocaine | 7.0 |
| Ropivacaine | 4.0 |

*Addition of a vasoconstrictor such as epinephrine or phenylephrine to local anesthetic solutions may prolong absorption and modestly increase the maximum recommended dose, but this is not reliable.

Ultrasonographically guided blocks may decrease the overall local anesthetic requirement, and thereby toxicity, by providing real-time data regarding spread of the injected solution in proximity to the targeted structure. This imaging modality is also likely to decrease risk of complications such as inadvertent intrathecal, intravascular, intrapleural, or intraperitoneal injection. Although small-scale studies suggest improvement in outcome, larger-scale studies are currently under way regarding the improved safety and efficacy of ultrasonographic guidance over conventional methods of nerve blockade.[268–271] Lidocaine provides dense analgesia but has a relatively short duration of action and often induces motor block. In topical preparations, lidocaine is commonly combined with prilocaine, which may cause methemoglobinemia, particularly in large doses or in small patients. Bupivacaine is widely used in children because of its longer duration of action and relative selectivity for sensory over motor block. It is highly cardiotoxic, however, and thresholds for cardiac and neurologic toxicity are similar; dysrhythmias may occur before obtundation or seizures are noted. Ropivacaine has moderately greater selectivity for sensory over motor block than does bupivacaine, with a relatively higher threshold for cardiac toxicity, but widespread use is limited primarily by cost. Adherence to maximum recommended doses (Table 13-12) reduces the risk of toxicity.

## TOPICAL ANESTHESIA

Numerous formulations of local anesthetics provide cutaneous analgesia without the need for injection (Table 13-13), potentially reducing or eliminating the need for systemic analgesia and sedation.

Eutectic mixture of local anesthetics (EMLA) cream is a combination of 2.5% lidocaine and 2.5% prilocaine. Applied in a thick layer and covered with an occlusive dressing for at least 60 minutes, EMLA provides effective cutaneous analgesia for minor procedures, including circumcision and even chest tube removal.[188,272–275] Analgesia increases with application up to 4 hours.[276] EMLA cream is easy to apply; patients and families can do so at home. Side effects include erythema, blanching, and rash. The prilocaine component has caused concern about the risk of methemoglobinemia, particularly with generous application or in infants, but this is rare when the product is used appropriately.

Several other preparations of topical anesthetics are available. ELA-Max is an over-the-counter preparation of 4% or 5% liposomal lidocaine.[277] Numby Stuff is a unique system of topical anesthesia using mild electrical current to promote rapid iontophoretic intradermal transport of a solution of 2% lidocaine and 1:100,000 epinephrine.[278,279] TAC (tetracaine, adrenaline, cocaine) is available in a variety of preparations and provides effective cutaneous analgesia for the repair of superficial lacerations in children.[280–283]

**TABLE 13-13**
**Topical Anesthetic Formulations**

| *Product* | *Ingredients* | *Comments* |
|---|---|---|
| ELA-Max | Liposomal lidocaine 4% or 5% | Apply for 30 min<br>No dressing required<br>Nonprescription |
| EMLA | Lidocaine 2.5% + prilocaine 2.5% | Apply for 1-4 hr<br>Requires occlusive dressing<br>Prilocaine may cause methemoglobinemia |
| Numby Stuff | Iontocaine (lidocaine 2% + epinephrine 1:100,000) | Apply for 10 min<br>Requires specialized electrodes, generator<br>Tingling sensation may frighten some children |
| TAC | Cocaine 4%-11.8% + tetracaine 0.5%-1% + epinephrine 1:2000-4000 | Apply for 20 min<br>Avoid mucous membranes<br>Avoid terminally perfused areas<br>Potential cocaine toxicity |

## INFILTRATION ANESTHESIA

Infiltration with local anesthetic provides effective analgesia for minor procedures and can be performed in cooperative or older patients without sedation or anesthesia. Any appropriate solution may be used. The acid pH of many local anesthetic solutions enhances solubility and prolongs shelf life but is responsible for much of the pain associated with injection. Buffering pH helps reduce pain in awake patients and may increase efficacy. Addition of 1.0 mEq sodium bicarbonate to 10 mL local anesthetic significantly reduces pain during injection without precipitation of the solution.[284] The bicarbonate is added immediately before use. Infiltration anesthesia provides adequate analgesia after minor, but not major, surgical procedures.[285] The technique is straightforward, and the risk of local anesthetic toxicity is low if maximum recommended doses are not exceeded. Wound infiltration during inguinal hernia repair in children provides analgesia similar to that afforded by ilioinguinal-iliohypogastric nerve block [286,287] or caudal block [288] for 2 to 4 hours after the procedure. Longer-term analgesia is inferior, however.[289]

## PERIPHERAL NERVE AND PLEXUS BLOCKS

Successful block of virtually any peripheral nerve or plexus is possible with appropriate equipment and sufficient practitioner interest.[289,290] Regional anesthesia has been advocated for potentially optimizing analgesia, minimizing opioid

requirements, and improving pulmonary function.[291] Peripheral nerve blocks are readily performed in children; several are particularly applicable to pediatric surgical patients. Plexus blocks are performed less frequently in children than in adults, often secondary to practitioner inexperience but also because of logistic challenges in the application of adult techniques to pediatric practice. IV regional anesthesia of the extremity, or Bier block, has been described in children,[292] but its application may be limited by the risk of local anesthetic toxicity. Performance of peripheral nerve and plexus blocks before surgical incision offers the theoretical advantages of preemptive analgesia and lessened overall pain experience, but this has not been reliably demonstrated in clinical practice, particularly in children.[176,177,182] Timing appears to be less important than the regional block's performance.

## RECTUS SHEATH BLOCK

Recent interest in umbilical surgery in children, particularly the application of laparoscopic techniques, has prompted research on the use of regional anesthesia for such procedures. Terminal cutaneous branches of the lower thoracic intercostal nerves supply the skin of the anterior abdominal midline. Although infiltration anesthesia is readily accomplished in this area, specific nerve block offers the advantage of prolonged analgesia. Rectus sheath block for repair of umbilical and paraumbilical hernias in children has been described[293] and with minor modifications has been described as paraumbilical block.[294] Injection is made halfway between the umbilicus and the lateral linea alba (Fig. 13-8).[294] A blunt-bevel needle is introduced through the skin with slight medial angulation until a pronounced give or "pop" is felt as the needle pierces the external rectus sheath. After negative aspiration for blood and a negative test dose to reduce the likelihood of intravascular injection, 0.25 to 0.5 mL/kg of local anesthetic is deposited; little or no resistance should be felt. The needle may be withdrawn and a subcutaneous weal made toward the umbilicus for improved coverage of distal cutaneous braches. Injection is then repeated on the contralateral side. Rectus sheath block can be used at other dermatomal levels for the repair of midline ventral hernias above or below the umbilicus.[290]

## ILIOINGUINAL-ILIOHYPOGASTRIC BLOCK

The ilioinguinal and iliohypogastric nerves are terminal cutaneous branches of the lumbar plexus. The ilioinguinal nerve arises from the first lumbar spinal nerve roots and supplies much of the external genitals and part of the proximal thigh; the iliohypogastric nerve arises from the 12th thoracic and 1st lumbar spinal nerve roots to innervate the skin of the anterior abdominal wall above the inguinal ligament. The two nerves are usually blocked in conjunction, providing analgesia for procedures on the ipsilateral groin, including inguinal hernia repair and orchiopexy.[295]

Injection is made 1 to 2 cm medial and 1 to 2 cm superior to the anterior superior iliac spine (Fig. 13-9).[267] A blunt-bevel needle is introduced perpendicular to the skin until a distinct give or "pop" is felt as the needle pierces the Scarpa fascia, adherent to the aponeurosis of the external oblique muscle. After negative aspiration for blood and a negative test

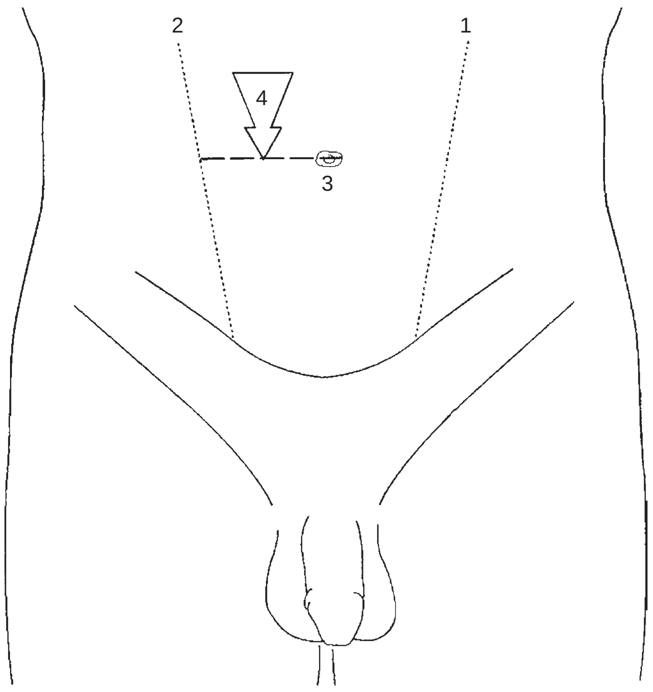

**FIGURE 13-8** Landmarks for rectus block at the umbilicus. Injection is made halfway between the umbilicus and the lateral linea alba. Left and right lateral lineae albae *(1* and *2)*. Umbilicus *(3)*. Right-sided injection site *(4)*. The left-sided injection site is symmetrically located. (From Courreges P, Poddevin F, Lecoutre D: Para-umbilical block: A new concept for regional anaesthesia in children. Paediatr Anaesth 1997;7:211-214.)

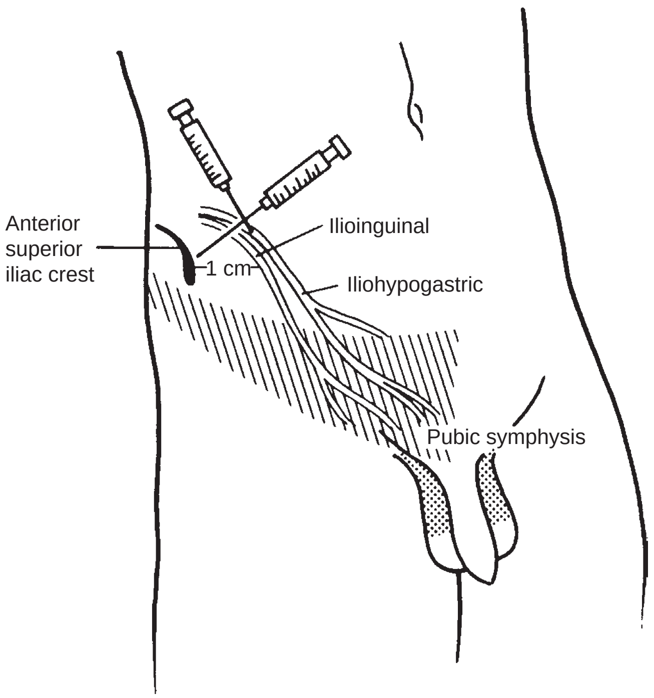

**FIGURE 13-9** Landmarks for ilioinguinal-iliohypogastric block. Injection is made 1 to 2 cm medial and 1 to 2 cm superior to the anterior superior iliac spine. Cutaneous innervation of the ilioinguinal nerve includes much of the external genitals and part of the proximal thigh; cutaneous innervation of the iliohypogastric nerve includes the skin of the anterior abdominal wall above the inguinal ligament. (From Yaster M, Maxwell LG: Pediatric regional anesthesia. Anesthesiology 1989;70:324-338.)

dose to reduce the likelihood of intravascular injection, 0.5 to 1.0 mL/kg of local anesthetic is deposited. Total volume of local anesthetic required for adequate blockade may be reduced with ultrasonographic guidance.[296] The needle may be withdrawn and a subcutaneous weal made toward the umbilicus for improved coverage of distal cutaneous branches of the iliohypogastric nerve. Ilioinguinal-iliohypogastric block provides only cutaneous analgesia; supplemental anesthesia is required for visceral manipulation. Because of this lack of visceral coverage, ilioinguinal-iliohypogastric block is inferior to caudal block at blunting the neuroendocrine stress response to orchiopexy.[297] The ilioinguinal-iliohypogastric block may also be paired with a caudal block for superior analgesia.[298] Bilateral block can be performed, but application may be limited in small children by the dose of local anesthetic required.

## FASCIA ILIACA BLOCK

The femur and anterior thigh receive innervation from the femoral nerve; the medial and lateral proximal thigh are supplied by the obturator and lateral femoral cutaneous nerves, respectively. Simultaneous block of all three nerves can be accomplished by various techniques, including fascia iliaca block, with resultant analgesia of the proximal leg, although sparing the posterior thigh. This block is appropriate for procedures involving the bony femur or soft tissues of the proximal thigh and may be particularly useful in children undergoing quadriceps muscle biopsy for evaluation of myopathy, in whom volatile anesthetic agents are best avoided. Fascia iliaca block is increasingly common in pediatric practice[290,299] and ultrasonographic guidance appears to result in a technically superior block.[300] Injection is made 1 to 2 cm medial and 1 to 2 cm inferior to the anterior superior iliac spine, just inferior to the junction of the middle and lateral thirds of the inguinal ligament (Fig. 13-10).[289] A blunt-bevel needle is introduced with slight inferior and lateral angulation, perpendicular to the iliac wing, until two distinct gives or "pops" are felt as the needle pierces first the fascia lata and then the fascia iliaca; the former is usually more pronounced than the latter. Alternatively, the needle may be advanced until encountering the iliac wing and then withdrawn slightly. After negative aspiration for blood and a negative test dose to reduce the likelihood of intravascular injection, 0.5 to 1.0 mL/kg of local anesthetic is deposited; little or no resistance should be felt. Continuous fascia iliac block in children has been described.[301] Bilateral block can be performed, but application may be limited in small children by the dose of local anesthetic required.

## PENILE BLOCK

Penile block provides analgesia for circumcision and other distal penile procedures, including simple hypospadias repair; caudal block is preferred for more proximal procedures, such as repair of complex hypospadias.[302–305] In general, penile

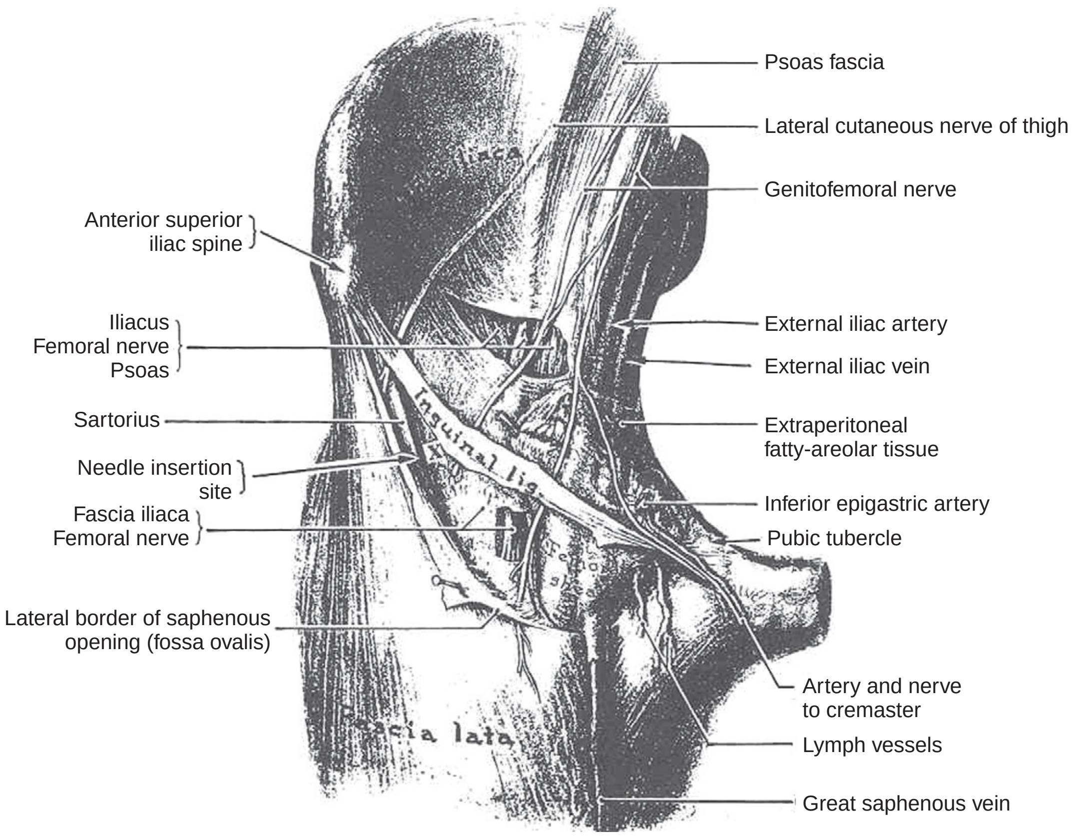

**FIGURE 13-10** Landmarks for fascia iliaca block. Injection is made 1 to 2 cm medial and 1 to 2 cm inferior to the anterior superior iliac spine, just inferior to the junction of the middle and lateral thirds of the inguinal ligament. (From Sethna NF, Berde CB: Pediatric regional anesthesia. In Gregory GA [ed]: Pediatric Anesthesia, ed 3. New York, Churchill Livingstone, 1994, pp 281-318.)

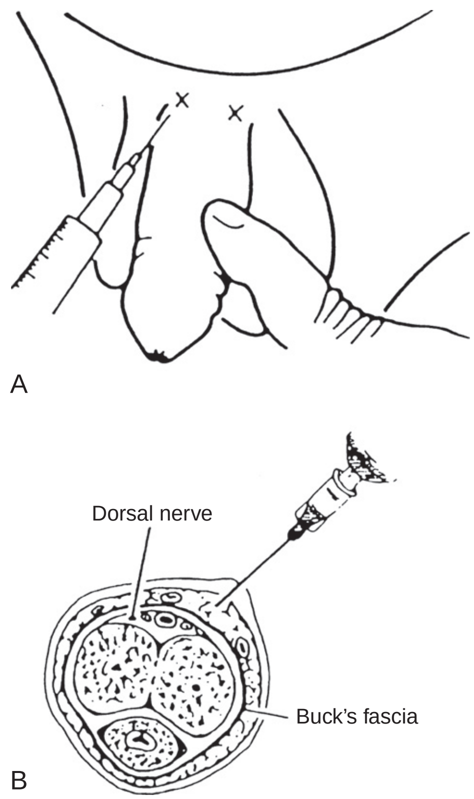

**FIGURE 13-11** Landmarks for penile block. **A,** Injection is made at the base of the penis lateral to the midline at approximately the 10 and 2 o'clock positions. **B,** The dorsal vein, two dorsal arteries, two dorsal nerves, and three corpora of the penis lie beneath the Buck fascia. **(A** From Yaster M, Maxwell LG: Pediatric regional anesthesia. Anesthesiology 1989;70:324-338. **B** From Rice LJ, Hannallah RS: Local and regional anesthesia. In Motoyama EK, Davis PJ [eds]: Smith's Anesthesia for Infants and Children, 5th ed. St Louis, CV Mosby, 1990, pp 393-426.)

block has fewer complications than does caudal block, in particular a lower incidence of motor block, but caudal block has a higher success rate and provides more prolonged analgesia. Penile block is not free of risk; puncture of dorsal penile vessels may lead to hematoma,[306] and gangrene of the glans penis has been reported. Local anesthetic solutions for penile block should not contain epinephrine or other vasoconstrictors. Injection is made at the base of the penis lateral to the midline at approximately the 10 and 2 o'clock positions (Fig. 13-11).[267,309] Alternatively, a single injection can be made in the midline. A blunt-bevel needle is introduced perpendicular to the skin until a distinct give or "pop" is felt as the needle pierces the Buck fascia. After negative aspiration for blood and a negative test dose to reduce the likelihood of intravascular injection, 0.5 to 1.0 mL/kg of local anesthetic, up to 10 mL, is deposited; little or no resistance should be felt. The process is then repeated on the contralateral side. Ring block at the base of the penis superficial to the Buck fascia provides equivalent analgesia and may reduce the risk of hematoma.[306]

## NEURAXIAL BLOCK

Neuraxial block involves either spinal or epidural techniques. Spinal block, with injection of anesthetic directly into the cerebrospinal fluid of the spinal subarachnoid space, is performed almost exclusively for procedures in infants at high risk of apnea after general anesthesia, although continuous spinal techniques are occasionally used for palliative analgesia. Epidural block, with injection of anesthetic into the potential space between the ligamentum flavum and the dura mater, is a far more common technique for procedural and perioperative pain management in children. Anesthetic can be administered as a single injection or by repeated injections or continuous infusion through an indwelling catheter. Contraindications to neuraxial block include patient or parent refusal, coagulopathy predisposing to neuraxial hematoma, local or systemic infection carrying the risk of neuraxial abscess or meningitis, increased intracranial pressure, and anatomic deformity. Most contraindications are relative; risks and benefits must be weighed in each patient.

## CAUDAL BLOCK

The most common neuraxial block in children is caudal block,[267] in which the epidural space is accessed via the sacral hiatus created by the failure of fusion of the spinous process of the fifth sacral vertebra. The technique is relatively straightforward, the success rate is high, and the complication rate is low.[310,311]

Injection is made between and slightly inferior to the sacral cornua (Fig. 13-12).[267] A blunt-bevel needle is introduced with approximately 45 degrees of cephalad angulation until a distinct give or "pop" is felt as the needle pierces the sacrococcygeal ligament, the most inferior aspect of the ligamentum flavum. If bone is encountered, usually representing the posterior aspect of anterior sacral elements, the needle is withdrawn slightly and redirected more parallel to the skin. Correct positioning of the needle tip within the epidural space is confirmed by loss of resistance to injection. After negative aspiration for blood and a negative test dose to reduce the likelihood of intravascular injection, the full dose of anesthetic is injected. Serious complications associated with caudal block include intravascular or intraosseous injection, inadvertent dural puncture with resultant spinal anesthesia, injury to pelvic contents, and hematoma; these complications are rare.[312] Caudal block is most commonly performed as a single injection of anesthetic providing reliable analgesia below the umbilicus in patients weighing less than approximately 30 kg. Perhaps because of their lower overall sympathetic tone, infants and children do not generally demonstrate hemodynamic instability after neuraxial block. Caudal block in pediatric patients induces significant changes in regional

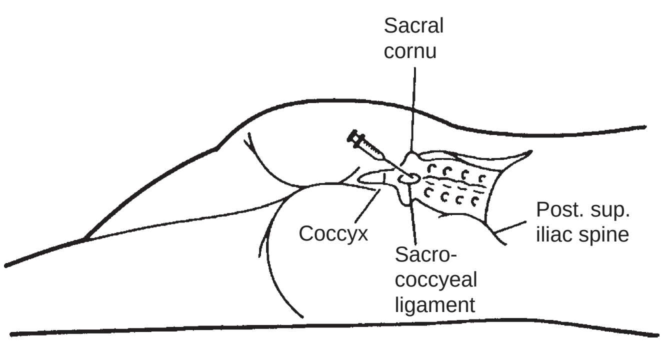

**FIGURE 13-12** Landmarks for caudal block. Injection is made between and slightly inferior to the sacral cornua. (From Yaster M, Maxwell LG: Pediatric regional anesthesia. Anesthesiology 1989;70:324-338.)

blood flow but does not significantly alter heart rate or blood pressure.[313] The agents administered determine the duration of analgesia after caudal block. Local anesthetic may provide analgesia for several hours and does not cause urinary retention at usual doses.[314] Bupivacaine 0.0625% to 0.25% is used most commonly. The addition of an opioid prolongs analgesia but increases the risk of side effects, particularly respiratory depression. Duration of analgesia and risk of side effects are greater with increasing opioid hydrophilicity, which promotes uptake into the cerebrospinal fluid and enhances distal spread. Caudal fentanyl, a highly lipophilic opioid, can be used for outpatient and ambulatory surgery in children. Caudal morphine, a highly hydrophilic opioid, provides analgesia for more than 12 hours but entails a significant risk of side effects, including pruritus and respiratory depression, for up to 24 hours.[315,316] Neuraxial morphine should not be used for outpatient analgesia. Caudal hydromorphone provides more prolonged analgesia than does caudal fentanyl, with less risk of respiratory depression than does caudal morphine. Caudal administration of clonidine[317,318] and ketamine[319] has been described and may be particularly advantageous in patients with potentially increased sensitivity to opioids, including neonates and children with chronic respiratory disease.

**TABLE 13-14**
**Agents for Epidural Infusion in Children***

| ***Local Anesthetic***† | ***Opioid***†,‡ |
|---|---|
| Bupivacaine 0.0625%-0.1% (max dose 0.4 mg/kg/hr) | Fentanyl 0.5-1.0 μg/kg/hr (adult dose, 50-100 μg/hr) |
| OR | OR |
| Levobupivacaine 0.0625%-0.1% (max dose 0.4 mg/kg/hr) | Hydromorphone 2.0-4.0 μg/kg/hr (adult dose, 150-300 μg/hr) |
| OR | OR |
| Lidocaine 0.1%-0.5% (max dose 3 mg/kg/hr) | Morphine 3.0-6.0 μg/kg/hr (adult dose, 250-500 μg/hr) |
| OR | AND/OR |
| Ropivacaine 0.1%-0.2% (max dose 0.5 mg/kg/hr) | Clonidine 0.25-0.5 μg/kg/hr (adult dose, 25-50 μg/hr) |

*Thoracic catheters commonly deliver 0.2-0.3 mL/kg/hr (max 5-10 mL/hr); lumbar catheters, 0.3-0.4 mL/kg/hr (max 10-15 mL/hr); and caudal catheters, 0.4-0.5 mL/kg/hr (max 15-20 mL/hr).
†Recommended local anesthetic and opioid doses should be reduced 25% to 50% in neonates and young infants.
‡Recommended opioid doses are for initial administration in opioid-naive patients; titration to clinical effect is required, and higher doses may be necessary.

## CONTINUOUS TECHNIQUES

Single-injection caudal block works well for pain anticipated to last less than 24 hours; even caudal morphine does not provide reliable analgesia beyond this time frame. For pain of longer duration, continuous techniques are preferred. Excellent analgesia can be provided by repeated injection or continuous infusion of anesthetic through indwelling epidural catheters, which can be placed via caudal, lumbar, or thoracic approaches to the epidural space in children.[320–322] Cervical epidural catheters for palliative care in children have been reported,[323,324] and tunneled catheters for prolonged analgesia have been described.[325] Epidural catheters are commonly placed directly at the desired vertebral level in patients weighing more than 5 to 10 kg. Once the epidural space is reached, the epidural catheter is advanced through the needle. Threading more than 3 cm beyond the needle often causes catheter coiling at the level of insertion.[326] The risk of spinal cord damage when placing thoracic or lumbar epidural catheters is always a concern, especially in the anesthetized or heavily sedated patient; these fears are largely theoretical, although neurologic complications have been reported.[327] Inserting the epidural catheter in the low lumbar or caudal space (after termination of the spinal cord) and threading a styletted catheter cephalad to the desired level may decrease the risk of direct spinal cord injury with high rates of success, particularly in neonates and young infants in whom the epidural fat is more gelatinous and the epidural space is largely free of fibrous septa.[263] This technique is often paired with conventional radiography, fluoroscopy, nerve stimulation, or electrocardiographic guidance to confirm correct catheter placement.[328–331] Ultrasonographic imaging of the spine may allow calculation of the skin-to-epidural space distance, localization of important bony and soft tissue landmarks, and even direct visualization of the epidural catheter in certain cases.[332–334]

Skin preparation with chlorhexidine rather than iodine-containing solutions confers a lower risk of subsequent catheter colonization.[335] The agent selected for epidural infusion depends on the dermatomal position of the catheter tip relative to the site of pain as well as on the distribution and intensity of analgesia desired. Numerous combinations of local anesthetic and opioid are commonly used in the United States (Table 13-14); other agents are used in other countries.[336,337] Concomitant administration of local anesthetic and opioid is synergistic and enables dose reductions of both agents, minimizing motor block and decreasing the risk of opioid side effects.[245,338] If the epidural catheter tip has been appropriately positioned in close dermatomal proximity to the site of pain, diluted local anesthetic with a lipophilic opioid such as fentanyl may be sufficient. If the epidural catheter tip is at a dermatomal level distant from the painful area, or if this area covers multiple dermatomes, addition of an increasingly hydrophilic opioid such as hydromorphone or morphine may be necessary. Epidural opioids provide excellent analgesia but are associated with side effects, including pruritus, nausea, urinary retention, and respiratory depression; risk of side effects increases with increasing opioid hydrophilicity. Opioid side effects can be managed with a variety of agents (see Table 13-8). Clonidine can be used to reduce or eliminate opioids in an epidural infusion, providing similar analgesia but avoiding opioid side effects.[339,340] This may be particularly advantageous in patients with potentially increased sensitivity to opioids, including neonates and children with chronic respiratory disease.

Close observation of patients receiving epidural infusions is essential. Continuous pulse oximetry and cardiorespiratory monitoring have been recommended for any child receiving an epidural opioid.[338] Alternatively, all patients receiving epidural infusions may be provided continuous pulse oximetry, with cardiorespiratory monitoring reserved for patients at increased risk of respiratory depression. Neonates and young infants, children with neurologic or pulmonary disease, and patients receiving a hydrophilic opioid such as morphine may merit more intensive monitoring.[234] Level of consciousness, adequacy of analgesia, degree of motor and sensory block, and presence of side effects should be assessed regularly and frequently for all patients receiving epidural

infusions. Continuous neuraxial techniques require significant caregiver diligence and expertise but provide superb analgesia for children with severe pain.

## COMMENTS

Appropriate pain management in children requires an understanding of developmental and physiologic issues unique to pediatric patients. A coherent plan encompassing the entire perioperative course should be developed, providing analgesia in proportion to pain and preempting pain whenever possible. Numerous tools are available to perform ongoing quantitative assessment of pain in all children.

Nonpharmacologic techniques may reduce the need for pharmacologic agents, and nonopioid analgesics may reduce the need for opioids. Opioids, however, remain the mainstay of therapy for moderate to severe pain and in appropriate doses can be used in patients of any age. Regional anesthesia with local anesthetic optimizes analgesia and reduces the need for systemic agents. Topical and infiltration anesthesia may be provided or specific peripheral nerve, plexus, or neuraxial blocks may be performed. Pain management is individualized, pain relief is assessed regularly, and regimens are modified as needed to optimize analgesia, minimize side effects, and facilitate recovery.

CHAPTER 14

# Clinical Outcomes Evaluation and Quality Improvement

Tamara N. Fitzgerald and R. Lawrence Moss

Decades of increasing resources for medical research and the explosion of information technology have created an enormous increase in the body of information available to practicing surgeons. In pediatric surgery, as in all disciplines, clinicians strive to offer their patients the benefit of all available data to provide the best care. Evidence-based medicine (EBM) is the practice of identifying the best available scientific evidence and applying this evidence to the medical care of patients. Sackett defined EBM as "the integration of best research evidence with clinical expertise and patient values."[1] EBM exists in two forms: the application of data to the care of individual patients and the development of evidence-based guidelines to guide the care of groups of patients within an institution or health system.

Actual medical decision making is best accomplished through a process by which the physician and patient (or family in the case of children) come to a health care decision based on the best available evidence, thoughtful application of the evidence to the patient, and personal factors such as quality-of-life and social or religious preferences. The development of clinical guidelines is a collaborative process by which relevant and knowledgeable practitioners critically review existing data and develop a plan of care for a set of patients with a particular disease process.[2] Patients treated by these guidelines are then followed prospectively to ensure that the anticipated improved outcome is realized. Guidelines are continually modified in an iterative process so that they can be refined, updated, and improved.

Several sources provide an extensive review of the principles of EBM and can provide the pediatric surgeon with a more detailed description than space allows here.[1,3–5] In this chapter, we provide an overview of the concepts that we believe are essential to the practicing pediatric surgeon who wishes to use most effectively the ever-growing body of information to provide the most rational, scientifically based, and current care to his or her patients. The first section discusses the concepts of study design and the second section focuses on the interpretation of data from clinical studies. The third section reviews the concepts of quality and outcomes assessment of one's own practice or institution in comparison to a standard.

## Study Design and Sources of Evidence

A basic understanding of the types of evidence that exist and the advantages and limitations of each study design is essential for the modern clinician. Varying levels of evidence are available for almost any imaginable clinical problem. The ability to understand which type of evidence a given study provides is critical to being able to determine the relevance of the study's findings to a particular patient or clinical situation. The spectrum ranges from personal anecdotal experience to large, multicenter clinical trials that examine specific questions in a rigorous but perhaps tangentially relevant manner. There is a hierarchy in study design, and the rating system used to evaluate diagnostic tests and therapies is described in Table 14-1. Studies are discussed in the following sections in order of increasing scientific rigor and reliability: case reports, case series, cross-sectional studies, case-control studies, retrospective cohort, prospective cohort, and randomized clinical trials.

### CASE REPORTS

Often when a clinician encounters a rare or interesting problem, it becomes the topic for a case report. In surgery, case reports are often used to introduce a novel procedure or technique. They are anecdotal in nature and represent the experience of just one or a few cases. Although they provide very little objective data, they serve to identify new disease processes or unexpected responses to treatment. They may also provide information and motivation for more rigorous clinical investigation. Case reports are particularly useful in the field of pediatric surgery in which the clinician frequently encounters rare or "never seen before" anomalies and responses to treatment. They can help the clinician realize possibilities beyond those discussed in a standard text and can allow the field to learn more collectively about rare conditions than would ever

**TABLE 14-1**
**Rating System Used to Evaluate Diagnostic Tests and Therapies**

| | |
|---|---|
| **Evidence Rating in Support of a Diagnostic Test** | |
| Class I | Evidence obtained from a blinded prospective study<br>Patient population represents a broad spectrum of persons with disease |
| Class II | Evidence provided by a blinded prospective study<br>Patient population may be a narrow spectrum of persons with disease |
| Class III | Evidence provided by a retrospective study<br>Patient population may be a narrow spectrum<br>Test is applied in a blinded evaluation |
| Class IV | Any design in which test is not applied in blinded evaluation<br>Evidence may be provided by expert opinion alone<br>May be a descriptive case series (without controls) |
| **Evidence Rating in Support of a Therapy** | |
| Class I | Prospective RCT<br>Masked outcome assessment in a representative population<br>Meets the following criteria:<br>a. Primary outcome is clearly defined<br>b. Exclusion/inclusion criteria are clearly defined<br>c. Adequate accounting for dropouts and crossovers<br>d. Relevant baseline characteristics are presented and equivalent |
| Class II | Prospective matched group cohort study with masked outcome assessment<br>RCT that lacks one criteria listed in a-d above |
| Class III | Other controlled trials in which outcome assessment is independent of treatment |
| Class IV | Evidence from uncontrolled studies, case series, or case reports |

RCT, randomized controlled trial.

be possible in a single practice or institution. However, the data in a case report are anecdotal and the application of any anecdotal data to one's own patient is quite limited.

## CASE SERIES

A case series is the observational experience of a surgeon or group of surgeons and reports on a series of patients with a particular disease or treatment. As such, there is usually no comparison between groups or any information about the outcome of a different treatment. Furthermore, the patient population usually represents a select group that has been referred to that surgeon or center for a particular reason, and the surgeon has often selected patients who are thought to be likely to do well with the procedure. This phenomenon is often referred to as "cherry picking." Data on patients at the same center who did not receive the operation being studied or data comparing the institution's patients with the disease to broader populations of patients are usually not provided. This markedly limits the reader's ability to determine the relevance of the results to his or her patients.

In case series, it is difficult for the authors to maintain objectivity. Investigators are often introducing a procedure or treatment that they truly believe "works" and they are motivated to demonstrate their success. Therefore, adverse events may be underreported and outcomes exaggerated. This bias is usually introduced subconsciously even with the best of intentions. In comparing one case series to another case series, there may also be variations in disease severity, comorbid conditions, operative technique, and postoperative care that are not addressed. Therefore, one cannot reliably make decisions about which treatment is superior based on case series data. In pediatric surgery, case series compose the vast majority of the clinical evidence.[6]

Consider the treatment for necrotizing enterocolitis (NEC). For years there were multiple case series that presented conflicting data as to whether laparotomy or peritoneal drainage was superior in the management of intestinal perforation. Proponents of laparotomy claimed superior results, whereas those in favor of peritoneal drainage reported data supporting a less invasive approach. Not until clinical trials were performed was it determined that the type of operation performed does not influence survival or other clinically pertinent early outcomes.[7–9]

The limitations of case series can also be seen in the history of in utero tracheal occlusion for congenital diaphragmatic hernia (CDH). In animal models, tracheal occlusion was shown to induce lung growth and respiratory maturation. Case series data were then published that showed tracheal occlusion improved lung function.[10] However, when a prospective randomized trial was conducted, the outcomes for infants treated with in utero tracheal occlusion were no better than those treated with standard postnatal care. In this randomized trial, survival in the control group was much higher than anticipated. Tracheal occlusion did not improve survival or morbidity rates.[11,12]

## CROSS-SECTIONAL STUDIES

Cross-sectional studies are useful for characterizing the prevalence of a condition or risk factor in a particular population. Measurements are made at a specified time in a population, one patient at a time. There is no longitudinal component of the investigation. For example, all children in the emergency room during a certain month may have their blood drawn once to determine the incidence of antibodies indicating prior exposure to a particular virus. These studies can be inexpensive and easy to conduct.

However, cross-sectional studies may not detect certain data depending on the timing and method of data collection. A good example is the hidden mortality of CDH. In Norway mortality from CDH was thought to be 30%, as reported from hospital records. However, on a more comprehensive survey of neonatal deaths it was found that many infants died soon after birth from CDH and never presented to a major referral center. The true incidence of CDH was at least 1 in every 5000 live births and the actual mortality from CDH was closer to 66%.

Cross-sectional studies have other limitations. Although they are useful for characterizing the prevalence of a condition or a risk factor in a study population, their inability to demonstrate a temporal relationship limits the ability to infer causation. However, these studies do provide preliminary data to justify further epidemiologic investigation.

## CASE-CONTROL STUDY

The case-control study begins with choosing an outcome of interest, with a goal to evaluate for exposures that are associated with this outcome. By design, these studies are retrospective.

Patients with a particular diagnosis (cases) are compared with similar individuals who are otherwise healthy (controls). For example, an investigator wishes to determine what factors are associated with the development of NEC in the newborn intensive care unit (NICU). Newborns with NEC are identified and comprise the case group. A second set of newborns would then be chosen from the NICU who do not have NEC (controls), but are "similar" in every other way to the case group. "Similar" is subject to interpretation and choosing the two groups appropriately is the key to success in this study.

A case-control study compares the relative prevalence of factors that might be associated with the outcome in the case and control groups. Using the example of patients with NEC, one might find that the incidence of a particular type of feeding was twice as prevalent in the group of newborns with NEC (cases) than other babies (controls). The study identifies the association but tells the investigator nothing definitive about the cause of NEC. It is entirely possible that the mode of feeding had nothing to do with the cause of NEC. Perhaps newborns fed the particular type of feeding were more likely to be small for gestational age or perhaps they were likely to come from a particular socioeconomic group with a high incidence of NEC. The case-control study can provide interesting hypotheses for further study but is only able to identify the odds of an association between a risk factor and outcome and *not* the relative risk of the outcome given the risk factor. This is a nuanced but critical difference.

It is also important that case controls studies "match" for the prevalence of certain characteristics that are known to affect the outcome so that the characteristics are found at the same prevalence in each group (e.g., gestational age). Ideally this requires that the investigators know in advance what all the factors are. This is, of course, not possible. If this was known, the study would be unnecessary.

This study design is easy to perform with relatively little expense. It is an efficient means to study rare conditions and infrequent outcomes, and several exposure variables can be studied simultaneously. Therefore this study design lends itself well to logistic regression models, which help elucidate the manner in which one factor is associated with another and to clarify the relationship of each individual factor to the outcome.

Disadvantages of case-control design include the tendency for bias and the fact that identifying all important potential confounding factors is almost impossible. Recall bias and survivorship bias are two notable problems. Recall bias stems from the phenomenon that those affected by a disease are more likely to remember potential risk factors than those not affected. For example, in neonates born with birth defects, mothers may be more likely to remember potential teratogenic exposures compared with those mothers with healthy newborns. Survivorship bias occurs when data from survivors are included and data from deceased patients are either excluded or cannot be obtained. This type of bias may also result when patients with poor outcomes are lost to follow-up.

A recent study regarding perforated appendicitis provides a good example of case-control design.[13] In this multi-institutional study, children with perforated appendicitis in whom postoperative abscess developed made up the case group, whereas those who did not develop an abscess comprised the control group. Multivariate analysis with logistic regression was used to determine the factors that were independently associated with postoperative abscess development. A sample population consisting of 75% of the data was used to create the model, and then the model was tested on the remaining 25% of the data. The results showed that several factors were independently associated with abscess formation. Although this design was not able to show that these factors were causative of abscess formation, this information could be used to develop treatment guidelines that could then be evaluated prospectively.

## RETROSPECTIVE COHORT

A retrospective cohort study is designed to compare the outcomes of two groups of patients after an exposure. In surgical studies, the exposure is typically the operation. The study is conceptualized and the hypothesis is created after the patients have been treated and the outcome has occurred. This creates important limitations. For example, suppose that an investigator wished to determine if laparoscopic fundoplication reduces the length of hospital stay. He or she must first define a set of criteria that determines the cohorts: for example patients younger than 15 years of age with reflux confirmed by pH probe who underwent fundoplication. Patients are then identified who meet these criteria and assigned to one of two cohorts based on whether their operation was open or laparoscopic.

Several limitations are immediately apparent. One could ask why some patients in the study underwent laparoscopic fundoplication while others had an open procedure. Certainly, there was no effort to have any similarity between the two study groups because the study was not conceived when the treatment was done. It is very likely that there are large differences in patient characteristics and in the characteristics of the surgeons performing the procedure. It is also likely that the criteria for operation versus medical therapy were different in the two cohorts. Although it is important for investigators to report on covariates (factors that may affect outcome, such as age, neurologic status, and length of medical treatment) it is impossible to ensure that they will be equal between the cohorts or to make appropriate statistical adjustments when they are not. Further, it is not even possible for the investigators to know what covariates might be important or to what degree. A further limitation is the subjectivity of the outcome variables. Outcomes like death are objective, but the timing of when a surgeon chooses to discharge a patient is subjective.

Data in a retrospective cohort study must be retrieved from the medical record. The record is frequently incomplete or inaccurate.[14] The record was created before the study was designed and solely to meet the clinical needs at the time. Therefore it is almost inconceivable that all or even most of what the investigator wishes to find will be present or available in a consistent manner.

A retrospective cohort study can use either concurrent or historical controls. Concurrent controls were treated during the same period as the study patients. Remember that just because they are treated during the same period does not mean that they have the same characteristics, but at least this design does not have the additional limitations seen in studies using historical controls.

Historical controls were treated during different periods. Factors that can change over time include but are not limited to referral patterns, operating surgeons, indications and

contraindications for operation, availability and quality of nonoperative treatments, accuracy of tests to measure the disease or outcome, prevailing practice patterns, and even the natural history of disease. Returning to our example of laparoscopic versus open fundoplication, many of these factors have changed over the past decade.[15,16] Medical therapy for reflux has evolved considerably.[17] Our ability to define severity of reflux objectively through pH and impedance measurements has improved.[18] The subset of patients with reflux who are referred for operation has changed considerably over time.[19]

## PROSPECTIVE COHORT

A prospective cohort study is designed to compare the outcomes of two groups of patients after an exposure. The study is planned and inclusion and exclusion criteria are created before the patients are enrolled and data collected. The resulting data are more complete than a retrospective study because the investigators can observe and record the appropriate findings as they occur. Various outcome measures can be prespecified and recorded, such as length of stay, disease recurrence, or side effects. Patients are followed until a set end point is reached. For example, intestinal failure has been studied in neonates with NEC. All neonates with suspected or confirmed NEC, as defined by preset entry criteria, were enrolled. Study end points were defined as the development of intestinal failure or the achievement of full enteral feeds. Risk factors such as birth weight, antibiotic use, requirement for mechanical ventilation, exposure to enteral feeding, and small-bowel resection at surgery were monitored and recorded.[20]

The strength of this study design is a predetermined set of criteria to assess outcomes. This protects against "data mining," a phenomenon in which one may find a statistically significant difference in outcomes between groups if multiple outcomes are investigated. For example, an investigator may perform a study to investigate whether birth weight, race, or sex are associated with the development of esophageal reflux. If the study is completed and none of the factors investigated was found to be related to reflux, the investigator may be disappointed and want to search other factors. He may then look back into the medical record for the presence of asthma, mechanical ventilation, or obesity. If the investigator continues to expand the number of outcomes investigated, he or she will eventually find an association, most likely based on chance and not a true relationship. Therefore predetermined outcomes in the prospective cohort study protect against "data mining."

Several limitations are inherent to this study design. Foremost, there is no randomization. To return to our previous example of neonates with NEC,[20] these babies may receive surgery or drain placement in the instance of a bowel perforation. However, the decision for operation was made by individual surgeon preference, not a randomization process. The choice of intervention (drain placement versus laparotomy) could influence the length of mechanical ventilation or time to enteral feeds. The extent of small-bowel resection was also determined at operation, and different surgeons are likely to have different thresholds for bowel that should be removed. However, the length of bowel remaining will certainly be a factor in how the infant will tolerate enteral feeds.

Although this study design is inferior to a randomized clinical trial, it is sometimes the only appropriate study that can be performed.[21] Prospective cohort studies can provide valuable information on outcomes and are less expensive to perform than are randomized trials. They can be used to generate data so that randomized trials can then be performed.

Prospective observational studies can raise ethical concerns. Ethicists and other members of the research community have questioned whether investigators have an obligation to address the underlying needs of special populations and not just exploit their condition for the purposes of research. This is of particular interest in disadvantaged communities and developing countries.[22]

The degree of study validity lies in the similarity and selection of groups and in the definition of the cohort. Statistical methods can be used to take into account inequalities in the cohort, but when possible, covariates that are likely to affect outcomes between groups must be matched. If highly selective inclusion criteria are used, this may limit the general applicability of the results. Because patients are not randomized, bias may select patients into treatment groups. Also, investigator bias may alter outcomes. For example, investigators have studied long-term pulmonary function after extracorporeal membrane oxygenation (ECMO).[23] Cohorts consisted of infants with meconium aspiration syndrome, CDH, sepsis, or persistent pulmonary hypertension. Because of the invasive nature of ECMO, it would have been unethical to subject patients with these diseases to ECMO if it was not necessary. However, these cohorts represent infants with very different disease processes, and the disparity of disease states may explain the difference in their lung function, which may or may not be related to ECMO. They were also compared with healthy infants who never received ECMO. Therefore bias is difficult to remove from this study design, and it is difficult to ascertain from this study the role that ECMO has in preserving lung function.

An additional challenge in the pediatric population is that disease states tend to be rare and a multicenter approach may be needed to gain enough patients. For this reason, these studies can often be expensive. However, they are useful to characterize the natural history of a disease and relative risks. Prospective cohort studies can also be used to develop multi-institutional prospective databases, which can be used to study multiple risk factors and outcomes simultaneously. One such example is the database generated by the National Institute of Child Health and Human Development Neonatal Research Network, a consortium of 16 tertiary neonatal centers within the United States. Among other studies, this database has been used to examine the incidence and morbidity of short-bowel syndrome.[24]

## PROSPECTIVE RANDOMIZED CONTROLLED TRIAL

The randomized controlled trial (RCT) is the gold standard to compare treatment outcomes and acquire necessary data.[25] The first RCT in health care was reported in the 1940s.[26] To illustrate the importance of rigorous scientific inquiry, Sacks and associates compared RCT and historical control

trials (HCT) by searching the literature for therapies studied by both methods. Seventy-nine percent of HCTs found the therapy better than the control regimen, but only 20% of RCTs agreed. Biases in patient selection may weight the outcome of HCTs in favor of new therapies.[27] Unfortunately, information gained from nonrandomized studies continues to guide many of our treatment decisions because of the lack of RCTs.[28] In 2001, there were only 134 RCTs in pediatric surgery, accounting for 0.17% of the articles published in 33 years.[29]

In RCTs the study population and the disease of interest are clearly defined, and patients are randomized into two treatment groups but are otherwise treated identically. It is essential that the only variable that differs between the two groups is the one that is being studied. Theoretically the randomized design ensures that any observed differences should be due to the treatment and not to other factors. By randomly assigning patients into two groups, there is a built-in control for unknown clinical parameters that may influence treatment response. Thus the randomization process should eliminate confounding covariates. The RCT is the gold standard of clinical evidence and is the most powerful study design. In addition to research benefits, patients may also benefit from participation in trials because participating centers may focus increased attention and resources on these patients and their disease processes. Participating patients have been shown to have improved outcomes regardless of assignment.[30]

The main weaknesses of the RCT are that they are time intensive and expensive to conduct. It is not unusual for a trial to cost upward of $5000 per patient.[31] Additional staff may be required to conduct surveys, obtain informed consent, record results, analyze data, and organize protocol requirements. For surgeons participating in the study, there is an increase in paperwork and administrative oversight.[32] As previously noted, pediatric disease states are rare and therefore an appropriately powered study will require the participation of several institutions and surgeons. This can significantly increase the complexity of data acquisition and maintenance of study uniformity.[33]

The RCT should include a broad patient population. If the inclusion criteria are too narrow, the results may not be applicable to a larger patient population.[34] For example, if an investigator wishes to study the routine use of a nasogastric tube after laparotomy in children, but then excludes all emergency cases and children with developmental delays, the results of the study are applicable only to elective cases in developmentally normal children. Likewise, if a trial is conducted in a geographic region that is racially homogeneous, the results of the study may not apply to children of other racial backgrounds.[35]

In addition, the ability of a randomized trial to control chance is limited by sample size. Therefore the RCT must be appropriately powered to yield accurate results. In many RCTs, the sample size calculation is not reported, is frequently incorrect, and is based on erroneous assumptions.[36] The CONSORT group is an international consortium that has issued guidelines for conducting and reporting results of RCTs.[37] It provides a minimum set of recommendations for reporting RCTs. In this way, authors can report trial findings in a complete and transparent fashion, thereby facilitating critical interpretation of the results. The CONSORT statement comprises a 25-item checklist.[38] According to this statement, calculation of sample size must be reported and justified. The CONSORT statement has been adopted by several journals, including the *Journal of Pediatric Surgery*.[39,40]

Conducting a surgical RCT poses several challenges. If the condition under investigation is rare, or if there is difficulty enrolling patients, the RCT may take years to conduct and there is a chance that the therapy may be obsolete before the trial has been completed. Surgical techniques may evolve over the course of the study. Skill level is variable between surgeons and therefore the outcome is operator dependant. It is difficult to standardize an operation, as surgeons have different techniques, operating facilities, and learning curves.[41] Most pediatric surgery RCTs require a multicenter study, which increases the variability in clinical care and makes consistency across patients difficult.

One such example is the Necrotizing Enterocolitis Trial (NET). This RCT has enrolled patients from neonatal surgical units in Europe, Asia, Australia, and Africa. In this study, infants were randomized to peritoneal drainage or laparotomy. The results indicated that peritoneal drainage does not immediately improve clinical status and that the evidence does not support using peritoneal drainage as a temporizing measure.[8] Similarly, a second study conducted in the United States and Canada showed that the choice of operation did not influence survival or other short-term clinical outcomes.[9] To accomplish statistical power in both of these trials, patients from a large geographic region were enrolled. These examples illustrate that enacting study protocols, standardizing the care of patients, and collecting data is more complex when multiple institutions must coordinate efforts.

True blinding of the investigators in a surgical RCT is difficult. In RCT involving medication, it is relatively simple to give one group of patients the therapeutic drug and the control group a placebo. However, if one group of patients receives laparoscopic surgery and the control group receives the traditional open procedure, both surgeon and patient will know which operation was performed. Some investigators have chosen to openly discuss the operation with patients and families and not attempt a blinded approach. This approach has been applied to open versus laparoscopic pyloromyotomy for pyloric stenosis. In the seminal study performed by St. Peter and colleagues, patients were randomly assigned to open or laparoscopic pyloromyotomy, but both the surgeon and the guardians knew the procedure to be performed. Postoperative pain management, feeding schedule, and discharge criteria were standardized for both groups. The laparoscopic technique was found to be superior to the open method in several outcomes.[42] However, one could argue that the surgeon's operating time or the perception of postoperative pain could be influenced by the knowledge of which technique was performed.

Investigators have attempted multiple blinding strategies in these situations. For example, while the patient is still under anesthesia, the surgeon may place identical wound dressings for both the laparoscopic and open operations.[43] When it is not possible to blind the investigators performing the procedures, it may be possible to blind the investigators evaluating the outcome. For example, a common scenario occurs in trials involving carotid endarterectomy versus stenting. In this situation, the patient and surgeon know the procedure performed, but a blinded practitioner such as a neurologist can assess for postoperative stroke symptoms and neurologic deficits.[44] When the outcome is soft (such as length of stay or pain), blinding is more difficult. Hard outcomes such as death or postoperative laboratory values are affected less by the blinding process.

In addition to study blinding, randomization may also pose a problem in surgical RCT. Patients may initially agree to be randomized but may change their minds after learning to which treatment group they have been randomized. For example, in a RCT comparing best medical therapy with surgery, patients may agree to be randomized, but after being placed in the best medical therapy group may decide that they would really like to receive surgical therapy or vice versa. In this scenario, investigators often address the problem with the "intention to treat" approach, whereby all patients are included in the analysis despite which treatment they did or did not receive. This analysis should be adequately performed and described in the data reporting.[45]

## SUMMARIES OF EVIDENCE

To make evidence-based decisions for a particular patient or group of patients, data from multiple sources must be combined. No single data source, not even a well-conducted RCT, can provide all the evidence that a practitioner needs to choose the appropriate course of therapy for a patient. The medical literature is full of papers that combine evidence, and three examples are discussed here: review articles, meta-analysis, and systematic reviews.

### Review Articles

Reading a review article on a disease process or treatment of interest can be an excellent first step toward familiarization with the current literature. It is a compilation of the existing literature and evidence deemed important or relevant by the author. However, the quality of the review is largely dependent on the author. The referenced articles are typically chosen by the author and the comments regarding the validity of these articles or their relevance to patient care are usually the author's opinion. In many cases the review may not be comprehensive because conflicting evidence is omitted.

For example, there may be an author who has written extensively about the repair of abdominal wall defects. This author is asked to write a review article on the topic by a respected journal. Imagine that this author is a long-standing advocate of early cesarean section and delivery. The author may be more likely to reference articles from institutions that share this view. He or she may be more familiar with the theoretical physiologic benefit of this approach and perhaps more likely to reference experimental studies with this perspective versus opposing views. Consider that the author is very experienced with this disorder and has a large referral base. She is likely to include excellent outcomes from her own institution in the review. These excellent outcomes could be due to myriad ways that her institution provides quality care that might have nothing to do with the fact that the treated babies were delivered by early cesarean section. The result is an article that provides important information on the topic but is decidedly slanted toward one viewpoint.

The author is probably a highly ethical and well-intentioned individual who truly believes in the superiority of her approach. Nevertheless, the structure of a review article and the lack of rigorous constraints on selection of articles and methods of review are likely to produce a result that strongly reflects the author's views. This is not necessarily negative, as viewpoints of experts can be of great value. However, it is crucial that the reader of a review article understand its inherent limitations and is able to place its conclusions in the broader perspective of other types of evidence. We would go so far as to suggest that even this chapter on EBM reflects our own biases and viewpoints and should be considered in the context of other information written by those with a different outlook.

### Meta-analysis

When there are data from several sources, a meta-analysis can be performed by combining the results of multiple clinical studies into aggregate data (Fig. 14-1). True meta-analysis is the analysis and compilation of data from randomized trials, but in the absence of RCTs, other data types are sometimes combined as well. It is assumed that the quality of studies is comparable and that the patient populations are equivalent. It also assumes that measurement techniques and factors examined are similar. The quality of the meta-analysis is therefore directly related to whether these assumptions are true and also to the quality of the original data.

In pediatric surgery, meta-analysis has been limited by the small number of RCTs and prospective cohort data. For example, meta-analysis was performed to evaluate laparoscopic versus open appendectomy in the pediatric population.[46] At the time of this analysis, only 30 studies had been performed over a 10-year period that matched the inclusion criteria. Of these studies, 12 were retrospective, 11 were prospective, and only 7 were randomized. Only 14 of the studies contained at least 50 patients in each group (laparoscopic or open). Therefore, meta-analysis is an important tool to gain a big-picture approach to a particular treatment and to incorporate data from multiple sources, but it is ultimately limited by the quality of the original data.

### Systematic Reviews

Systematic reviews use algorithms to search, analyze, and combine the existing literature. Often both published and unpublished results are included in the search. The rigorous search algorithm minimizes bias, and these reviews provide a highly accessible source of quality information. Unfortunately in pediatric surgery, there are limited topics on which systematic reviews have been performed because of the lack of primary data.

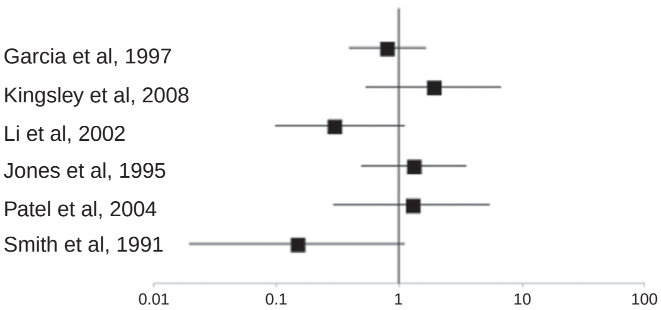

**FIGURE 14-1** A forest plot illustrates the relative strength of treatment effects in multiple RCTs contributing to a meta-analysis. The relative risk of a treatment in a single RCT is represented by a square, and the CI is represented by the extent of the horizontal line. The area of each square is proportional to the study's weight in the meta-analysis. When multiple studies fall either to the left or the right of the central axis (relative risk = 1), this indicates a strong treatment effect. When studies are scattered to the left and right of the central axis, this indicates a weak treatment effect.

An excellent source of systematic reviews is the Cochrane Collaboration and Best Evidence. The Cochrane Collaboration is an international consortium of physicians, statisticians, and epidemiologists. It is the first, largest, and most successful group, and they have provided a model for consortiums that have followed. The mission of the group is to review the scope of the world's literature, primarily through RCTs. Only treatments are included. Usually, diagnostic tests or risk factors are not reviewed. The resulting reviews can be found in the Cochran Collaboration database[47] and PubMed.

Best Evidence is another review that is edited by experts in EBM and tends to be highly clinical in nature. Unlike the Cochran Collaboration, Best Evidence also includes analyses on therapy, diagnosis, cost effectiveness, and complications.

## Application of Clinical Evidence

### HYPOTHESIS TESTING

When reviewing a study, one must have a basic understanding of the statistical methods and pitfalls that can result in erroneous conclusions. The discipline of statistics is dependent on the notion of chance, that there is a random nature to all outcomes. When two groups are compared (treatment versus no treatment), the null hypothesis is that there is no difference between the groups. The *P* value is the probability that the observed difference is due to chance alone. Results are commonly considered statistically significant when $P < 0.05$ (there is less than a 5% chance that the difference observed was by chance). If multiple outcomes are examined, at $P = 0.05$, 1/20 of these outcomes will occur by chance alone. Therefore it is easy to see how multiple hypothesis testing can result in erroneous conclusions. This is often referred to as "data mining" or "sifting the data." The most simple statistical method to correct for multiple comparisons is to define significance as the desired *P* value (usually $P < 0.05$) divided by the number of comparisons. This is called the Bonferroni correction. The confidence interval (CI) is the probability that the same difference would occur if the study were repeated an infinite number of times. Therefore, a CI of 95% means that a difference would be seen in 95% of the repetitions of the study. There are many tests available to calculate *P* and CI. The correct test is dependent on the number of observations, number of groups compared, whether the data is continuous versus categorical, and if risk adjustment is required.

### SUBJECTIVE VERSUS OBJECTIVE DATA AND RISK

Many kinds of outcomes can be studied, and data can be either objective (such as laboratory values or vital signs) or subjective (pain scales or physical examination). Objective data are more easily analyzed with statistical methods, and the results are often more straightforward to interpret. However, subjective data can be validated by using multiple observers. For example, if one outcome of a study is a radiographic finding, this type of data may vary depending on the radiologist examining the case. If multiple radiologists report their findings on the radiograph and are blinded to the opinions of their peers, a measurement of interobserver variability can be obtained. The measurement is known as the kappa value, for which a value of one indicates complete agreement between observers and a value of zero indicates no agreement.

Event rates and risk are important concepts to understand when deciding how a study result should impact the current standard of care. The event rate (ER) is the probability that an outcome will occur in a defined population. The control event rate is the probability that an outcome will occur with standard therapy, and the experimental event rate is the probability of the outcome with experimental therapy. Relative risk reduction and absolute risk reduction are the proportional and absolute risk values reduced by the experimental treatment, respectively. Number needed to treat (NNT) is the number of patients who need to be treated to prevent one adverse event. Therefore the impact of therapy depends on the event rate in the population, and the magnitude of risk reduction is greater for common events.

### ERROR

All diagnostic tests and clinical studies contain errors. A type I error is rejecting the null hypothesis when it is true. This is also referred to as the false-alarm rate or the false-positive rate. In other words, a difference is observed when there is none. Alpha is the probability of a type I error, and when alpha is low, the specificity of a study is high.

The type II error is failing to reject the null hypothesis when it is false (the study does not find a difference when one exists). When the type II error is small, the sensitivity is high. Usually this type of error occurs because the sample size was too small. Beta is the probability of a type II error and can be minimized by performing power calculations during the planning of the study to ensure an adequate sample size. The study's statistical power should be stated in the results section of the manuscript. Unfortunately, no amount of statistical prowess can compensate for insufficient power. Therefore, for the results of a study to be reliable, type I and II errors must be minimized.

### IDENTIFYING BIAS AND DETERMINING VALIDITY

Many types of bias exist and can be pervasive and difficult to recognize. Selection bias refers to an imperfection in the selection process. This can result in subjects who are not typical of the target population or subjects who are more likely to have the outcome of interest. For example, a study may conclude that laparoscopic colon resection is superior to the open technique. However, a bias may exist if patients who presented with nonemergent conditions were offered the laparoscopic procedure, whereas patients who presented with an acute abdominal process were treated with the open procedure.

Information bias can be introduced by the way data is obtained. Patients who are interviewed may recall different events than patients filling out a survey. However, patients completing an anonymous survey may be more likely to give truthful responses than those being interviewed. Recall bias refers to a selective memory of past events. For example, parents of children with digestive disorders or food allergies may be more likely to remember what the child ate in previous days than families with healthy children.

Before data from a study can be used in clinical decision making, the clinician must ask about the applicability and validity of the study. The characteristics of the patients in the study should be similar to the patient who will be treated. The clinician must ask, “Are the patients in the study similar to my patient?” and “Does the sensitivity analysis include values that my patient would use?” Also, the validity of the study must be examined. The evidence needs to meet minimum criteria and the conclusions must be logical and complete.[25] If there are “soft spots” in the evidence, these should be dealt with appropriately. If possible, the analysis should be validated in a prospective study.

## GUIDELINES AND PATHWAYS

Once several valid studies have been performed and there exists a body of clinical evidence, guidelines and pathways can be constructed. Health care entities are increasingly relying on clinical guidelines, which typically focus on managing a particular type of patient. Guidelines are useful for cost savings, outcomes improvement, and error reduction. The difference between algorithms, guidelines, and pathways is an important distinction. An algorithm is a checklist or detailed list of instructions to carry out a specific task. A guideline is a standardized set of recommendations for a specific problem. A pathway combines several practice guidelines into a set of recommendations and may track a patient through diagnosis, management, rehabilitation, and follow-up.

Guidelines can be created to improve outcomes, to minimize variation in practice between physicians, or to contain excessive costs. To create a guideline, practitioners agree on a standard of care based on the available evidence. If the evidence is inadequate, that step is either decided on by consensus or left to the discretion of the physician. It is important that key members of the community “buy in” to the guidelines for implementation to run smoothly. Outcomes should be measured before and after implementation for validation purposes. However, it has been shown that implementing guidelines improves patient outcomes.[48] This is due in part to the observation that obtaining consistency may be more important than finding the “best” guideline.

Advantages of guidelines include reduction in errors of omission (forgetting an order) and reduction in errors of commission (e.g., drug dosage errors). There is an increase in efficiency and a potential cost savings, and guidelines often minimize confusion among staff. Hospital lengths of stay are decreased and patients have better outcomes. Potential disadvantages include loss of physician autonomy and potential dissonance if not all providers agree with the guidelines, as there is a recommended acceptance of the value judgments inherent in the guideline. It may become cumbersome if different entities (e.g., Medicare and the American Heart Association) promote different guidelines. If guidelines do not account for individual variation between patients, harm can result. There is a potential for legal liability if an undesirable outcome results despite proper adherence. For this reason, clinicians are ultimately responsible for deciding if a guideline is valid and whether or not it is applicable to their patient.

In summary, before applying current evidence to patient care, the clinician must carefully analyze the available data. This includes understanding the benefits and limitations of the study design, as well as the statistical analysis and significance of the data. The clinician must determine if a study result is applicable to a particular patient. Over time, applying this information to patient care can improve the quality of care. Introducing guidelines and pathways is one way to improve patient outcomes, and must be validated. Therefore clinicians should have a basic understanding of quality assessment.

# Outcomes and Measuring Quality of Care

## QUALITY OF CARE ASSESSMENT

There is growing recognition that there is great variation in surgical care between institutions and practitioners. Patients and families want to make informed decisions and are asking for more data regarding their health care choices. In addition, clinical leaders want to improve the quality of care. Therefore there is a need to assess performance and patient outcomes. A good performance measure will guide patients toward hospitals and clinicians with better results. Performance analysis can include structural, process, and outcome measures. Transparency of performance measures leads all institutions to take steps to improve results and elevates the overall level of medical care.

### Specific Measurements

There are three widely used measures to determine healthcare “quality”: structure, process, and outcome. Health care structure consists of elements that are fixed characteristics of the system that will not vary between individual providers. Examples of structural measures include nurse/patient ratios and whether or not there is a dedicated intensive care team. Measures of health care structure are expedient and inexpensive because the data are generally obtained from preexisting administrative records. Measures tend to be efficiently analyzed; a single measure may be compared to several outcomes. Unfortunately the number of measurements is limited and measures do not reflect individual performance, which many clinicians find unfair. An example of comparing structural measures would be evaluating the inpatient mortality rates of teaching versus nonteaching hospitals. One may find that mortality is higher in teaching facilities. Although the correlation may be strong, the analysis reveals little about the causative relationship between the variables. It is possible that quality of care is worse in teaching hospitals. It is also possible that teaching hospitals have more complex or high-risk cases. The ability to perform accurate risk adjustment is relevant here as it is to both process and outcome measures as well.

A second way to measure health care quality is to evaluate processes of care. These are services provided, medications prescribed, and other interventions applied to the care of patients. Process measures reflect care that patients actually receive and are directly actionable for quality improvement. An example of a process measure would be determining how many patients are asked to rate their level of pain as part of routine vital signs or whether patients receive the appropriate antibiotics before surgical incision. One benefit of process measures is that risk adjustment is often unnecessary. For example, it is well established that all patients receiving

surgery should receive an antiseptic skin preparation before incision. Therefore it is unnecessary to collect data regarding illness severity for the purposes of risk adjustment. Process measures are designed to determine how closely the care actually delivered resembles the care that the facility intended to deliver.

Because process measures are easy to implement and enforce, they are often the focus of regulatory agencies. The Surgical Care Improvement Project (SCIP) is a national partnership that was formed to improve patient safety by decreasing postoperative complications.[49] SCIP focuses on antibiotic prophylaxis, perioperative glucose control, appropriate preoperative hair removal, postoperative normothermia, perioperative beta blockade, and venous thromboembolism prophylaxis. For example, the SCIP guidelines suggest that antibiotics should be received within 1 hour before surgical incision, should be appropriately selected for the procedure to be performed, and should be discontinued within 24 hours of surgery. Compliance with these types of guidelines can be easily monitored and publically reported.

Unfortunately, studies have shown that institutions that score high on process measures do not necessarily have better outcomes. For example, a recent study compared the rate at which facilities provided timely and appropriate preoperative antibiotics to actual wound infection rates. Many of the centers with the highest rate of compliance with antibiotic use unexpectedly had the highest rate of wound infections.[50] In addition, hospitals that scored high on performance measures for the treatment of heart failure did not show any difference in patient outcomes within 1 year of discharge.[51] An additional limitation is that there is currently a lack of reliable data infrastructure. Many databases contain information on outcomes, and lack information on process of care. Therefore, measures may be difficult to define with existing databases, and the link between the measure and important patient outcomes is variable.

The third type of measurement is outcome data, which is the measurement most familiar to clinicians. End points can include variables such as mortality, complications, length of hospital stay, patient satisfaction, and readmission. Direct outcome measurements are appealing because they have inherent face validity and directly address variables that are most clinically important. Outcome measures are easily accepted by clinicians and hospitals. For example, ability to compare morbidity and mortality between centers in the Veterans Administration (VA) Hospitals through the National Surgical Quality Improvement Program (NSQIP) allowed improvements to be instituted that improved patient outcomes.[52] Collection of accurate outcome data requires a highly skilled data collection team and is time and resource intensive. Comparative outcome data between centers is of limited value without adequate risk adjustment. For example, hospitals and physicians who avoid high-risk patients or complicated procedures may appear to have better outcomes if a thorough risk adjustment is not performed. The most robust and accurate models for risk adjustment in surgical patients have been developed by the American College of Surgeons' NSQIP.[53,54]

## Improving Performance

Several organizations use performance measures to make recommendations regarding guidelines and to focus efforts to improve outcomes. The National Quality Forum (NQF), Joint Commission of Accreditation of Healthcare Organizations (JCAHO), and the Center for Medicare and Medicaid Services (CMS) have focused mainly on process measures and hospital-based care. The LeapFrog Group is a consortium of employers and health care payers who developed an extensive set of quality measures for value-based purchasing assessment.[55]

## Databases and Networks

Several collaborative efforts have been undertaken to create databases for quality improvement and outcomes research. The most well known is NSQIP, which was developed to improve the quality of surgical care on a national level. The American College of Surgeons (ACS) adopted this system after it was successfully implemented in the VA system. NSQIP provides reliable and risk-adjusted outcomes data. Because of the national scope of the project, surgical quality can be compared between hundreds of institutions. A rigorously trained clinical nurse reviewer collects information from the medical record. Data are collected prospectively and reported as the observed/expected ratio for mortality and numerous specific morbidities. Since the implementation of NSQIP in the VA system, 30-day mortality and morbidity were reduced by 45% and 27%, respectively (Fig. 14-2).[52] This translates to tens of thousands of lives saved.

The most important strength of NSQIP is that risk adjustment is done effectively and in a manner that is widely accepted as valid. Also, participating institutions can access

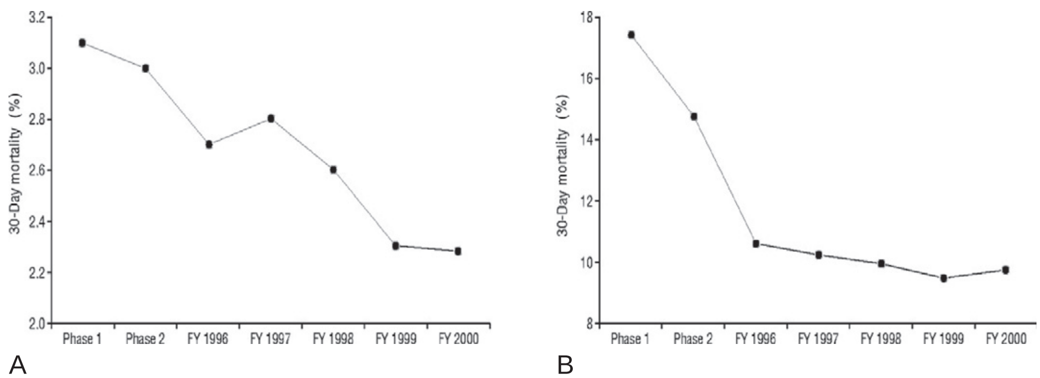

**FIGURE 14-2** Thirty-day postoperative mortality **(A)** and morbidity **(B)** for all major operations performed in the Veterans Affairs hospitals throughout the NSQIP data collection process. A 27% and 45% decrease in mortality and morbidity, respectively, were observed.[60] FY = fiscal year.

their own outcomes and compare their results against others. The program is expensive to implement, as it requires an annual fee as well as the salary of a dedicated nurse. It is not yet designed for assessing procedure-specific performance. At this juncture NSQIP provides informative data regarding general and vascular surgery in adults. The program is evolving to provide procedure- and specialty-specific outcomes in many disciplines. A separate pediatric program is under development.[56]

The Children's Oncology Group provides a wonderful success story of how large cooperative trials and evidence-based practice were used to decrease mortality for children with cancer. Through modification of therapeutic regimens based on multicenter RCTs, this group was able to decrease mortality from acute lymphocytic leukemia by 70%, without the development of any new drugs.[57,58] More recently, the American Pediatric Surgical Association (APSA) Outcomes and Clinical Trials Center was established in 2000. The objective of the center is to promote evidence-based guidelines through research efforts and outcomes analysis. Capabilities of the center include project coordination, database management, and data analysis.[59] These research efforts will no doubt be instrumental in providing new outcomes data, which will then be used to determine clinical guidelines.

## Conclusions

With the numerous sources of data available to surgeons, the application of EBM to patient care has become a complex and rewarding endeavor. Study design in many ways determines the strength of the data and to which patients the results can be applied. Therefore it is essential that pediatric surgeons understand the strengths and limitations of clinical studies and basic principles of statistics when evaluating clinical evidence. In addition, outcomes research and quality of care measurement is in a state of evolution and is already influencing the practice of surgery. Therefore clinicians should continue to carefully evaluate clinical evidence, as well as their own outcomes, so that we can constantly improve the health of our patients.

CHAPTER 15

# Ethical Considerations

Benedict C. Nwomeh and Donna A. Caniano

Ethics is concerned with questions of right and wrong. Medical ethics, also known as bioethics, outlines the standards, principles, and rules of conduct that govern physician behavior, the practice of medicine, and the conduct of biomedical research and training. However, although the core principles of medical ethics are immutable, our notion of what constitutes ethical practice is constantly challenged by evolving cultural norms, particularly within the milieu of an increasingly multicultural society and the rapid pace of technologic advancement. Furthermore, there are significant overlaps between the distinct disciplines of law and medical ethics, such that evolving standards of one affects the other.[1] Thus a new statute or court ruling sets a standard of conduct that often compels adjustment in the rules of ethical conduct. Conversely, the pronouncement of new ethical guidelines by professional medical organizations frequently influences the work of legislatures and the courts. Ethics tells us what we ought to do but the law stipulates what we must do. Together, law and ethics define the rules of conduct within which medicine is practiced, but like medicine itself, both are dynamic disciplines that undergo constant adjustment.

Beauchamp and Childress have articulated certain *prima facie* principles that define the most fundamental foundations of medical ethics.[2] The tetrad of principles includes beneficence, nonmaleficence, autonomy, and justice. The first two of these principles, beneficence and nonmaleficence, are derived from the Hippocratic obligations to "act in the best interests of the patient" and to "do no harm." The other two principles, based on relatively recent concepts, are (1) autonomy, which respects the right of competent persons to give informed consent for medical treatment and to have control over their bodies and (2) justice, which involves the fair and equitable distribution of the benefits (and risks) of medical care to all persons.

Although principle-based and duty-based ethics tend to be given the most attention, some ethicists make a strong case for virtue-based ethics and contend that virtue is derivable from the nature of medicine as a human activity and is an irreducible element in medical ethics.[3] Ethical principles, per se, focus on the action or actions that give rise to dilemmas, such as withdrawing life-sustaining treatment from a terminally ill patient. In contrast, virtue ethics emphasizes the agents (physicians) and the recipients (patients) of principle-based actions and decisions. Pellegrino and Thomasma cite the relevance of virtues such as trust, compassion, prudence, justice, courage, phronesis or common sense, fortitude, integrity, honesty, and self-effacement in confronting practical problems such as care of the poor, research with human subjects, and the conduct of the healing relationship.[3] In practice, physicians' ethical behavior is shaped as much by the core ethical principles as by the special bond that sickness and the response to it creates between healer and patient. In addition, pediatric surgeons are challenged by issues that are distinctive to the profession of surgery and other factors that are unique to the care of infants and children.

In this chapter we review some of the basic ethical concepts and responsibilities pertinent to pediatric surgery and explore thorny issues related to the extremes of prenatal care and the end of life. We address common surgical and ethical dilemmas in operative management, such as in adolescent bariatric surgery. We also highlight new areas of ethical concerns such as surgical error, and aspects of professionalism in the relationships between physicians and industry. Finally, we discuss the ethical imperatives of multiculturalism and why the prevailing ethical landscape should not deter much needed research and innovation in pediatric surgery.

## Resolution of Ethical Dilemmas

The essence of pediatric surgery was underscored by Potts in his classic monograph *The Surgeon and the Child*, in which he noted that "the satisfaction of correcting a deformity in a newborn infant lies in the fact that all his life lies before him. Parents hope for miracles, but are grateful for the best that can be given by a mere human being."[4]

This profound statement is applicable, whether the pediatric surgeon is repairing a major congenital anomaly, treating a devastating traumatic injury, or resecting a malignancy. However, in the course of providing the best possible care to children and their families, the pediatric surgeon will occasionally encounter ethical and moral issues.

A classic moral dilemma arises when two or more conflicting ethical principles support mutually inconsistent actions. A common situation is when there is a conflict between the

principles of autonomy and beneficence—when parents desire a course of treatment for their child that does not align with the opinion of the pediatric surgeon. The pediatric surgeon may also encounter moral dilemmas in the form of moral uncertainty and moral distress when the prognosis is unclear for a given condition, when two or more equally valid treatment options are available, or when parents disagree with each other, or the surgical recommendations, or both. Therefore the need often arises to resolve the moral basis by which decisions should be made, who should make those decisions, and how decisions should be implemented.

Little[5] has identified five pillars that mark the moral domain of the surgeon-patient relationship: rescue, proximity, ordeal, aftermath, and presence. These factors may be present in other therapeutic relationships as well, but they have a special intensity in surgery. The term *rescue* acknowledges the elements of surrender and dependency that patients and their families experience when they have little control over the proposed surgical remedy. This situation can be mitigated if the pediatric surgeon confronts and negotiates the patient's (and family's) surrender and dependency within the context of the surgeon's power. *Proximity* refers to surgeons' acknowledgment of the close, intimate interactions they have with their patient, who must forgo their autonomy, acknowledge dependency, face risk, and yet place trust in the surgeon. *Presence* is both a virtue and a duty for surgeons, to be a visible and engaged presence throughout the entire surgical experience. In pediatric surgery, this professional obligation extends to the long-term follow-up of patients, often into young adulthood.

The foregoing ethical and moral principles and virtues are brought to bear in the ordinary course of a pediatric surgeon's daily work, in which ethical dilemmas are frequently encountered. Resolution of ethical problems in a given pediatric surgical patient requires a patient-centered approach that uses all members of the health care team working together in a manner that promotes respect for all parties and all views.

As we and others have noted, successful outcomes require that the team (1) develop common moral language for the discussion of moral issues, (2) have training in how to articulate their views about issues, (3) have common experiences on which to base recommendations, and (4) agree on a moral decision-making method for all to use in the course of their deliberations.

Bayliss and Caniano previously outlined the following set of guidelines to provide a framework for the effective resolution of difficult moral problems[6]:

1. Identify the decision makers. For most cases in pediatric surgery, the decision makers will be the parents, unless the patient is a mature minor.
2. Ascertain "value data" from the parents and other relevant family members. These may include their views on the sanctity of life, spirituality and religious beliefs, cultural norms, and community values.
3. Collect all relevant medical information, including the prognosis. Clarify the areas of uncertainty and identify whether additional diagnostic testing would be of value in the decision making process.
4. Define all treatment options, including their benefits, risks, and chances of achieving the desired outcomes.
5. Provide the parents with a professional recommendation for the best treatment option.
6. Seek a consensus resolution that can be accepted by all participants.

In order for the above paradigm to be successful, the health care team must accept that rational people of good will may hold divergent views that are irreconcilable, even after extended discussions. The goal of reaching a consensus decision should be viewed as a successful outcome for all participants.

# Informed Consent and Assent

The doctrine of informed consent is based primarily on the ethical principle of respect for individual autonomy, but also on beneficence and justice. These three pillars, established in the Belmont Report[7] to guide human subjects' research, have become the basis for ethical and legal requirements for informed consent for research as well as clinical care. Respect for patients' *autonomy* recognizes the right of each person to make their own decisions. The principle of *beneficence* requires physicians to propose only those interventions intended to promote the well being of the patient, and *justice* requires that the patient be treated in the same manner as any other individual under similar circumstances.

In pediatric surgery, fulfillment of a child's autonomy typically requires surrogate decision makers (in most cases, the parents) to speak, understand, and consent on behalf of infants, children, and adolescents. In some cases, court-appointed guardians or other spokespersons may fulfill this role, depending on applicable laws. In some jurisdictions, and in certain specific circumstances, adolescent patients may be granted authority to make their own decisions about the health care they receive. This situation is particularly applicable to adolescents with chronic illnesses, such as sickle cell disease, cystic fibrosis, and advanced malignancies. However, when an adolescent's consent to or refusal of surgery is in direct opposition to parental wishes, the assistance of social services and legal counsel may be required.

Recognition of children as "persons" with inherent rights underscores the necessity for their participation in the decision-making process.[8] Therefore, the traditional emphasis on the child's "best interests" may be insufficient to address the child's "rights," and although the *informed permission* given by parents may be sufficient for ethical purposes and is required for legal purposes, it does not satisfy the strict moral standards of the doctrine of informed consent. Therefore, a specific role has been advocated for children in their own decision making, particularly for older children and adolescents. This concept of pediatric *assent* was articulated by William Bartholome when he wrote, in 1982, that "assent of the child is indeed an idea before its time. It is a fragile idea that can easily be crushed amidst the boulders of consent, autonomy, rights, and competence. It's an idea that is so foreign to adult reality that its central thrust is missed even by astute minds."[9]

Several decision-making models have been proposed as a template for pediatric assent, but they differ primarily on the relative roles assigned to the child and the parents and whether they should be guided by the principle of autonomy or follow a best-interests design.[10] Nevertheless there is broad agreement that, depending on the circumstances, the *assent* of the pediatric patient should be sought as appropriate to their development, age, and understanding in conjunction with informed permission from the parent or legal guardian. Every state has enacted minor consent statutes that seek to

determine instances in which children can give their informed consent, as highlighted in a policy statement by the American Academy of Pediatrics (Table 15-1).[11] However, in most instances parent/guardian consent is required by law. Pediatric surgeons have an ethical duty to familiarize themselves with their own institutional guidelines and appropriate local statutes.

For surgical procedures, the essential components of the informed consent process include (1) a surgeon who provides adequate information to facilitate decision making and (2) a competent patient or legal proxy who indicates full understanding of the intervention, including the indications, risks, and possible alternatives, and who voluntarily consents to the proposed intervention.[12,13]

In the unique triadic relationship between the pediatric surgeon, parent, and child, surgeons bring the values and ethical principles of their profession, which give priority to the interests and well-being of their patients and families. In their landmark book, *Surgical Ethics*, McCullough and colleagues[14] present patients' rights related to the surgical encounter, each of which implies a key professional value. They remind us that "(patients have the right) . . . not to be killed intentionally or negligently by the surgeon, not to be harmed by intent or negligence of the surgeon . . . not to be deceived by the surgeon . . . to be adequately informed about the risks and benefits of surgery, to be treated by a knowledgeable, competent practitioner, to have his or her health and well-being more highly valued than the surgeon's own economic interest, and to decide whether to accept treatment under the conditions described."[14]

## Prenatal Surgical Consultation

Routine prenatal screening with ultrasonography and biochemical markers now permit detection of major fetal anomalies that may require operative intervention shortly after birth, or rarely, in utero. When a significant fetal malformation is detected by screening, consultation with the pediatric surgeon or other specialists is usually offered to prospective parents. Ethical issues that may arise during the course of a prenatal consultation include (1) the possibility of prenatal intervention or termination of pregnancy; (2) the timing, location, and mode of delivery; and (3) potential postnatal surgical intervention.[15]

The prenatal surgical consultation should be guided by the same ethical principles of autonomy (self-determination), beneficence, and justice, and in addition respect for the woman's choice and her reproductive freedom. The proper role of the pediatric surgeon is not only to give information but also to provide a supportive, caring environment for informed decision making. In theory, a value-neutral norm that promotes objectivity and client autonomy may be considered ideal, but such an approach usually proves insufficient as the moral basis for prenatal surgical consultation. Value neutrality and moral detachment on the part of the surgeon creates an obstacle to forming a professional relationship with prospective parents who are seeking compassion, honesty, and integrity, virtues cited by Pellegrino and Thomasma as being essential components of the physician-patient relationship.[3]

Very few prospective parents consider termination of pregnancy when they present for a prenatal surgical consultation.

**TABLE 15-1**

**Types of Minor Consent Statutes or Rules of Common Law That Allow for the Medical Treatment of a Minor Patient Without Parental Consent***

| *Legal Exceptions to Informed Consent Requirement* | *Medical Care Setting* |
|---|---|
| The "emergency" exception | Minor seeks emergency medical care |
| The "emancipated minor" exception | Minor is self-reliant or independent:<br>• Married<br>• In military service<br>• Emancipated by court ruling<br>• Financially independent and living apart from parents<br>In some states, college students, runaways, pregnant minors, or minor mothers also may be included |
| The "mature minor" exception | Minor is capable of providing informed consent to the proposed medical or surgical treatment—generally a minor 14 yr or older who is sufficiently mature and possesses the intelligence to understand and appreciate the benefits, risks, and alternatives of the proposed treatment and who is able to make a voluntary and rational choice (*in determining whether the mature minor exception applies, the physician must consider the nature and degree of risk of the proposed treatment and whether the proposed treatment is for the minor's benefit, is necessary or elective, and is complex)* |
| Exceptions based on specific medical condition | Minor seeks:<br>• Mental health services<br>• Pregnancy and contraceptive services<br>• Testing or treatment for human immunodeficiency virus infection or acquired immunodeficiency syndrome<br>• Sexually transmitted or communicable disease testing and treatment<br>• Drug or alcohol dependency counseling and treatment<br>• Care for crime-related injury |

From Committee on Pediatric Emergency Medicine: Consent for emergency medical services for children and adolescents. Pediatrics, 2003. 111: p. 703-706.
*These laws vary by state and the surgeon should refer to the applicable jurisdiction.

In fact, most are seeking the pediatric surgeon's knowledge and reassurance that their unborn fetus can be treated with a good outcome. These prospective parents typically provide the surgeon with their most current fetal ultrasonogram and other diagnostic tests, its gender, and its first and middle names. The stage is therefore set for the pediatric surgeon to forge an ongoing professional relationship that is centered on the care of the future infant and that both parties share in making ethically responsible and medically sound decisions for the fetus.

We suggest the following as guidelines for pediatric surgeons during a prenatal surgical consultation:

1. Empathize with the inevitable grief and sorrow that the prospective parents feel on the recent unexpected and frightening diagnosis of a fetal malformation.
2. Candidly disclose the benefits, harms, and alternatives for the given fetal condition and offer recommendations that balance maternal and fetal interests.
3. Foster an atmosphere that facilitates the exchange of medical information and help the prospective parents make decisions that are consistent with their own beliefs, goals, and values.
4. Promote responsible efforts to improve access to the full range of prenatal services available at high-risk perinatal centers for women from all socioeconomic, ethnic, and cultural groups.

On occasion, ethical conflict may arise if the pregnant woman, in the exercise of her reproductive freedom, chooses a course of action that is inconsistent with conventional pediatric surgical recommendations. For example, a decision on the part of the woman to terminate the pregnancy because of a nonlethal anomaly, such as gastroschisis, could provoke emotional, moral, and professional conflict with the pediatric surgeon. Sadly, termination rates for gastroschisis remain high, particularly in Europe, where 29% of prospective parents in the EUROSCAN study[16] and as much as 44% in another study[17] elected termination for a condition with such a favorable prognosis. Prenatal counseling, when successful, should allay parental anxiety and reduce the rate of unnecessary terminations. Fortunately, other European studies have reported termination rates for gastroschisis of 5% or less.[18,19]

When, despite the objective medical fact of the low lethality of the fetal malformation, the woman insists on termination or other action detrimental to the fetus, it is not clear whether the pediatric surgeon can interfere with her choice. Under usual circumstances, a pediatric surgeon might invoke the power of the state when they believe that a pediatric patient's best interests are not being protected by the parents. However, there is no similar authority to intervene on behalf of the fetus. There has also been some concern that in situations in which maternal and fetal interests diverge, the obstetrician and the pediatric surgeon might be drawn into an ethical conflict as they seek the best interests of the mother and fetus, respectively.[20]

## End of Life

Advances in technology and development of new diagnostic and therapeutic interventions have created new life-sustaining treatments that can prolong a patient's life. These "high tech" measures (e.g., renal dialysis, ventilators, and organ transplantation) as well as new applications of existing therapies (e.g., antibiotics, fluids and nutrition delivered by enteral tubes or intravenous means) and chemotherapy increase the potential to extend life after critical illness. Depending on the therapeutic goal, surgical treatment could correct a surgical anomaly, provide palliation of symptoms, or merely improve selected physiologic parameters. In many cases, attainment of the defined therapeutic goal can allow an infant to develop normally or a child to pursue a meaningful life. However, in some cases the price of success is a relatively poor quality of life and a burden of care that could overwhelm some families. The question therefore is no longer whether pediatric surgeons *can* save the life of an infant with severe malformation or other neonatal disease but whether they *should* save it.[20]

Determination of what constitutes an optimal quality of life and the threshold below which life-saving measures should not be undertaken is a difficult moral, ethical, spiritual, and legal problem. Decisions to withhold life-sustaining treatment are generally made in advance and agreed on by the parents and physicians. However, there are limits to parental authority to make end of life decisions for their children as illustrated in the United States by the Baby Doe case.[21] Baby Doe was born in Bloomington, Indiana in 1982 with Down syndrome and esophageal atresia. The infant died after 6 days when the obstetrician recommended, and the parents agreed, to no surgical intervention. The Surgeon General at the time, C. Everett Koop, himself a pediatric surgeon, publicly expressed disagreement with this decision, which he believed was made on the basis of the infant's mental retardation rather than on the prospect for success after surgery. Several months later, Dr. Koop was again drawn into opposition when the parents of a second infant, "Baby Jane Doe" born with spina bifida cystica, decided not to have operative treatment. This time, a "right-to-life" lawyer and subsequently the federal government brought a court action, but the court ruled that the parents refusal was "a reasonable one, based on due consideration of the medical options available, and on genuine concern for the best interests of the child."[22]

Although several courts upheld the parental decisions in these and subsequent cases, public outcry led to federal intervention. Congress passed the Baby Doe law that specified criteria under which withholding of life-saving treatment can be permissible as follows:

- Child is irreversibly comatose
- Treatment is "virtually futile" in terms of survival
- Treatment would only prolong dying

Although the Baby Doe rules were designed to protect the child's right to life-saving treatment, regardless of the parents' wishes, the intent was not to mandate unnecessary or inappropriate treatments. To the contrary, the Baby Doe law positively directs physicians to make treatment recommendations to parents based on "reasonable medical judgment." Unfortunately, the law has been widely misinterpreted and misunderstood among physicians. In a 1988 survey, one third of pediatricians stated that maximal life-prolonging treatment was not in the best interests of the infants, but because of the Baby Doe law they would provide such treatment.[23] Some critics of the law also complained about federal imposition of medical decisions that would lead to proliferation of severely handicapped children without assurance of the resources needed to care for them.[22]

In both infants and older children, medical advances have created ethical dilemmas in the initiation or withdrawal of medical care for conditions with poor prognosis, particularly in situations in which treatment may prolong survival with an unacceptable quality of life. Although many individuals believe it is "worse" to discontinue life-sustaining treatment than to never institute such treatment, ethicists, moral philosophers, and legal scholars find no ethical or legal distinction between not starting treatment and stopping treatment.

A common situation in the neonatal intensive care unit is when a premature infant with several comorbid factors, such as chronic lung disease and intraventricular hemorrhage, requires surgical exploration for necrotizing enterocolitis or midgut volvulus. Issues that may arise include the appropriateness of extensive small bowel resection and whether care should be withdrawn in the face of poor prognosis. If bowel resection leads to short-bowel syndrome, will the infant be a candidate for intestinal or liver transplantation, or both? This situation typifies an all too frequent ethical dilemma faced by pediatric surgeons. When making decisions to prolong life or to discontinue life-sustaining treatment for an infant with critical illness, the *best interests standard* is generally used to focus on issues that are patient centered and to assess the benefits and burdens of continued treatment for a *particular infant*. In this case the infant's best interests standard would include consideration of the following:

- Severity of the medical condition
- Availability of curative or corrective treatment
- Achievability of medical goals
- Presence of serious neurologic impairments
- All associated medical conditions
- Life expectancy
- Extent of suffering
- Proportionality of treatment benefits to burdens in both the short term and long term

In making these difficult decisions, the medical team must work cooperatively with the parents. and their wishes should be given due consideration. There is an emerging consensus that great discretion should be given to parents in making decisions on nonintervention or withdrawal of life-saving treatment.[24] The guidelines issued in 2007 by The American Academy of Pediatrics encourage a family-centered, patient-oriented approach.[25] When there is disagreement, continued engagement between physicians and parents will often lead to an agreement. Conflict resolution may require transfer of care to another physician or consultation with the institution's ethics committee.

With life-threatening illnesses, such as terminal cancer, in older children and adolescents, parental protective instincts may come into conflict with the child's autonomy to participate in end-of-life decisions. However, older children who are capable of giving assent in ordinary situations are equally competent to do so when forced to confront their mortality. In fact terminal illness may impact the developmental understanding of pediatric patients by accelerating their grasp of serious illness and by promoting their wishes to control decisions about their health care. The stresses of their illness may "make them grow up faster" and make them wiser than their same-age peer group. For example, a 12-year-old child with terminal cancer may ask to discontinue chemotherapy or other unpleasant treatments and request to have "one final special vacation."

Because children cannot give morally or legally valid consent to or refusal of treatment, practice among physicians in the past was to shelter dying children from the truth of their dire circumstances. Current practice, favored by The American Academy of Pediatrics, acknowledges that these patients usually have a much more mature understanding of their situation than previously realized by their physicians and parents and that they should be told the truth about their prognosis and included in discussions about their care.[26,27] These discussions should include the extent of desired life-sustaining treatments, whether a do-not-resuscitate (DNR) or an allow natural death (AND) status is to be invoked, the role of palliative procedures in granting a better quality of life, and their desire for hospice services.

## Ethical Issues in Pediatric Bariatric Surgery

Bariatric operations in the pediatric population are increasingly used as an effective means of achieving weight loss and thereby relieving comorbidities such as type 2 diabetes, cardiovascular dysfunction, hypertension, obstructive sleep apnea, and dyslipidemias. These and other unsuspected comorbidities are present in nearly one third of all patients treated at the Center for Healthy Weight and Nutrition at Nationwide Children's Hospital. Morbidly obese children are likely to remain so in adulthood and carry with them the increased risks of premature morbidity and mortality. From a public health perspective, there is a rising childhood obesity epidemic that could dramatically increase the cost of medical care and cause a decline in life expectancy, thereby eroding the gains in longevity achieved during the 20th century in developed countries.

A multidisciplinary approach is currently used in the treatment for morbid obesity. The range of success with these approaches varies, and research is needed to better assess them, particularly in the pediatric population. Medical therapy that includes a comprehensive program of exercise and diet has not been successful in adults over the long term. Few children's hospitals have developed comprehensive medical obesity programs. Thus there is scant evidence in the pediatric literature about the outcomes of such programs. For adults with morbid obesity, surgical therapy is quite popular because it has been successful in achieving weight reduction with acceptable morbidity and mortality rates. Based on the good results in the adult population, it is not surprising that pediatric surgeons are being asked by the public—in particular, eager patients and their parents—to provide bariatric surgery for children and adolescents with morbid obesity.

Roux-en-Y gastric bypass and gastric banding, both performed laparoscopically, are the two bariatric operations performed most frequently in North America and Europe. Although both achieve weight loss, gastric banding does not alter the anatomy and is reversible; gastric bypass alters the anatomy in an essentially irreversible manner. Gastric bypass is very effective in achieving weight loss not only because it reduces the size of the stomach but also because it causes malabsorption. Long-term studies in adults indicate that gastric banding is somewhat less effective in achieving major

weight loss but is successful in reducing the comorbid conditions of hypertension and diabetes.

As noted by Caniano,[28] both principle-based ethics (autonomy, beneficence, nonmaleficence, and justice) and virtue-based ethical considerations (trustworthiness, compassion, phronesis, fortitude, integrity, and self-effacement) must be included in order to fully capture the moral complexity of pediatric bariatric surgery. Also, because bariatric surgery remains an innovative treatment, insofar as its long-term consequences for pediatric patients remain unknown, there are additional ethical obligations for evaluation of outcomes and for clinical research. All of these factors must be considered when (1) a pediatric surgeon recommends a bariatric operation to an individual patient, (2) the pediatric patient and her or his family decide to have bariatric surgery, (3) hospitals establish pediatric bariatric programs, and (4) the major professional surgical organizations endorse the performance of pediatric bariatric interventions. The following discussion examines how various ethical principles apply specifically to bariatric surgery.

True *autonomy* for the morbidly obese adolescent considering bariatric surgery is reflected by adequate informed consent. More than most other cases, the balance between parental permission and the child's assent weighs heavily toward the latter. Unfortunately, true autonomy under these settings is under severe pressure from the flurry of information available in the media, lay publications, and the Internet, which often highlight former morbidly obese individuals who became svelte after their intervention. The desire to have a body that is socially acceptable and free of comorbidities may interfere with a deep understanding of the operative risks and the irreversible nature of some of the proposed procedures. The burden of providing informed consent to the adolescent patient and his or her family rests on the surgical team, which should include at the least medical specialists, psychologists, and pediatric surgeons. Interested readers are referred to the guidelines proposed by Raper and Sarwer on the elements of informed consent that constitute the minimum amount of information to be discussed with prospective adolescent patients interested in bariatric treatment and their families.[29]

*Beneficence* obliges physicians to seek to reverse the physical and psychological derangements that interfere with well-being in morbidly obese children. If nonsurgical interventions—such as calorie-restriction diets, exercise programs, and behavioral therapy—were effective in achieving substantial weight loss with reversal of comorbidities, beneficence would favor these approaches. However, adolescent patients whose body mass index (BMI) exceeds 40 $kg/m^2$ have only a 3% reduction in BMI after 1 year of intensive medical weight management, a result that is insufficient to reverse comorbidities.[30] However, given the risks associated with bariatric surgery, beneficence warrants that prospective patients undergo thorough assessment of their metabolic and psychological parameters, receive a "reasonable" trial of medical/behavioral weight loss treatment, and continue such treatment if it proves effective. For most patients who are unsuccessful with this approach, bariatric surgery upholds the principle of beneficence in enhancing health and well-being.

The well-known risks of harm during and after bariatric procedures impose an obligation of *nonmaleficence* in recommending treatment choices. Although reported rates of serious short-term risks of bariatric surgery are low, adolescent patients who are eager to lose weight may not appreciate the potential impact of such complications in terms of lengthy hospitalization, reoperative surgery, and other unanticipated problems. Furthermore, assessment of possible harm must include consideration of complications that may develop several years later. Wilde, in a 2004 law review article, observes that physicians trust that morbidly obese adult patients can put all the known risks and complications into perspective before agreeing to a bariatric operation, but it is not clear that pediatric patients and their families have that same perspective given the uncertainty of outcomes decades after the operation.[29a]

The principle of *justice* (also a virtue) requires that each person share equitably in the benefits and risks of health care. Studies have found significant disparities in access to adult bariatric surgery for African Americans, Hispanics, low-income individuals, and males.[30] Similarly, justice is threatened when disparities occur in the manner in which pediatric hospitals and their bariatric programs provide access to and participation in surgical treatments. The mission and values of pediatric hospitals generally include the provision of health care for all patients, regardless of their socioeconomic status. Pediatric obesity in the United States affects one in three socially disadvantaged children, with particularly high rates among African American girls and Hispanic and Native American children of both genders.[31] Children from socially and economically challenged families fare poorly on most childhood health indicators and may not have ready access to medical weight management and bariatric services. The "conscience" of the pediatric hospital system, within the context of its local and regional community, will be the driving force behind distributive justice relative to many children and adolescents with morbid obesity. Organized efforts to support costly multidisciplinary weight management and behavioral therapy programs, as well as bariatric programs, require professional leadership that advocates for equitable access for all children. Any pediatric bariatric program that excludes patients based on lack of insurance or financial resources would violate the principle as well as the virtue of justice.

## Surgeons and Industry

There are many benefits to patients and the general public when physicians work together with pharmaceutical, medical device, and biotechnology companies. Much of the development in new tests, drugs, and devices that have vastly improved the quality of medical care have been the direct outcome of industry support for medical education, research, and innovation. In fact, industry funds about 50% of the costs of continuing medical education (CME) programs and 60% of clinical research in the United States.[32,33] However, renewed focus on professionalism in medical education and practice has raised the concern that these relationships may create conflicts of interest (COI), potentially resulting in undue influence on professional judgments. Industry practices that cross the line between patient welfare and profit seeking can induce physicians to perform unnecessary tests and treatments that may be harmful to patients and contribute to rising health care costs.[34] Increasing scrutiny by the public, patient advocacy groups, and Congress has therefore led most

medical institutions and professional organizations to adopt stricter COI policies.

From an ethical standpoint, COIs are not inherently immoral or even unethical. However, COIs increase the potential for unethical physician behavior. There are three characteristics of a COI:[35]

1. A fiduciary relationship exists in which a physician acts in a fiduciary role in which they act primarily in the patient's best interest.
2. The fiduciary agent (physician) has self-interests that can be influenced and potentially override the agent's primary concern and obligation to the patient's interest.
3. A relationship with another entity (industry) exists that has the capacity to influence the physician to shift primacy of concern from the recipient of the fiduciary relationship (patient) to one that is motivated by direct or indirect self-interest.

It becomes readily apparent that COIs can exert a corrosive effect on several moral and ethical principles, particularly those of fidelity, beneficence, and nonmaleficence. Of these, fidelity is the most directly applicable to COI. The principle of fidelity establishes the physician's responsibility to carry out duties carefully and completely and in doing so demonstrate loyalty to, and in turn receive the trust of, the patient.[3] COIs erode the trust of the patient and compromise the physician's fiduciary role.

The ethical response to COI may take one or a combination of two forms: disclosure and avoidance. Disclosure of COI tends to dominate policies adopted by many institutions and professional bodies, in keeping with Brandeis' famous maxim that "sunshine is the best disinfectant."[36] However, there are distinct limitations to the power of disclosure alone as an effective antidote to COI. One possible reason is that full disclosure may not be attainable because the primary source of funding can be obfuscated through a labyrinthine maze that could involve front organizations or even accredited medical education companies.[37] Even a full disclosure, while raising the suspicion of bias, is too ambiguous to help the recipient of information from financially conflicted individuals to determine whether bias is present.[38] In fact, disclosure may allow some physicians to maintain or even strengthen their conflicts and has no inbuilt mechanism to actually eliminate bias. Therefore some have proposed that the only true way to eliminate industry bias in physician behavior is to avoid it whenever possible. Physicians, they argue, should avoid situations that unnecessarily introduce COI. However, avoidance is not always practical and may be impossible if physicians and investigators are going to pursue industry-funded research that has the potential to benefit patients.[38] This has produced somewhat of a backlash among those who complain that the new COI rules are too stringent and that the pendulum has swung far in the direction of stifling innovation and jeopardizing patient care.[39]

The 2009 report "Conflict of Interest in Medical Research, Education, and Practice" issued by the Institute of Medicine (IOM) has brought renewed urgency to this issue.[40] The IOM stresses the importance of preventing bias and mistrust rather than trying to remedy damage after it is discovered, and it encourages the enactment of policies and laws that identify, limit, and manage COI without negatively affecting constructive collaborations between the medical profession and industry.

## Multiculturalism

With the increasing diversity of modern society, pediatric surgeons are faced with the difficult task of providing care to children from culturally heterogeneous backgrounds. Many pediatric surgeons, like other physicians, may consider themselves culturally competent and perhaps take pride in their personal commitment to providing equitable care to all patients. However, an ever-increasing body of evidence continues to highlight disparities in several areas of health care delivered to ethnic minority populations.[41] A contributing factor to this problem might be a failure among physicians to appreciate and actively counter cultural bias in their own relationships with their patients.

*Culture* is a term that may have different meanings, but in this context we define culture as the common and accepted way of thinking, feeling, and acting for a group of people. This includes a set of shared beliefs, values, attitudes, patterns of meanings, and behaviors that characterize a group of people. However, we must not restrict the definition of a "group of people" to political borders, religious practices, or physical characteristics. Focusing on such distinctions risks objectifying those whose appearance, language, or national origin is different from the majority into overly simplistic categorical stereotypes.[42]

It may be tempting for physicians, who are socialized by traditional values inherent in Western medical training, to view with suspicion attitudes from other cultures that challenge deeply held normative values. Western attitudes to health are based on a set of assumptions and values about disease and well-being that are not necessarily shared by other cultures. For example, Western medicine views health in biologic terms, with disease being the consequence of disruption of anatomic form or malfunctioning in biologic processes. In contrast, some cultures may ascribe spiritual, superstitious, or metaphysical causes to various illnesses and may have less trust in Western medicine as they pursue an assorted variety of alternative medicine or natural cures. In meeting parents and children whose culture is different, the pediatric surgeon should inquire about their beliefs, goals of treatment, and concerns.[43]

Individuals from minority cultures differ in the extent to which they assimilate the values of the larger society. Some parents will be informed by Western values on some issues, whereas maintaining their own cultural beliefs in others, and individuals from a similar cultural background or even within the same families may disagree on specific issues. Therefore the pediatric surgeon must resist the tendency to assign stereotypes of beliefs or behavior to individuals based on their identification with a cultural group. For example, some immigrant Chinese-American patients and families base their disease management decisions on their concerns for family well-being, family face, and the reciprocal responsibilities required by varied family roles,[44] but not all Chinese-American patients will be motivated by such values.

Along with cultural diversity, language barriers are increasingly encountered in our health system and may contribute to disparities for patients with limited English proficiency (LEP).[45] U.S. Census data shows that, other than English, more than 100 other languages are spoken by 47 million

people in the United States, and the proportion of those with limited English proficiency nearly doubled from 4.8% in 1980 to 8.1% in 2000.[46] Fortunately, health disparities due to language barriers can be reduced or eliminated entirely when physicians use the services of trained interpreters.[47,48] Whenever possible, however, pediatric surgeons should avoid using family members or older siblings of the patient for translation to ensure accuracy of transmitted information both to and from the parents and child patient, to avoid translation bias, and to help in reading nonverbal and verbal cues about underlying concerns. A recent study identified specific risks of working with family interpreters, such as imposing their own agenda (rather than the patient's agenda) and controlling the consultation process.[49]

How then does a pediatric surgeon deal with cultural practices that are different from the norm, particularly when they affect parental acceptance of and compliance with recommended treatments? First we must consider that our patients (including children and their parents) experience illness as represented by their personal, interpersonal, and cultural reactions to the disease. Therefore the key is to understand *how* and *why* parents of a particular culture react in a certain way and hold certain attitudes when faced with illness in their children. We previously outlined the following strategies to reduce cross-cultural conflicts: asking questions about the parents' values and listening to their responses, indicating to the parents that their views are important, allowing enough time to deal with the parents whose culture is different, and seeking assistance from "experts" who understand the parents' cultural beliefs when significant differences arise in the course of treatment.[43]

## Surgical Error

The 1999 Institute of Medicine (IOM) report "To Err Is Human"[50] focused the spotlight on the high incidence of medical errors and alerted the health care community and general public in the United States on the significant impact medical errors have on patient outcomes. The IOM report estimated that as many as 98,000 patients die each year as a result of medical error. The report also noted that many more patients undergo serious harm from a medical error that prolongs their hospitalization, causes unnecessary suffering, and increases the cost of care. Common examples of errors encountered during surgical treatment include wrong diagnosis, wrong patient (or site) procedures, and retained foreign bodies.

The process of medical decision making may be considered in four phases (1) data gathering, (2) integration or processing of data, (3) confirmation of diagnosis, and (4) treatment.[51] Medical errors are often due to deficiencies in medical judgment rather than knowledge, but other contributing factors include inadequate experience, carelessness, and fatigue. The core problem is often a defect in medical decision making, whether in formulating a diagnosis, choosing an appropriate surgical technique, or in the initial response to an adverse outcome. An analysis of the process of data integration among physicians identified four common sources of error: (1) wrong synthesis (lack of knowledge leading to an incorrect conclusion), (2) premature closure (incomplete consideration of all disease processes), (3) inadequate synthesis (data do not support conclusions), and (4) omission (important diagnostic information was not obtained).[52]

Considerable effort has been directed at establishing patient safety practices that minimize the incidence of errors. In contrast, there has been relatively less attention to how to respond after an error has occurred. Historically in the United States, fear of malpractice litigation has fostered a "code of silence" among physicians that is detrimental to efforts to improve patient safety, breeds mistrust, and fractures the therapeutic relationship between physicians and their patients. However, concern regarding legal liability should not affect the pediatric surgeon's honesty with parents. There is also a "human dimension" to the problem, as the silence, shame, anger, and guilt exacts an emotional toll on everyone involved, including physicians.[53] Research indicates that patients want full disclosure, a sincerely framed apology, and clear admission of responsibility.[54] Most parents desire an explicit acknowledgment that an error had occurred, what the error was, how the error occurred, how the error will affect their child, and what efforts are being made to prevent occurrence of similar errors in the future. Studies indicate that patients were more likely to trust physicians who participated actively in disclosing a serious error. In addition, fears that disclosure of an error will increase the likelihood of a malpractice claim have not been substantiated.[55]

In the United States, most medical institutions, professional organizations, and regulatory agencies consider full disclosure of a surgical error to be an ethical imperative. When a surgical error has occurred, the pediatric surgeon should proceed to inform the patient and parents in clear language about the nature of the error, the anticipated consequences, and how the error will be managed in the patient. This conversation requires that the pediatric surgeon explain how the error occurred, offering an empathetic apology about the commission of the error. The offering of an apology with disclosure of the error is a key step in the process. The apology must acknowledge the error and its consequences; the pediatric surgeon must assume responsibility and communicate regret, shame, or humility for having caused harm and in some cases offer reparation.[56] Most parents want to know that specific action will be taken to prevent the same error from harming another child. In some situations, an offer of compensation or early settlement offers by hospitals can dramatically reduce malpractice claims. In countries with no-fault compensation systems, malpractice claims are much less common. There is a movement in the United States to encourage physicians to offer an apology to patients and families when medical error occurs. More than 30 states in the United States and several Canadian provinces have passed "apology laws" to enhance medical error reporting and medical safety. Such laws make it possible for physicians to be able to use the dreaded phrase "I am sorry," without the statement being construed as an admission of liability.

Now, more than a decade after "To Err is Human," the subject of medical errors has gained wide currency in our society. Language such as adverse events, root cause analysis, disclosure, and risk management are commonly used in the lay press. Medical schools and residency training programs are rapidly adopting simulation modules, virtual patients, and other novel educational strategies to minimize the risk of harm to patients, while meeting needs of educating the next

generation of physicians.[53] The opportunity seems ripe for competency-based medical education, initiated by the Accreditation Council for Graduate Medical Education (ACGME), to firmly embrace patient safety. In fact a proposal has been made that the identification of medical error recognition and disclosure be recognized as a *seventh* core competency to be adopted in our medical education.[57]

## Innovation and Research

Innovation involves the introduction of a new method, idea, treatment, medication, or device to benefit the individual patient.[58] A surgical innovator is motivated by the belief that the new technique or therapy, or modification of an existing procedure, will improve the care of an individual patient. Such innovations often proceed without prior study and occur in real time. Sometimes the surgeon employs the innovative procedure in a small series of patients, using an iterative process to perfect the technique one patient at a time. In contrast, clinical research involves formal testing of different approaches to treatment with the aim to discover new knowledge that will benefit humankind, although there may be no benefit to individual study subjects. Therefore the results of formal research are generalizable, but the results of innovation initially apply to only a single patient.[59] Despite these distinctions, innovation and research are intertwined, and one cannot proceed effectively without the other.[60]

In pediatric surgery, much advancement has been brought about by research and development of innovative surgical techniques. Pediatric surgeons have been among the most notable surgical innovators, and many of the procedures beneficial to children today, including appendectomy and pyloromyotomy, may never have passed the rigor of randomized trials. Even with the advent of randomized trials, many innovative procedures have been widely adopted without evidence to support their advantage over standard techniques. For example, minimally invasive surgery has become the preferred approach for treating many childhood conditions, although rigorous evaluation of its role has rarely been undertaken.[61] Yet too little regulation creates the potential for abuse and can be harmful and dangerous. For example, some innovative procedures that were intuitively appealing when first proposed such as sympathectomy for Hirschsprung disease and jejunoileal bypass for morbid obesity were subsequently abandoned and may never have been widely used in the first place if a stricter regulatory regimen were in place. Also, some operations have failed to withstand the process of rigorous research evaluation. Recent experience with fetal surgical treatment of congenital diaphragmatic hernia provides a case in point. Thus far all randomized trials comparing prenatal intervention to standard postnatal therapy for congenital diaphragmatic hernia have shown no benefit to prenatal intervention.[62]

The fundamental ethical question is how to balance the need for research and innovation to advance human progress against the potential risks to patients who are the first recipients of the new procedures or the subjects in a clinical trial. Current ethical standards for the conduct of clinical research in the United States are derived from several standards, including the Nuremberg Code, the Declaration of Helsinki, and the Belmont report. Similar standards are in place in most progressive societies. Recent implementation of the Privacy Rule now requires the investigator to protect not only the safety but also the privacy of the research subject. In most institutions, compliance with these requirements is promoted by the institutional review board (IRB). The editors of most pediatric surgery journals have joined a growing coalition of medical journals requiring IRB approval before publication of results of research studies. In contrast, patient protections in innovative surgery are informal and rely primarily on the surgeon's competence and integrity.[59] In considering a new procedure, the surgeon must balance competing ethical principles, and relevant questions include whether it should be performed outside of a formal research protocol, what level of disclosure is needed to achieve an adequate informed consent, what research design meets the desired standard of evaluation, and how the burdens and benefits of such research can be distributed fairly.[63]

Randomized clinical trials (RCTs) are the most effective method to evaluate new procedures, but the specialty of pediatric surgery has lagged behind some other surgical specialties in the numbers of RCTs that guide our practice. Although RCTs compose 3% to 6% of studies reported in adult surgical literature, Moss and colleagues found that a trivial 0.17% of pediatric surgical studies were RCTs.[64] A recurrent obstacle cited for the reluctance among pediatric surgeons to participate in RCTs is the lack of clinical equipoise.[64,65] The meaning of equipoise is often misunderstood. The concept of equipoise was introduced by Charles Fried to express the uncertainty that a physician may have in choosing the best treatment out of competing alternatives.[66] Although this definition is useful in guarding the physician's fiduciary relationship with his or her patient, it could intensify a physician's state of uncertainty about whether a patient should be enrolled in a clinical trial. Freedman subsequently proposed the notion of clinical equipoise (or community equipoise), a state of uncertainty or professional disagreement within a professional group or clinical specialty regarding the relative merits of competing treatments.[67] In declaring clinical equipoise as the basis for participating in a clinical trial, the physician acknowledges that there is a reasonable uncertainty within his profession about the best treatment, even though he or she may have a strong preference for one option. Acceptance of clinical equipoise as sufficient ethical and moral justification for RCTs will increase enrollment in such trials.

Ultimately pediatric surgeons must be conservative guardians in surgical innovation. We agree with McKneally that the terminology of innovation has a seductive connotation of added value that attracts patients seeking the "latest and greatest" treatment.[68] Instead it should be replaced by the term *nonvalidated* as proposed by Levine because it more accurately reflects the ethical and medical hazard entailed in new procedures.[69] The concept of a nonvalidated operation is more transparent and honest because it embodies the fact that the proposed operation has not been subjected to rigorous investigation. This awareness may nudge both parents and pediatric surgeons toward supporting the ideal of RCTs, when a state of clinical equipoise exists about the role of a new procedure, before it is widely imposed on vulnerable and trusting patients and their families.

# Conclusion

The ethical principles of beneficence, nonmaleficence, autonomy, and justice, and virtues such as trust, compassion, prudence, justice, courage, phronesis, fortitude, integrity, honesty, and self-effacement provide a sound basis to navigate the moral dilemmas we encounter in pediatric surgery practice and research. Although there is no universal solution to a given ethical problem, we think that an acceptable solution can be reached if these principles are followed. Formal teaching of clinical bioethics has been lacking in most pediatric surgery training programs.[70] Recently, a case-based, practice-oriented ethics curriculum was developed by the American Pediatric Surgical Association (APSA) for pediatric surgery training programs in North America. In addition to all the topics discussed in this chapter, these case studies cover important ethical concerns related to child abuse, conflict resolution, and the disruptive surgeon. The APSA curriculum is an invaluable clinical bioethics learning resource for both trainees and practicing pediatric surgeons and is available on the APSA web site.[71]

CHAPTER 16

# Patient- and Family-Centered Pediatric Surgical Care

Sherif Emil

*"I am a mother of a child who was born with trisomy 13. My daughter died at home on April 13, 2010, at age 5, surrounded by her loved ones. She was not supposed to live that long, but she had great determination to beat the odds. During her last few months, I was introduced to the supportive/palliative care service. This program focused on helping her to live life to the fullest—her life, my life, our family's life. I wish there had been this program when she was born. By focusing on the quality of her life, rather than trying to fix things, my daughter would have had less hospitalizations and more special time with us at home. She would have had better pain management and would have been able to live life to the fullest, which I believe she did during those last few months."*

**Fundraising email sent by Rachel Llanos, mother of Kellie Llanos, a child with trisomy 13 who died at age 5 after a plethora of medical and surgical interventions.**

This is the first edition, in the long history of this illustrious textbook, that dedicates a chapter to patient- and family-centered care (PFCC). It is befitting, because the 21st century has seen the principles of PFCC quickly permeate through all areas of medicine, including pediatric surgery. Some may feel that these principles are self-evident, politically correct terms of what surgeons have always practiced. Although it is true that a competent, empathetic, ethical surgeon with good listening and communication skills is very likely to practice PFCC, the concept is far more than one of competency, empathy, or communication. Over the last 20 years, PFCC has evolved into a health care discipline, with a significant volume of research, publication, and programs. Systematic reviews show that PFCC increases adherence to management protocols, reduces morbidity, and improves quality of life for patients.[1] This chapter aims to introduce surgeons to this relatively new discipline and to emphasize the potential positive impact PFCC can have on pediatric surgical practice.

## Definition

The Institute for Patient- and Family-Centered Care (IPFCC) in Bethesda, Maryland is a non-profit organization that was founded in 1992 with a mission to advance the understanding and practice of PFCC and to partner with patients, families, and health care professionals to integrate PFCC concepts in all aspects of health care.[2] The institute defines PFCC as *an innovative approach to the planning, delivery, and evaluation of health care that is grounded in mutually beneficial partnerships among health care providers, patients, and families.* The core concepts of PFCC are (1) respect and dignity, (2) information sharing, (3) participation, and (4) collaboration.[2] In a recent technical report and policy statement, whose lead author is a pediatric surgeon, the American Academy of Pediatrics (AAP) deemed these same concepts essential to professionalism.[3,4] The Institute offers a plethora of resources on its Web site, and partners with practice groups and health care organizations to help integrate these concepts into the health care environment. Some of the contrasts between traditional medical care and PFCC are shown in Table 16-1.

## Background

In what is perhaps the oldest pediatric surgical textbook in the English language, published in 1895, D'Arcy Power wrote the following:

> "When an operation has been decided upon, it will generally be found that better results are obtained if the child be removed from its accustomed surroundings and is placed in the charge of those who have special experiences in nursing sick children. Only in very exceptional cases can a mother be trusted to nurse her own child after a serious operation, and in many instances the recovery of a spoilt and fractious child is seriously retarded by the presence of those who love it best. It is therefore acting in the best interests of the child, to recommend that it should be placed in a surgical home, or in the charge of an experienced children's nurse."[5]

This was essentially the paradigm for the surgical care of children in the first half of the 20th century. In 1953, Robert Gross included a section on "psychic preparation" for surgery in his seminal pediatric surgical textbook.[6] He challenged the paradigm of the child's separation from his family by emphasizing that abandonment "can seriously undermine the

**TABLE 16-1**

**Contrasts Between Traditional Care and Patient and Family-Centered Care**

| *Traditional Care* | *Patient- and Family-Centered Care* |
|---|---|
| Doctor knows what is best for the patient | Doctor and patient/parents together decide what is best for the patient |
| Exclusion of religious and cultural issues from medical decisions | Inclusion of religious and cultural issues in medical decisions |
| Psychosocial issues are ignored or approached separately | Psychosocial issues are included in the overall care plan of the patient |
| Parental role is minimized in overall care | Parental role is optimized in overall care |
| Parental absence during invasive procedures, resuscitation, or anesthetic induction | Parental presence during invasive procedures, resuscitation, or anesthetic induction |
| Withholding of information, particularly regarding poor outcomes or complications | Open and transparent information sharing, including admission of error or adverse events |
| Minimal preoperative preparation | Thorough preoperative preparation |
| Reactive approach to pain management | Proactive approach to pain management |
| Separate specialty clinics for complicated diseases | Multidisciplinary clinics for complicated diseases |
| Outcome studies analyze only physical or biological factors | Outcome studies also analyze quality of life factors pertaining to patient and family |

faith of the child in his mother or father."[6] He emphasized the importance of preoperative mental preparation at home and the role parents can play in the child's surgical experience. Dr. Gross's desire for an enhanced familial role probably was far ahead of the resources available at the time, because the same chapter shows a postoperative child shackled to the bed by her wrists and ankles in order to receive intravenous infusion.[6] As pediatric surgeons continued to tackle and win more surgical battles, their attention began to turn to psychosocial issues surrounding pediatric surgical care. In the mid-1990s, Caniano ushered in the field of pediatric surgical ethics, inevitably bringing attention to family dynamics and "the big picture" during fetal consultation, management of congenital anomalies, and pediatric surgical care in general.[7,8] In the last decade, outcome studies for a variety of pediatric surgical conditions started to look at emotional and developmental results on the child, in addition to the physical ones. Recently, these outcome studies have begun to investigate the effects of interventions on parents and caregivers. In one recent study, Zaidi and colleagues investigated the caregiver's perspective after esophagogastric dissociation in neurologically impaired children with severe gastroesophageal reflux disease, arguing for a greater role for this procedure because of the unexpectedly high caregiver satisfaction.[9] Another recent study looked past the typical outcomes of treatment, to analyze the child's emotional quality of life as well as the degree of parenting distress, in two arms of a randomized controlled trial for perforated appendicitis with abscess.[10] These types of studies are bringing to light the concept that successful physical outcomes may not necessarily translate into the best patient and family-centered outcomes. Finally, Paice and colleagues recently raised the possibility of parental presence in the operating theatre.[11] Pediatric surgery has come a long way in 100 years!

# Core Concepts

## RESPECT AND DIGNITY

All persons should be treated with respect and regard for individual worth and dignity, including sensitivity to gender, race, and cultural differences, as well as maintenance of patient confidentiality when appropriate.[4] Pediatric surgeons, particularly in developed countries, find themselves practicing in increasingly multicultural settings. The forces of immigration and globalization have created many international cities and communities, where people of diverse cultures, faiths, beliefs, and economic circumstances seek surgical care for their children. The parents' background and belief system, in turn, influences their interaction with the medical system; their expectations of medical personnel; and their decisions regarding their children's health care. At times, the surgeon may find himself or herself at odds with the approach or the decision of the child and/or the parents. The surgeon does not have to agree with the family. However, the principle of respect implies recognition that rational people may hold opposing and irreconcilable views.[8] The surgeon can demonstrate respect for the family and acknowledge their dignity by listening carefully, understanding their perspectives, and attempting to see beyond his or her own personal experience. Respect does not imply compromising the surgeon's primary responsibility to his or her patient's welfare. For example, the AAP has repeatedly called for the equal application of legal interventions whenever children are endangered or harmed, without exemption for actions based on religious beliefs.[12,13] It has also opposed religious or cultural practices, such as ritual genital cutting of female minors, that consistently harm children, and it has called on its members to actively dissuade families from carrying out these practices.[14]

## COMMUNICATION

We live in the age of information. Accurate and timely information sharing with patients and parents is one of the hallmarks of medical practice in the 21st century. Parents of children undergoing surgery desire comprehensive perioperative information. In fact, Fortier and colleagues recently reported that the vast majority of children older than 7 years also desire comprehensive information about their surgery.[15] The responsibility for providing this information lies mainly with the surgeon, because it has been shown that information acquired from elsewhere (general practitioner, books, popular magazines, Internet) does not necessarily improve the parents' understanding of the child's operative risk.[16] Clinicians may feel an impetus to withhold information, to decrease parental anxiety. This notion has been disproven by strong evidence.[17,18]

Information sharing is often used interchangeably with communication. However, effective communication goes well beyond information sharing, to include understanding, empathy, compassion, transparency, and advocacy. One of the few acts that require more trust than surrendering oneself to a surgeon is surrendering one's child to a surgeon. This intense trust is built on many factors, including the surgeon's reputation and competence, but none more important than effective communication. Good communication skills are essential core competencies that are associated with improved health outcomes, better patient adherence, fewer malpractice claims, and enhanced satisfaction with care.[19] Communication obviously serves the pediatric surgeon well on a daily basis, but certain situations require particular attention to communication if PFCC is to be provided. These include prenatal consultations, planning for correction of congenital anomalies, relaying a diagnosis of cancer, provision of end-of-life care, communicating the death of a child, and transmission of information regarding surgical errors and adverse events.

Prenatal consultation with pediatric surgeons by parents carrying a fetus with a congenital anomaly has become routine in the developed world. Although these consultations have not been proven to improve outcomes, they serve the vital purpose of relaying information to the parents before the stressful events of childbirth. They also help the surgeon establish early rapport with the parents and start building a trusting relationship. Parents are typically interested in more than a description of the anomaly, its treatment, and its potential outcome. They usually seek to learn what the future may hold for their baby, including his or her potential social function and interaction with family and society.[8] Caniano and Baylis stress the importance of compassion in such interactions, particularly in situations where couples may choose to end much-wanted (and sometimes difficultly acquired) pregnancies associated with life-threatening fetal malformations, for which there are no effective surgical interventions.[8] After examining prenatal surgical consultations for congenital diaphragmatic hernia (CDH), Aite and colleagues found that 70% of patients found it difficult to follow the surgeon's explanations or ask questions because of fear and other intense emotions.[20] Interestingly, consultations for lesions associated with better prognoses, such as congenital cystic adenomatoid malformation, were less effective in decreasing parental anxiety than consultations for CDH.[21] The reasons for this were uncertainty about prenatal outcome and lack of a defined management plan.[21] These data point to a possible deficiency in a single prenatal consultation, where the surgeon relays all the pertinent information. Follow-up by the surgeon or ancillary medical personnel after the initial consultation may enhance communication in this regard.

The setting of surgically correctable congenital anomalies, especially in the absence of prenatal diagnosis, presents another communication challenge for the pediatric surgeon. Families, even relatively sophisticated ones, often have never heard of the anomaly and are overwhelmed by the notion that their newborn baby can undergo and survive a major operation.[22] Provision of written and illustrated material can significantly enhance communication.[20–22] Before the operation, families are most interested in the description of the anomaly and its prognosis, whereas after the operation, they are most interested in the recovery process and assessment of the long-term quality of life.[22] Many congenital anomalies produce permanent and profound effects on the family dynamic, with potential marital, social, and financial implications. In an analogy to the five stages of grief described by Elizabeth Kubler-Ross, Drotar and colleagues described five stages of parental reaction after the birth of an infant with a congenital malformation (Table 16-2).[23] Understanding these stages can allow the pediatric surgeon to effectively relate to the family in the immediate perioperative period and beyond.

A new diagnosis of cancer presents a major crisis in the life of the patient and family. Fortunately, most pediatric solid and hematologic malignancies have better prognoses than their adult counterparts. This could be mentioned early in the discussion, because most parents will automatically remember a family member or loved one who died of cancer. The hospital and community resources available to the family should be clearly described, convincing the family that they will not be alone during this difficult experience. The emotional state of the parents is often associated with very poor receptiveness and comprehension on their part when the diagnosis is first relayed.[24] Repetition and constant clarifications of treatment plans and other details are typically necessary. Although information should be shared liberally with the parents, and often the child, the surgeon should remember that hope is not statistical. Hope is often recognized as an important component for healing; therefore, while remaining realistic in the expectation of cure, the surgeon should not try to remove all hope from the patient and family.

Communication with the family when the end of the child's life is in sight, or after the death of a child, presents particular challenges to the surgeon, who often has to deal with his or her own emotions. A sense of failing the child or family can interfere with the surgeon's ability to care for and comfort the family, when cure is no longer possible. The physician needs to find the strength to discuss life-threatening illnesses in an open, sympathetic, and direct manner, because families resent evasive or brief interactions.[25] Researchers at Children's Hospital Boston have identified six parental priorities for end-of-life care in the pediatric intensive care unit—namely, honest and complete information, ready access to staff, communication and care coordination, emotional expression and support by staff, preservation of the integrity of the parent–child relationship, and faith.[26] One can see that most of these priorities relate to communication. The pediatric surgeon's role does not end with the death of a child. The families a surgeon often bonds with the most are the ones whose children's funerals the surgeon has attended. A pillar of American pediatric surgery, Dr. Morton Woolley, chose the subject of a child's death as his last publication, in an attempt to help pediatric surgeons provide appropriate responses when confronted with the death of a child.[27]

Finally, communication, in general, and transparent communication, in particular, is exceptionally important in

**TABLE 16-2**
**Five Stages of Parental Reaction After the Birth of an Infant with a Congenital Malformation[23]**

| Stage I | Shock |
| Stage II | Denial |
| Stage III | Sadness and Anger |
| Stage IV | Adaptation |
| Stage V | Reorganization |

decreasing litigations.[28] The American College of Surgeons Closed Claims Study identified failure to communicate as the major cause of litigation in 22% of claims.[29] The adverse consequences of these failures included medical errors, escalation of the consequences of otherwise nonpreventable adverse events, and anger or mistrust even when the standard of care was met. A policy of transparent disclosure of error with an apology or expression of regret when preventable adverse events were identified, coupled with an offer of reasonable compensation, has been shown to dramatically decrease medicolegal costs.[30]

Effective communication between health care team members is also essential in providing PFCC to complex pediatric patients. In one study, Meltzer and colleagues found that physicians, faced with difficult patients or families, were more likely to distance themselves or refer the family to the psychosocial profession, while nurses were more likely to consult with colleagues.[31] Communication skills and relational abilities in pediatric health care can be significantly improved by formal training.[19]

## PARTICIPATION

Surgery is often described in terms of doing things *to* patients, and not *with* patients. It is not surprising, therefore, that the patient's and family's active participation in the surgical experience has constituted the most controversial aspect of PFCC over the past 2 decades, a period that has seen a flurry of research into issues such as preoperative family preparation, parental presence during induction of anesthesia (PPIA), and parental involvement in the choice of potentially anxiolytic preoperative and postoperative maneuvers. Preoperative anxiety in young children undergoing surgery is associated with more pain during the recovery period, as well as higher incidences of emergence delirium, postoperative anxiety and sleep disturbance, and postoperative maladaptive behavior.[32,33] The parents' preoperative anxiety may also influence outcomes. For example, many mothers who exhibit a high desire to be in the operating room are also very anxious, and their children are likely to exhibit high anxiety levels during induction of anesthesia.[34] Interventions to decrease the mother's anxiety during PPIA were found to also decrease the child's anxiety on entrance to the operating room and during introduction of the anesthesia mask.[35] Most of the research, therefore, is aimed at identifying maneuvers that may decrease child and parental anxiety during the perioperative period, outcomes that are understandably difficult to assess. Nevertheless, multiple scales, such as the Motivation for Parental Presence during Induction of Anesthesia (MPPIA),[34] the Yale Preoperative Anxiety Scale (mYPAS),[36] and the Child-Adult Medical Procedure Interaction Scale,[37] have been developed in an attempt to provide some objective data. Chorney and Kain have recently presented a comprehensive model of family-centered pediatric perioperative care.[38] This model covers the preoperative, intraoperative, and postoperative environments, and includes family factors, such as anxiety and previous medical experience, as well as provider and system factors, such as training and organizational policy.[38]

### Preoperative Preparation

Most children's hospitals currently have some type of preoperative preparation program for surgical patients. These programs generally include an orientation to the operating room (OR), a description of the anticipated events on the day of surgery, and, in some instances, psychological preparation of the parent and pediatric surgical patient.[39,40] Certain patient factors identified during the preoperative preparation, such as age, previous anesthesia, and anxiety level, have been found to predict poor behavioral compliance during inhaled induction.[41] These factors may help identify children who could benefit from behavioral or pharmacologic interventions. Targeting the parents in such programs is also important, because there is evidence that the parents' anxiety on the day of surgery is highly associated with the child's anxiety.[42] During the preoperative visit, options such as PPIA may be discussed, if available in the institution. These visits also afford the anesthesiologist an opportunity to assess the family as a whole and formulate a plan for induction. For example, a preoperative assessment of the anxiety level of parent and child, in addition to other specific factors, such as age, temperament, and coping style, were found to predict which child-parent pair is likely to benefit from PPIA.[43,44] Kain and colleagues have performed two randomized controlled trials to assess the value of preoperative preparation.[45,46] In the first study, an extensive preoperative program (OR tour + videotape + child-life preparation), produced limited anxiolytic effects, which were seen only in the preoperative period and did not extend to induction or postoperative recovery.[45] In a more recent study, an ADVANCE program (*A*nxiety reduction, *D*istraction, *V*ideo modeling and education, *A*dding parents, *N*o excessive reassurance, *C*oaching, and *E*xposure/shaping) was compared with three other arms: standard of care, PPIA, and oral midazolam. The ADVANCE program resulted in multiple improved outcomes for children and parents.[46] Children in the ADVANCE group exhibited a lower incidence of emergence delirium, required significantly less analgesia in the recovery room, and were discharged from the recovery room earlier than children in the three other groups.[46] A more recent Brazilian study also showed improvement in anxiety levels and behavior during the postoperative period in children who received preoperative psychological preparation prior to undergoing elective surgery.[40]

### Intraoperative Period

The main controversy surrounding PFCC during the intraoperative period is PPIA. PPIA was an almost natural extension of increased parental participation and presence during critical procedures on their children, including trauma resuscitations, emergency room resuscitations, bedside invasive procedures, and cardiopulmonary resuscitations. Many of these situations also involve the pediatric surgeon. This movement has significantly grown in strength in the last quarter century. Parental presence during these procedures, in many institutions, now occurs routinely. Although there are no research studies that point to a patient benefit if the family is present, there appears to be at least a major psychological benefit to the family. Research suggests that families want to be given the option to be present during invasive and resuscitative procedures, and they often choose that option.[47–49] Those who are present generally report favorable experiences.[47] Parents who witnessed a terminal medical event involving their child in the pediatric intensive care unit (PICU) were less distressed than those who did not and felt that their presence helped them cope with their child's death.[48,49] Family

presence has not been found to prolong time to computed tomography (CT) imaging or to resuscitation completion for pediatric trauma patients.[50] Uninterrupted care can be delivered with the family present.[51] Physicians and nurses have become increasingly comfortable with family presence in critical situations.[47,52–55] Major professional organizations, including the AAP and the American College of Emergency Physicians, have endorsed the practice.[56–58]

However, many do not see PPIA as a natural extension of parental presence during other clinical scenarios. Critics of PPIA cite decreased OR efficiency, additional staffing requirements, increased cost, and possible medico-legal implications as potential arguments against its practice. There are no data to support these arguments. On the other hand, data regarding positive outcomes of PPIA are also mixed. Kain and colleagues reported several randomized trials of PPIA over the past 15 years.[59–63] In the first study, published in 1996, PPIA did not reduce any behavioral or physiologic measures of anxiety during induction.[59] A benefit was seen in specific subgroups of children when cortisol levels were measured, an outcome of questionable clinical significance.[59] In another study, oral midazolam was superior to PPIA in reducing anxiety and increasing compliance of the child during the perioperative period.[60] Interestingly, that study also showed that parents of children in the midazolam group had lower anxiety scores after separation from their children.[60] In a study comparing oral midazolam alone to oral midazolam plus PPIA, children in both arms exhibited similar levels of anxiety.[61] However, parents in the PPIA arm had lower self-reported anxiety scores and higher satisfaction stores.[61] The physiologic effects of PPIA on parents were specifically investigated in another trial, which found that parents in the PPIA arms, regardless of whether a sedative was also given to their child, manifested a significantly higher physiologic stress response during induction (increased heart rate and skin conductance level), than parents in the control arm.[62] The most recent study investigated the presence of one versus two parents during induction.[63] The presence of two parents did not affect observed child anxiety, but reduced parents' self-reported anxiety.[63] Chundamala and colleagues recently published a comprehensive evidence-based review of the effects of PPIA on parent and child anxiety and concluded that, contrary to popular belief, PPIA does not appear to alleviate parents' or children's anxiety.[64] These authors, from Toronto's Hospital for Sick Children, raise the possibility that PPIA may be driven by market forces and hospital competition in the United States. The use of PPIA has certainly grown in the United States.[65] However, the practice is far more frequent in Britain, where support for PPIA is dramatically higher than in the United States among both anesthesiologists and pediatric surgeons.[66,67] In fact, the practice has become so routine in Britain, that some are raising the possibility of parental presence during the surgical procedure.[11] One would be hard pressed to cite the market as the driving force for PPIA in Britain. Chorney and Kain, with practices in very different health care settings (Halifax, Nova Scotia and Orange County, California), argue that the focus on efficacy data has misguided the debate over PPIA.[38] They stress that PPIA is overwhelmingly preferred by parents, increases parental satisfaction, and improves hospital public relations.[38] Some parents may see it as a basic right.

PPIA is an instrument that may work well for many, but not all, families. Medical personnel are therefore encouraged to respect the family's decisions and preferences.[38] There is undoubtedly a strong demand for this option. The number of parents in our practice who are asking for PPIA is exponentially increasing. The demand is particularly strong among parents whose children have undergone prior surgery with or without PPIA.[68] PPIA is therefore not a passing fad, but rather a practice well on its way to becoming a standard of care.

### Postoperative Care

Postoperative care and recovery are facilitated if adequate preoperative preparation is given and a positive intraoperative surgical experience ensues.[38,40,69] A quick reunion with the parents in the recovery room now occurs routinely. Daily, clear updates to the parents of hospitalized children are a must. When pediatric surgery fellows or other house staff are part of a surgical service, a special effort should be made to give the patient and parents clear and nonconflicting information. Inadequate pain management is of utmost concern to the child and parents. This should be addressed appropriately, and preemptively, when possible. If the child is on a treatment protocol or algorithm, the relevant details and end points should be clearly explained to the parents. Support for the parents and the child during recovery at home is also essential. Home health care resources should be mobilized as early as possible to allow the child to continue care at home, when it is deemed appropriate and safe. Clear and detailed discharge instructions should be given both directly and in writing. Some data suggest that many children do not receive optimal pain management at home after day surgery.[70] A follow-up phone call from the surgeon or nurse during the first 72 hours after day surgery is highly appreciated by the parents. In the late 1990s, reports of successful phone follow-up for select pediatric surgical operations, with the intent to provide convenient and cost-effective care, appeared in the literature.[71,72] Following these reports, our service began an active phone follow-up program for the majority of day surgery cases and many simple inpatient cases (e.g., nonperforated appendicitis, pyloric stenosis).[73] This has been extremely popular with parents, because it avoids an unnecessary postoperative visit, while identifying those patients who require or request follow-up. More recently, a 90% satisfaction rate has been reported with a similar strategy.[74]

## COLLABORATION

Collaboration can be best defined as a health care environment that regards the parents and family as health care team members, and not spectators. In fact, the family should be seen as the most consistent and permanent member of the health care team, because nurses, ancillary medical staff, social workers, and even the attending staff surgeon may change from time to time. This concept is often referred to in the literature as *partnership*—the physician and health care team partnering with the family to provide the best care possible to the patient. This is not such a new or modern concept. Surgeons who have practiced in missionary settings or underdeveloped countries will attest to the huge role the family plays in the active medical care of the patient.

Partnerships are formed when the health care team values the information given by parents, actively seeks their input in decisions affecting their child, acknowledges their positions

**TABLE 16-3**

**Montreal Children's Hospital Division of Pediatric General Surgery Pledge to Patients and Families**

| |
|---|
| We will treat every child and family with dignity, compassion, and respect. |
| We will draw on the expertise of the entire team and other hospital services to offer the best care to each child. |
| We will discuss with patients and families all relevant alternatives for treatment. |
| We will serve as advocates for each child within the health care system. |
| We will keep patients and families fully informed of the treatment plan, and address concerns in an open and honest manner. |

**TABLE 16-4**

**PFCC Best Practices in Pediatric Surgery**

| |
|---|
| A commitment to respect the culture, faith, and belief system of each family, while always advocating for the child's best interests |
| A commitment to keeping the patient and family united as long as possible during the perioperative period |
| Inclusion of family advisors as partners in facility design of surgical waiting rooms and perioperative areas |
| Inclusion of family advisors in the review and formulation of surgical documents, including preoperative instructions, consent, and discharge forms |
| Encouragement of families to ask questions, share concerns, and offer feedback to surgeons, anesthesiologists, and surgical staff |
| Open, honest, and continuous sharing with families of procedural risks and safety precautions |
| Provision of information to families on how they can actively partner with staff to reduce risks and optimize outcomes |
| Provision of information to families on pain management and recruitment of their feedback on its efficacy |
| Provision of information to families on the roles and responsibilities of the members of the surgery team, as well as clear instructions on who to contact for questions and concerns |
| Open and honest disclosure of surgical complications and adverse events |

and concerns, and acts on their feedback. The United States Maternal and Child Health Bureau defines a positive family–provider partnership as a core program outcome.[75] Denboba and colleagues found that a sense of partnership between the families of children with special health care needs and their physicians was associated with improved outcomes across a number of important health care measures.[75] However, poverty, minority racial and ethnic status, and absence of health insurance placed families at elevated risk of being without a sense of partnership.[75] An extra effort, therefore, is needed to build partnerships with certain at-risk populations. Partnerships are also created when parents feel that they have full access to the health care team. Parents who desire to meet with the entire tumor board, fetal diagnosis and treatment group, or any other multidisciplinary treatment team, to obtain comprehensive information, should be encouraged and invited. Partnerships can also be integrated into daily patient care. An example comes from Cincinnati Children's Hospital, where families can choose to be part of attending physician rounds.[76] Integration of the family into multidisciplinary rounds was found to require an additional 2.7 minutes per patient and affect the medical decision-making discussion in 90% of cases—an excellent investment![77] Collaboration is particularly important in the long-term care of pediatric surgical patients with congenital anomalies, such as imperforate anus or esophageal atresia, which become lifelong chronic medical conditions after repair. Rahi and colleagues recently offered a detailed and practical account of how a support program for children with a newly diagnosed lifelong disability can be built in collaboration with family, counselors, and health care personnel.[78]

# Putting It All Together: PFCC in Action

Many individual surgeons, surgical practices, and institutions apply the principles of PFCC intuitively. However, an intentional commitment to PFCC can have a transforming effect on pediatric health care. Our hospital, like most children's hospitals, saw itself as a child- and family-friendly hospital. However, after a visit from a national leader and advocate of PFCC in October 2009, the hospital made a firm commitment to examine its practices and traditions. Such examination showed ample potential for growth in PFCC. Specific actions included the formation of a PFCC working group, with representation from all areas of the hospital, stronger collaboration with the hospital's family advisory forum and their inclusion in planning and policy making, the hiring of a PFCC coordinator to act as a liaison between the hospital and families, and taking PFCC issues into account in the design and building of a new hospital. Within our Division of Pediatric General Surgery, we adopted a new mission statement that reflects a strong commitment to PFCC, as well as a pledge to patients and families (Table 16-3). The mission statement and pledge are included in a color brochure that provides core information about our services and our staff, which is given to all families who come in contact with our division. A color chart containing the names and pictures of all members of the pediatric surgical service, including students, residents, and fellows, is also given to all admitted patients so that families are always clear about the roles of each member of the team. Our surgery and anesthesia departments started to investigate the incorporation of PPIA into the OR culture and to explore other ways of enhancing the role of parents in the operative experience.

A list of 10 PFCC best practices, relating to pediatric surgery, is shown in Table 16-4. These are practical steps that can be taken to apply the principles discussed in this chapter. In addition, the Web site of the IPFCC has many additional concrete examples of PFCC in action from children's hospitals throughout the United States that have been leaders in the adoption of PFCC principles and practices.[2] These principles and practices are as important to the psychosocial aspects of pediatric surgical care in the 21st century as evidence-based medicine is to the biological aspects.

CHAPTER 17

# Injury Prevention

Gina P. Duchossois and Michael L. Nance

*"If a disease were killing our children in the proportions that injuries are, people would be outraged and demand that this killer be stopped."*

**—C. Everett Koop**

Injury presents the greatest threat to life of all diseases in the pediatric population. More children die each year from injury than all other causes combined.[1] More than one in nine children will require medical attention for an injury each year. Many more children will be injured but not require or seek medical care (Fig. 17-1). The economic costs of injury are staggering. In addition to direct costs for care, there is the additional loss of future productivity as well as loss of productivity by parental caregivers who must provide for the injured child. For the year 2000, these costs were estimated to top $130 billion in total costs, with nearly $25 billion due to direct medical costs.[2] The significance of the costs of injury become even more provocative when one considers the potential financial savings that can be realized from injury prevention strategies (Table 17-1).

William Haddon, in the 1970s, reported his classic characterization scheme (the Haddon "matrix") and approach to injury prevention.[3] This system argued against the traditional idea that injury was an accident, leaving the burden of prevention on the individual. Rather, he suggested that injuries result from predictable events and thus offer an opportunity for systematic intervention and injury reduction. This strategy, which considers injury in pre-event, event, and post-event phases, each offering opportunity for intervention, is still relevant today (Table 17-2). Pre-event (primary) prevention measures seek to prevent the event leading to the injury through education, intervention, and/or safety design measures. For example, crosswalks and count-down timers are effective safety engineering actions to make our roadways safer for pedestrians. Measures aimed at altering the event (secondary) seek to lessen the severity of an injury if it occurs. For example, child safety seats are not designed to prevent a motor vehicle collision but rather minimize (or eliminate) the severity of any injuries if a collision occurs. Finally, post-event (tertiary) injury prevention is the strategy used by most health care providers. It seeks to mitigate the consequences of the injury once it has occurred. For example, management of intractable intracranial hypertension through hemicraniectomy is tertiary prevention. Advances in health care have led to marked improvements in outcome for children with traumatic injuries. However, quite clearly, primary prevention, averting the event altogether, is the optimal approach. Haddon provided 10 countermeasures to use when addressing the prevention of a particular injury (Table 17-3).[4] These concepts can be applied to most any injury and help break down the problem into potentially actionable steps.

## Prevention Priorities

Injury prevention resources are finite. As such, priorities for these prevention efforts must be established. These priorities may vary depending on the individual, the community, or perhaps the nation interested in prevention. A variety of factors are integral to the decisions regarding how best to deploy these limited resources. At the individual level, one might favor efforts to minimize in-home injury and "child-proof" the surroundings. A community might work toward pedestrian safety efforts in neighborhoods in which such injuries have been predominant. Finally, a nation (e.g., the United States) might focus efforts to reduce motor vehicle–related injuries, the leading cause of injury death. Simply counting the number of deaths from a particular injury mechanism may not provide an accurate or adequate representation of the burden of injury (by mechanism) in the geographic area of study. For instance, an injury mechanism that is highly lethal (e.g., hanging) but infrequent may not be an optimal prevention target. Nor might efforts to reduce an injury that is common but usually of limited severity (e.g., assault) be the ideal strategy. An injury that is both common and severe would, in most settings, represent the ideal target for mitigation efforts. To help define such injuries, Haider and colleagues used an injury prevention priority score.[5] This calculation takes into account both the frequency of an injury and the mean severity of an injury by mechanism. In a comparison of pediatric populations from two geographically distinct trauma centers, they noted differences in injury patterns. In the inner city, auto/pedestrian injuries achieved the highest priority score, while in the community center, motor vehicle–related injuries ranked highest. Wiebe and colleagues applied this methodology to a national trauma center population and demonstrated that motor vehicle–related injuries, falls, and firearm-related

injuries, respectively, were the highest ranking injury mechanisms (Table 17-4).[7] In addition, Wiebe and colleagues also created additional scores that take into account the relative mortality of an injury mechanism (mortality priority score), the cost of an injury (hospital cost priority score), and the years of productive life lost (years of productive life lost priority score) to further characterize the burden of a particular injury. As suggested by Haider in his original publication, the methodology is easily applied to individual populations, such as that of a trauma center or a county or a state, to help determine how best to deploy prevention

TABLE 17-3
**Haddon Measures to Combat Injury and Their Application to Firearm Injury**

| *Haddon Countermeasure* | *As Applied to Firearm Injury Prevention* |
|---|---|
| Prevent the creation of the hazard in the first place | Eliminate handguns |
| Reduce the amount of the hazard brought into being | Limit the number of handguns allowed to be sold or purchased |
| Prevent the release of the hazard that already exists | Install locks on handguns |
| Modify the release of the hazard that already exists | Eliminate automatic handguns |
| Separate, in time and space, the hazard and that which is to be protected | Store handguns only at gun clubs rather than at home |
| Separate, by material barrier, the hazard and that which is to be protected | Keep guns in locked containers |
| Modify the relevant basic qualities of the hazard | Personalize guns so they can be fired only by the owner |
| Make that to be protected more resistant to damage from the hazard | Create and market bullet-proof garments |
| Counter damage already done by the hazard | Provide good access to emergency care in the prehospital period |
| Stabilize, repair, and rehabilitate the object of the hazard | Provide high-quality trauma care in hospitals |

resources. Using data to better understand the scope of the problem is essential to designing effective prevention strategies.

## INJURY PREVENTION DESIGN STRATEGIES

Effecting behavior change is always a difficult task to accomplish in injury prevention. As the Haddon matrix suggests, a multifaceted approach is necessary when designing effective injury prevention programs. It is important to understand the injury problem, associated risk factors, and the target population. The most successful prevention strategies are those that combine comprehensive methods and models. Most prevention models employ a variety of methods, often referred to as the three "Es": education, engineering (modification of the environment), and enforcement (policy change).[8] The fourth "E" that is often incorporated into prevention strategies is encouragement (e.g., economic incentives).

Education is the most common prevention strategy employed, with the goal of affecting behavioral modification. It is hoped that with understanding of risk will come behavior change. However, increased knowledge through education does not always translate readily into a behavior change. For example, although an adult may realize that using a crosswalk is the safest way to cross a busy street, crossing midblock is much quicker. This strategy incorrectly assumes the public will voluntarily and preferentially adopt a safe behavior.

Enforcement (policy change) uses the force of the law to increase compliance and change behavior. This strategy is most effective when combined with education. There are many studies highlighting the positive impact that laws can have on injury prevention. As an example, the use of safety belts in motor vehicles increased by 15% after law enforcement agencies began issuing traffic citations.[9] Government regulations and industries have done much to offset poor behavior choices in order to save lives. Safety features have been introduced throughout our everyday lives, from air bags and crumple zones in cars to child-resistant caps on medicines to fire-resistant clothing for children. Other legislation requires an active response from the end user, such as the installation of smoke alarms in the home or wearing a bicycle helmet. Legislation is generally regarded as one of the most powerful tools in injury prevention, and has affected a positive behavior change.

Engineering (modification of the environment or product) is often used because this approach eliminates the need to change behavior in the individual. Effective engineering

modifications for pedestrians include the introduction of sidewalks, barriers, and pedestrian signs. Engineering is often the most expensive strategy and at times even cost prohibitive. To decrease the likelihood of crossing midblock, a roadway barrier can be put in place to eliminate crossing midblock. The cost to a governmental agency or to a product manufacturer must be weighed against the potential societal benefit in determining efficacy of such prevention strategies.

## SELECTED INJURY PREVENTION INITIATIVES

### Child Passenger Safety

One of the most dramatic examples of the efficacy of injury prevention strategies is that of child passenger safety efforts (Figure 17-2). Motor vehicle crashes are the leading cause of death for ages 3 to 14 in the United States. However, research has shown that lap/shoulder seat belts and child safety seats, when used, save lives. Vehicle seat belts reduce the risk of fatal injury to front seat occupants of passenger cars by 45%, while child safety seats reduce fatal injury by 71% for infants and 54% for toddlers in passenger cars.[10] The challenge is to make sure every passenger (regardless of age) is properly secured, every single ride.

Studies suggest that efforts to reduce injury risk to children in a motor vehicle should promote use of child restraint systems through a combination of education, distribution programs, and appropriate laws governing use.[11] Pierce and colleagues illustrate the importance of providing ongoing education combined with legislation and enforcement during a booster seat giveaway program in a Head Start program.[12] The program measured the knowledge level of Head Start providers, parents, and students regarding booster seats. It combined education along with the provision of age-appropriate restraints and direct observation following the program. The project was successful in increasing the use of booster seats, although the majority (66%), while restrained, were done so suboptimally. Despite the demonstrated efficacy, child passenger restraint misuse and inappropriate use is common (>72%) and offers additional room for prevention efforts.[13]

In a systematic review of five different interventions designed to increase child safety seat use, Zaza and colleagues demonstrated that the most successful interventions were those that did not stand alone but rather were multifactorial.[14] There was insufficient evidence for education-only programs. However, they identified strong evidence for effectiveness of child safety seat laws and distribution plus education programs. Also, community-wide information plus enhanced enforcement campaigns and incentive plus education programs had sufficient evidence of effectiveness.[14] Based on these findings, as well as other evidence-based programs designed to reduce injury risk to children in motor vehicles, efforts should promote use of child restraint systems through improved laws combined with education and disbursement programs.

### Fire Safety

Because the causes for residential fires are multifactorial, efforts to prevent fire-related morbidity and mortality should also consider multiple approaches. A smoke alarm is arguably the single most important piece of safety equipment to prevent fire-related morbidity and mortality. The risk of dying in a residential fire is cut in half when a functioning smoke alarm is present.[15] Two efforts thought to be essential in reducing fire-related injury are the use of smoke alarms and identifying an escape plan for use in the event of a fire; both require action on the part of the resident. Previous research has demonstrated that the most effective and cost-efficient method to distribute smoke alarms is through direct home visits.[16] Harvey and colleagues have proven that direct installation is much more effective than voucher distribution for a free fire alarm.[17]

There are other passive preventive techniques that are also as effective, such as flame-resistant clothing for children. Half of the persons who start reported fires by playing are 5 years of age and younger. Most child-playing home fires are started with matches or lighters.[18] Legislatively, there are a variety of laws and standards that are designed to save lives, such as the requirement of smoke alarms on every level of the home and in every bedroom, sprinkler systems in some dwellings, and cigarette lighter standards. The U.S. Consumer Product

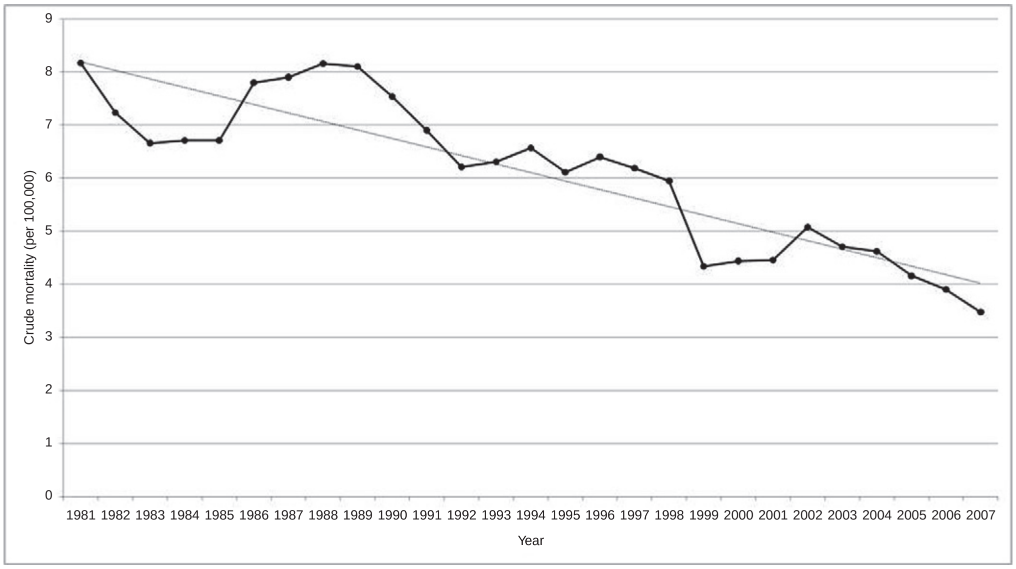

**FIGURE 17-2** Decline in crude mortality rate for child occupants (age 0 to 19 years) in motor vehicle crashes for the period 1981 to 2007. (Data from National Center for Injury Prevention and Control.[1])

Safety Commission has issued a safety standard for cigarette lighters, which requires that disposable cigarette lighters be resistant to operation by children younger than the age of 5. In an analysis of this standard, it has been proven to reduce fire injuries, deaths, and property loss by children playing with cigarette lighters and can be expected to prevent additional fire losses in subsequent years.[19] Some states are now enacting novelty cigarette lighter legislation to protect against lighters that are being mistaken for toys. Continued efforts are necessary to maximize prevention efforts.

### Firearm Storage

Firearm-related injuries have posed significant prevention challenges. With one of the highest case fatality rates of all injury mechanisms, prevention of the initial exposure is vital. However, with more than 250,000,000 firearms in circulation in the United States, that task is daunting.[20] The presence of a firearm in the home has been shown to increase the risk of unintentional firearm death (3.7-fold), suicide (3.4-fold), and homicide death (1.4-fold) versus households without firearms.[21,22] The effectiveness of educational programs geared to children and firearm use have been questioned. In a classical behavioral study, Hardy and colleagues demonstrated persistence of curious behaviors among children who encountered a firearm despite having undergone prior gun safety education.[23] Efforts to limit access to firearms by children have also had mixed results. A survey of parents visiting pediatrics practices revealed unsafe gun storage practices in 70% (gun unlocked 61%, gun loaded 15%, gun unlocked/loaded 7%, gun locked/unloaded 30%) of the homes.[24] The outcome of strategies geared toward parental firearm storage behaviors was summarized by McGee and colleagues, who did note an improvement in reported storage practices following counseling and education.[25] However, evidence to demonstrate a reduction in injury related to improved safety measures is limited. Grossman and colleagues were able to demonstrate that several factors were associated with a protective effect when examining the risk of youth unintentional and suicide firearm injuries: keeping a gun locked and unloaded, and storing ammunition locked and in a separate location.[26] Although firearm injury mitigation strategies have been of uncertain success, continued efforts are warranted given the ongoing risks that exist.

### Helmet Use

Bicycle riding is enjoyed by millions of children and adults every day. Learning to master the technical challenges of a two-wheeled bicycle is a rite of passage for most children. However, because of its popularity and widespread use, bicycle riding is also a common source of injury in the pediatric population. Helmet use has long been advocated to mitigate the risk of serious head injury. Helmet use has been demonstrated to reduce head injury of all types, serious head injury, and facial injury related to bicycle collisions.[27–29]

Both educational initiatives as well as legislative mandates have been used to encourage routine helmet use among pediatric riders. Educational programs promoting use of bicycle helmets have been shown to increase their routine use. Rivara and colleagues demonstrated an increase in helmet use from 5.5% baseline to 40.2% after introduction of a community-wide bicycle helmet campaign.[30] At the same time, the rate of bicycle-related head injuries decreased by 67%. The effects of bicycle helmet use campaigns seem to be most effective in the younger-aged children and in the higher socioeconomic status populations.[31,32] Parkin and colleagues demonstrated the efficacy of legislative approaches to improving helmet use in children, with a significantly increased observed rate of use from 46% to 68%.[33] Interestingly, the least impact of the legislation was noted in the highest socioeconomic groups. However, these groups also had the highest rates of baseline use, suggesting perhaps the efficacy of prior educational campaigns. A side benefit of mandatory laws may be heightened awareness of riders in areas not covered by helmet use laws. For example, in a Canadian study, the risk of bicycle-related head injury declined 45% in areas with mandatory use but also by 27% in areas without mandated use.[34]

Although a less common issue in the pediatric population, motorcycle helmet use has similarly been shown to reduce the incidence of serious head injury and death related to motorcycle accidents. A Cochrane collaborative reported a reduction in mortality of 42% and serious head injury of 69%.[35] Evidence was lacking regarding helmet use and risk of facial injuries. Mandatory motorcycle helmet use laws frequently are met with stiff opposition from riders, but such laws save lives and reduce serious head injuries.[36]

### Pedestrian Injury

Pedestrian injuries in children resulted in 573 deaths (2007) and more than 47,000 injuries (2009) in the United States.[1] The burden of injury globally is far greater where pedestrians represent the largest category of child road traffic casualties.[37] A Cochrane Collaboration review demonstrated the effectiveness of pedestrian education programs geared toward children.[38] Programs included direct education of the child by professionals as well as use of the parents as educators. An improvement in knowledge was exhibited along with changes in baseline pedestrian behaviors, but a correlation with risk reduction was not possible. Most studies have been carried out in developed nations. As pedestrian injuries are increasing in developing nations along with an increase in motor vehicle use, effective prevention strategies are warranted. Somewhat paradoxically, most pedestrian injuries in children occur in optimal driving conditions (daylight hours, dry road conditions, no adverse weather conditions).[39] The majority of child pedestrians struck were crossing the street at the time of injury, frequently obscured by an obstacle.[39,40]

Engineering modifications to vehicles offer tremendous hope. Improving sight lines, optimizing visualization of the area surrounding the vehicle (through mirror placement and use of rear-facing cameras), and design changes to mitigate energy transfer at common impact points (e.g., front bumper) may reduce the burden of injury.[41] Efforts to change the environment, such as “traffic calming” techniques, have demonstrated efficacy.[42,43] The calming measures might include the use of speed humps, lower posted speed limits, traffic circles, installation or enhancement of crosswalks, and use of crossing aids.

### Poisoning

Drug overdose death rates in the United States have never been higher. Rates of unintended ingestions have increased roughly fivefold since 1990, a leading cause of death in the pediatric population.[44] In addition, the Drug Abuse Warning Network (DAWN) reports the number of emergency

department (ED) visits for legal drugs is now comparable to visits from illegal drugs.[45] Most fatal poisonings in the United States are from drug misuse (i.e., overdose). Overdose may include attempts at self-harm (suicide), assault (intentional), and accidental ingestion (unintentional).[44]

Among children, ED visits for medication poisonings are most common in children less than 6 years of age.[46] Emergency department visits for medication poisonings are twice as common as poisonings from other household products.[47] One of the most effective injury prevention initiatives in poison prevention was the introduction of child-resistant packaging for aspirin and oral prescription medicine that went into effect in the early 1970s.[48]

For children, caustic agents such as household cleaners that are marked with clear warning labels are not the only items in the home that can be dangerous to children. Everyday items such as cleaning supplies and medicines can be poisonous as well and should be kept out of the reach of children. The national poison control hotline (800-222-1222) provides parents and practitioners with readily accessible information about the toxicity and treatments for specific ingestions.

## Measuring Success (Programmatic Evaluation)

Measuring the success of an injury prevention program or prevention initiative is imperative. There are many injury prevention programs in the community that appear to be effective. However, without adequate evaluation of the efforts, there is no way to verify if a program is actually achieving the goal of injury mitigation.

The most important aspect of evaluation is an adequate measurement of the problem conducted before, during, and after the intervention. The evaluation process should be dynamic. Assessment is started early, immediately after a program idea is conceived, and should continue through the intervention phase until the program is complete, when one determines whether the program has met its overall goal. In some cases, evaluation may continue for years after the intervention is complete to assess the durability of the desired outcome.

Evaluation is also critical to prove to funding agencies that their support is making a difference. A successful evaluation can also be used to strengthen funding proposals and to continue or replicate the program in other areas. A program that has rigorous, scientifically proven success is much more likely to receive continued funding. The same standards are necessary to publish the work in professional journals and disseminate prevention ideas to professionals in other communities.

Evaluation has four essential stages that are intertwined throughout the planning and intervention phase of a program. These stages are formative, process, impact, and outcome evaluation.[49] A well-designed formative evaluation will give the program a better chance at success, along with elucidating areas of improvement. In the formative stage, a targeted issue is identified (e.g., bicycle helmet use to lessen head injury) and may include an assessment of existing resources and deficiencies. During this stage, it is important to identify barriers to success (e.g., age, access to target population, education). Inclusion of community stakeholders at this stage increases the likelihood of long-term success.

Through process evaluation, the second stage, a plan is formulated to measure whether or not the program is reaching the desired audience. This stage typically requires documentation of the number of people reached during the educational or interventional program, for instance, the number of bicycle helmets distributed or the number of students taught bicycle safety. Such data will provide the foundation for sound assessment of the program.

Impact evaluation is a measure of how well the program is progressing toward its goals. It is a measurement of knowledge, attitudes, and beliefs. This assessment may be through direct observation of a particular behavior, or perhaps though survey or questionnaire. Preintervention and postintervention data collection (e.g., observed bicycle helmet use) will provide insight regarding the success of a program.

The final phase, outcome evaluation, measures whether or not the program met its goal of decreasing incidence of injury, morbidity, and/or mortality. Demonstrating long-term success (beyond the intervention stages) is ideal, but such study can be time consuming and resource intensive. However, demonstration of sustained injury reduction is likely to lead to dissemination of practices and ongoing funding.

Injury is the leading cause of death and disability in the pediatric population. Although trauma systems have evolved to provide optimal care, prevention is the preferred approach. Prevention strategies should be tailored to the target population and studied to ensure efficacy. For additional Internet-based injury prevention resources, see Table 17-5.

CHAPTER 18

# Infants and Children as Accident Victims and Their Emergency Management

Jeffrey R. Lukish and Martin R. Eichelberger

## Epidemiology of Childhood Injury

Preventable injuries take an enormous financial, emotional, and social toll on the injured children and their families, but also on society as a whole. Worldwide, childhood injuries are a growing problem. Every year, approximately 875,000 children are killed, and nonfatal injuries affect the lives of between 10 million and 30 million more globally (Fig. 18-1).[1] In the United States, unintentional injury is the leading cause of death among children ages 18 and younger, claiming more than 12,000 child lives annually, or an average of 30 children each day. In addition to the deaths, there were 9.2 million medical visits for unintentional injury among U.S. children, accounting for 151,319 hospitalizations.[2] More than 16% of all hospitalizations for unintentional injuries among children result in permanent disability.[3]

The unintentional injury fatality rate among children ages 14 years and younger declined 45% in the United States since 1987. Despite this decline, unintentional injury remains the leading cause of death among children ages 1 to 14 years in the United States. In fact, 5,162 children ages 14 years and younger died in 2005 from an unintentional injury, and 6,253,661 emergency room visits for unintentional injuries in this age group occurred in 2006.[4] From 2000 to 2005, the leading cause of fatal unintentional injury among children was transportation-related followed by drowning and airway obstruction injury. Falls were the leading cause of nonfatal, hospital emergency room–treated childhood injury and accounted for 2.8 million visits in 2005.[1]

Leading causes of unintentional injury-related death vary according to a child's age and are dependent on developmental abilities and exposure to potential hazards, in addition to parental perceptions of a child's abilities and injury risk. Falls were the leading cause of nonfatal injury for all age groups less than 15 years. The least progress in the injury death rate decline was among infants less than 1 year of age, who had a decline of only 10%, compared with children in the age groups 1 to 4 years (42%), 5 to 9 years (42%), and 10 to 14 years (40%). Children less than 1 year of age have the highest rate of unintentional injury-related death, with a rate more than twice that of all children. Airway obstruction is the leading killer in this age group. In children, ages 1 to 4 years of age, drowning was the leading cause of injury death followed by transportation-related injury. The lowest rate of unintentional death among children less than 14 years of age is in the group of children 5 to 9 years of age. The most common cause of death in this age group and those children aged 10 to 14 years was motor vehicle occupant injury (Fig. 18-2).[2]

In all age groups, male children are at higher risk for unintentional injury than females. This can be attributed to a variety of factors, including biology (differences in temperament), exposure to risky behavior, gender socialization, and cognitive differences.[3] Race and ethnicity are also important factors in the risk for unintentional injury in children. American Indian and Native Alaskan children have the highest unintentional injury death rate at 15.3 per 100,000, and Asian or Pacific Islanders have the lowest fatality rate at 4.24 per 100,000. African-American and white children have approximately the same fatality rate, which has declined 44% and 48%, respectively, in these groups since 1987. In 1990, Hispanic and non-Hispanic children had similar fatality rates from unintentional injury at approximately 12.11 and 12.48 per 100,000, respectively. Since then, the fatality rate has declined by nearly 40 percent for Hispanic children and only 30 percent for non-Hispanic children. In 2005, 4,229 non-Hispanic children and 922 Hispanic children in the United States died from unintentional injuries. Although the number of fatal injuries among Hispanic children increased, the rate of injuries declined because of the increased population size. These racial and ethnic disparities have more to do with economic conditions than with biologic differences, because living in impoverished communities is a primary predictor of injury. Fatality rates from unintentional injury declined in each of the four regions of

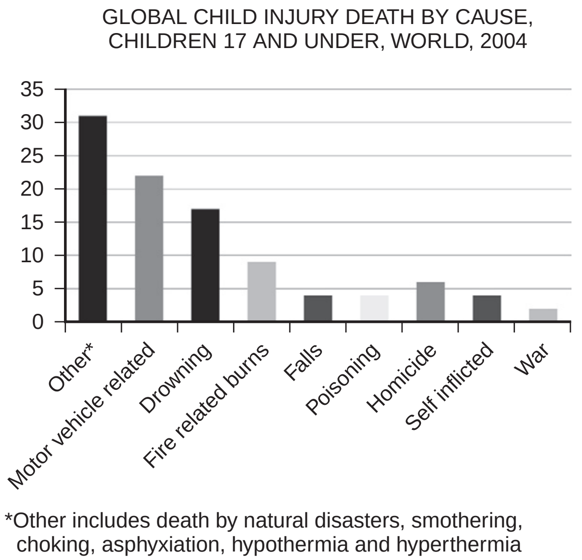

**FIGURE 18-1** Percentage of fatal injuries in children 17 years of age and younger worldwide in 2004. (From Peden MM, UNICEF, World Health Organization: Geneva, Switzerland, World Health Organization, 2008.)

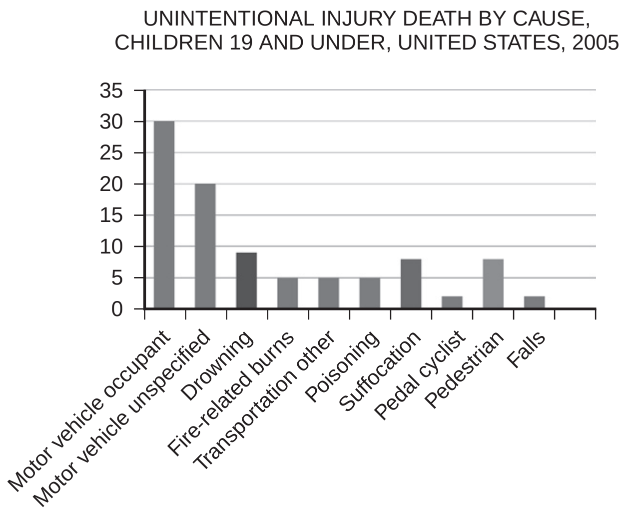

**FIGURE 18-2** Percentage of unintentional injury death in children 19 years of age and younger in the United States from 2000 to 2005. (From Borse NN, Gilchrist J, Dellinger AM, et al: CDC Childhood Injury Report: Patterns of unintentional injuries among 0-19 year olds in the United States, 2000-2006. Atlanta, Ga, Centers for Disease Control and Prevention, National Center for Injury Prevention and Control, 2008.)

the United States between 1987 and 2005. The largest decrease, almost 60%, was in the Northeast, while the Midwest had the smallest decrease, 40%. Since 1987, the South has consistently had the highest rate of fatality, 10 per 100,000 in 2005, and the Northeast has had the lowest, 4.56 per 100,000. Geographic differences in injury fatality rates reflect demographic differences and different levels of exposure to hazardous activities. At the state level, rates of unintentional injury fatality tend to be highest in the South, potentially because of large rural populations with high rates of poverty and limited access to trauma care. Overall, states with the lowest injury death rates were in the Northeast. Fire and burn death rates were highest in some of the southern states. Death rates from transportation-

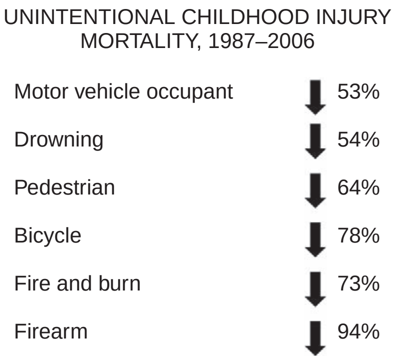

**FIGURE 18-3** Percentage decrease of unintentional injury mortality in children 19 years of age and younger in the United States from 1987 to 2006. (From Wallace AL, Cody BE, Mickalide AD: Report to the Nation: Trends in unintentional childhood injury mortality and parental views. Washington, DC, National Safe Kids Campaign, April 2008.)

related injuries were highest in some southern states and some states of the upper plains, while the lowest rates occurred in states in the northeast region.[1,4]

Over the last 20 years there has been a dramatic reduction in childhood injury death (Fig. 18-3). These extraordinary decreases in the injury death rate are due to multifaceted prevention strategies.

Intentional injury results in a fatal outcome from homicide, child abuse, or suicide. National and state efforts in this regard have led to continued reductions, and now these deaths represent a much smaller percentage of fatalities in children in the United States. Recognition of this intent requires referral to the child protection service for assessment. The resuscitation of these children is frequently a challenge, because abuse may be chronic, which results in a child with a limited physiologic reserve (refer to Chapter 27 on child abuse).[4]

## Resuscitation and Impact on Outcome

Resuscitation of the injured child includes the actions necessary to reverse and control the sudden alterations in physiologic homeostasis that occur as the result of injury. Children are remarkably resilient; however, the initial period of stability has been shown to be significantly shorter as age decreases.[5] Therefore, resuscitation is not complete until injuries have been definitively treated and the child displays physiologic stability without continued intervention.

Differences between children and adults with respect to patterns of injury, physiologic presentation, and management are important. Physicians who treat injured children must recognize and understand the important distinctions so that the resuscitation process addresses the special needs of the child.

The principle of a trimodal pattern of trauma-related mortality and morbidity in adults must be modified for children. In the trimodal model, the first group of injured children dies very rapidly after injury, within seconds or minutes, because of injuries to the central or peripheral nervous system and the central vasculature. Survival can only be improved in this group through prevention efforts, such as education, social awareness, and behavior modification. A second peak occurs from minutes to hours after the injury and is due to mass lesions in the central nervous system (CNS) (usually subdural

and epidural hematomas), solid organ injury, or collection of fluid in the pleural and pericardial space. These are the specific injuries that require rapid identification and treatment and are the focus of the advanced trauma life support (ATLS) protocol. Although initial physiologic compensation may have been sufficient to achieve some temporary accommodation, progressive dysfunction and exhausted reserves bring about a critical impairment of oxygen delivery and the child's eventual demise. Advances in the aggressive and systematic delivery of emergency medical services (EMSC) for children have a salutary effect upon preventable death in children. A third mortality peak occurs days to weeks after the initial injury and is the result of complications of injury, such as sepsis and systemic inflammatory response syndrome, leading to multiple organ failure syndrome.[6] This late peak in trauma-related mortality is less frequent in younger children.

# Resuscitation Principles

## PREHOSPITAL CARE

Systematic management following an injury to a child is essential to survival. The resuscitation process begins when emergency transport personnel first encounter the child in the field. The fate of any given child can turn on the decisions and interventions that transpire during these first crucial moments. In general, children fare worse than adults in the out-of-hospital phase of resuscitation. The injury-adjusted death rate for children is twice that of adults. Similarly, the survival rate for out-of-hospital cardiac arrest in children is only half that of adults.[7] Although part of this discrepancy results from the different causes of cardiac arrest in children and adults, unfamiliarity and inadequate training with children contributes to poor outcome. The failure rate for resuscitation interventions in the field is twice as high in children as adults; the failure rate for prehospital endotracheal intubation of children is close to 50%.[8] Unfamiliarity with pediatric resuscitation skills is understandable; trauma is the most common indication for pediatric ambulance transport, but accounts for less than 10% of total paramedic patient volume in most metropolitan areas.

The most important objectives for emergency personnel in the field are

- Recognition and treatment of immediate life-threatening dysfunction
- Assessment of the mechanism of trauma and extent of injuries
- Documentation of pertinent medical data
- Triage to the appropriate-level pediatric trauma facility

Add to these the additional challenges of comforting a terrified and hurt child, as well as a distraught parent, and the paramedic's task becomes formidable. Consequently, prehospital personnel function best by adopting strict protocols to treat the injured child. The priorities and techniques associated with pediatric field resuscitation are similar to those for emergency department care.

## PRIMARY SURVEY AND TREATMENT OF LIFE-THREATENING INJURIES

When the injured child encounters medical personnel, whether in the field or in the emergency room, events transpire in a rapid sequence that is dictated by a systematic protocol to recognize and treat acute injuries. This approach is designed to standardize diagnostic and treatment decisions so that individual variations in patterns of injury do not distract caregivers from recognizing and treating subtle injuries that can have a profound impact upon outcome. This systematic framework comprises a primary survey, a resuscitation phase, and a definitive secondary survey. The primary survey is the initial process of identifying and temporizing injuries that are potentially life-threatening and follows the "ABCDE" sequence (*A*irway, *B*reathing, *C*irculation, *D*isability, and *E*xposure). The system relies upon simple observations to assess physiologic derangement and immediate intervention to prevent death.

### Airway and Cervical Spine Control

Provision of airway control is perhaps the least controversial of all priorities in pediatric trauma management. The inability to establish and maintain a child's airway, leading to hypoxia and inadequate ventilation, continues to be a common cause of cardiorespiratory arrest and death. Significant clinical hypoxia is suspected when oxygen saturation is less than 95%.

Assessment of the airway includes inspection of the oral cavity; manual removal of debris, loose teeth, and soft tissue fragments; and aspiration of blood and secretions with mechanical suction. If a child is neurologically intact, phonates normally, and is ventilating without stridor or distress, invasive airway management is unnecessary. Airway patency can be improved in the spontaneously breathing child by use of the jaw-thrust or chin-lift maneuvers.

An airway that is unsecured because of coma, combativeness, shock, or direct airway trauma requires endotracheal intubation. A nasopharyngeal or oropharyngeal airway can improve management during bag mask ventilation but are temporizing measures until definitive control is established. In most cases, orotracheal intubation with in-line cervical spine stabilization is the preferred approach to airway control. Although nasotracheal intubation is recommended in nonapneic adult with potential cervical spine injury, this approach is not indicated and poorly tolerated in children.

The pediatric airway anatomy is unique and affects management technique. The child's larynx is anatomically higher and more anterior than that of the adult patient, necessitating an upward angulation of the laryngoscope to place the endotracheal tube properly. Removing the anterior half of the rigid cervical collar allows access to the neck for gentle cricoid pressure. The pediatric epiglottis is shorter, less flexible, and tilted posteriorly over the glottic inlet. Because of this, direct control of the epiglottis with a straight blade is usually necessary for proper visualization of the vocal cords. The vocal cords themselves are more fragile and easily damaged. The narrowest point in the pediatric airway is the subglottic trachea at the cricoid ring, as opposed to the glottis in adult patients. Therefore passage of the endotracheal tube through the vocal cords does not guarantee safe advancement into the trachea or avoidance of subglottic injury. The selection of an appropriate endotracheal tube is an important part of pediatric resuscitation. Internal diameter sizes can range from 3.0 to 3.5 mm in newborns to 4.5 mm at 1 to 2 years of age. After 2 years of age, internal diameter can be estimated by the following formula: internal diameter $=$ age/4 $+$ 4. Approximating the diameter of the patient's little finger is also useful. Because of the narrow subglottic trachea, an uncuffed endotracheal tube is indicated in children 8 years of age or younger (Fig. 18-4).[8,9]

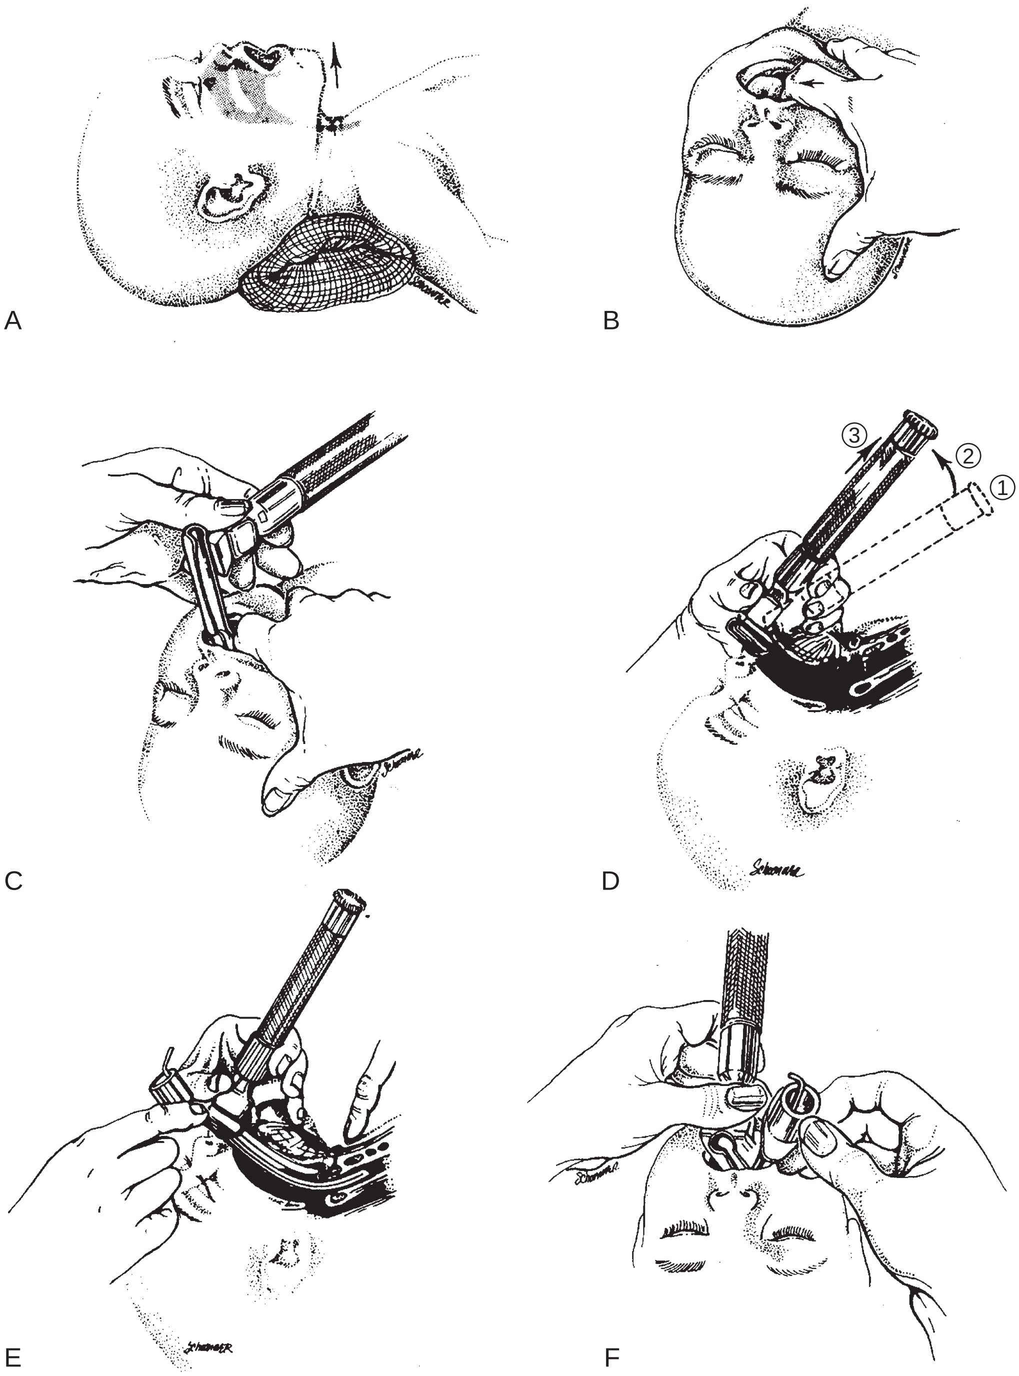

**FIGURE 18-4** Endotracheal intubation. **A,** The pediatric larynx and supraglottic space are anterior and angled cephaled compared with the position in adults. A posterior neck roll optimizes visualization of the vocal cords in children. **B,** The tongue is large relative to the space in a child's oral cavity. The tongue should be moved to one side of the oral cavity to facilitate exposure of the posterior pharynx and supraglottic area. **C,** The laryngoscope blade is inserted from the right side of the mouth and slides back along the vallecula. **D,** With the blade in the proper position and the child's neck slightly extended in the sniffing position, lifting the handle (positions 1, 2, and 3) raises the epiglottis and brings the vocal cords into direct vision. **E,** In all except newborns, the straight blade should be placed over the epiglottis to lift it, along with base of the tongue, to expose the larynx. A stylet with the tip curved within the endotracheal tube facilitates successful intubation. **F,** The endotracheal tube is held in place while the laryngoscope is removed and secured after verification of bilateral breath sounds. (From Eichelberger MR: Pediatric Trauma, Prevention, Acute Care, Rehabilitation. St Louis, Mosby, 1993.)

The technique of intubation depends on the urgency of establishing an airway. In the hypotensive, hypoxemic, comatose child, orotracheal intubation is accomplished without delay as an integral part of the resuscitation. In a more elective situation, more attention is given to adequate preoxygenation and premedication. An adequate oxygen saturation (i.e., more than 95%), as measured by pulse oximetry, is attempted by bag-mask ventilation with 100% oxygen. Thoracic trauma can preclude and make attainment of adequate oxygen saturation impossible before intubation. Inducing hypocarbia ($Pco_2$ = 28 to 32 torr) by hyperventilation is advantageous and can reduce intracranial hypertension.

Following preoxygenation using mask ventilation, children should receive atropine sulfate (0.1 to 0.5 mg) to ensure that the heart rate remains high during intubation. It is important to maintain heart rate, because this is directly proportional to cardiac output; stroke volume does not change in a child. Also, the child should be premedicated with intravenous sedatives and muscle relaxants. Appropriate sedatives include short-acting barbiturates, such as thiopental sodium (5 mg/kg), if volume status is normal, or a benzodiazepine, such as midazolam (0.1 mg/kg), if hypovolemia is suspected. Muscle relaxation is achieved with short-acting nondepolarizing agents (vecuroniurn bromide, 0.1 mg/kg) or shorter-acting depolarizing agents (succinylcholine chloride, 1 mg/kg). The presence of burns and devitalized tissue precludes the use of succiny1-choline because of the risk of hyperkalemia. Continuous monitoring of the intubated child with end-tidal carbon dioxide ($CO_2$) and pulse oximetry is essential to safe resuscitation.

In the rare circumstance, when tracheal intubation is not possible as a consequence of oral maxillofacial trauma or congenital anomaly, a surgical airway is indicated. A surgical crycothyrotomy is the preferred approach in older children (>10 years). Because this crycothyroid membrane is easily exposed through a transverse skin incision, placement of a small, uncuffed endotracheal tube via this incision is possible. The morbidity is less because of the superficial location of the crycothyroid membrane in contrast to an emergency tracheostomy. The crycothyrotomy should be converted to a formal tracheostomy, when the child is stabilized, to avoid subglottic stenosis.

In small children, the cricoid cartilage is a delicate structure and provides the majority of support to the trachea. Injury of this membrane during emergency cricothyrotomy can lead to significant morbidity and lifelong laryngotracheomalacia. To avoid this complication, children younger than 10 years of age should undergo needle cricothyrotomy and jet insufflation of the trachea. A 16- to 18-gauge intravenous catheter is used to access the tracheal lumen through the crycothyroid membrane, and is connected to a 100% oxygen source at a high flow rate of 10 to 12 L/min. Needle-jet ventilation is limited in children by hypercarbia that occurs in approximately 30 minutes; therefore this method is a temporary means of ventilation. Following stabilization of the child, endotracheal intubation or formal tracheostomy is necessary.[9]

### Breathing

Compromised breathing and ventilation in the injured child usually results from either head injury (impaired spontaneous ventilatory drive), or thoracic injury (impaired lung expansion). Recognition of the head-injured child is usually clear, while recognition of a thoracic injury that impairs lung expansion requires a detailed survey. The potential seriousness of these injuries is underscored by the fact that mortality rates for thoracic trauma in children approach 25%.[10]

Following thoracic trauma, air, fluid, or viscera can occupy the pleural space. Compression of the pulmonary parenchyma can result in impairment of gas exchange sufficient to produce respiratory distress. In the case of traumatic rupture of the diaphragm, loss of muscular integrity also has a direct effect on lung expansion. The pediatric mediastinum is extremely mobile; as pressure increases in the pleural space, the mediastinum is displaced to the opposite side, causing compression of the contralateral lung. The distortion of mediastinal vascular structures, along with the elevated intrathoracic pressure, can result in a critical reduction of venous return to the right atrium.

Loss of chest wall integrity from flail chest impairs ventilation and oxygenation. Consequently, paradoxical chest wall movement occurs during inspiration preventing complete lung expansion; treatment is best by assisted positive-pressure breathing. The force required to fracture multiple ribs in a child is enormous and is transmitted to the underlying lung parenchyma, resulting in a pulmonary contusion. Regions of parenchymal hemorrhage and edema impair ventilation-perfusion matching; the decrease in pulmonary compliance can dramatically increase the work of breathing, which can precipitate ventilatory failure.

Recognition of ventilatory compromise is usually not difficult, especially with a high index of suspicion. The sound of air movement at the mouth and nares is assessed, as are the rate, depth, and effort of respirations. On inspection, asymmetric excursion of the chest wall suggests a ventilatory abnormality. Percussion elicits dullness or hyper-resonance, depending on the presence of fluid or air in the pleural space, while breath sounds are decreased. With tension hemopneumothorax, mediastinal shift may be detected by tracheal deviation, displacement of the point of maximal impulse, and distention of neck veins caused by impaired venous return to the heart.

Mechanical ventilatory failure is life threatening and requires immediate treatment during the primary survey. All children require supplemental oxygen by nasal cannula, mask, or endotracheal tube. Endotracheal intubation and assisted ventilation are sufficient to treat hypoventilation caused by head injury, pain from rib fractures, flail chest, and pulmonary contusion. Simple hemopneumothorax may be well tolerated with supplemental oxygen until tube thoracostomy can be performed after the primary survey (Fig. 18-5). In cases of hemopneumothorax, which results in compromised ventilation or hypotension, a thoracostomy tube is required, often combined with endotracheal intubation and intravenous access for rapid fluid infusion. If tension is present, the hemodynamic derangements can be minimized by needle thoracostomy in the second intercostal space at the midclavicular line, followed by definitive thoracostomy tube. When endotracheal intubation has been performed, the child should receive 100% $Fio_2$, with a tidal volume of 10 to 12 mL/kg at a respiratory rate of 15 to 20 cycles/min. Oxygenation and ventilation should be manipulated to maintain an arterial $Po_2 > 80$ mm Hg and a $Pco_2$ of 28 to 32 torr, with a positive end-expiratory pressure (PEEP) not to exceed 5 cm $H_2O$. The goal is to prevent secondary brain injury by optimizing oxygenation and cerebral perfusion by minimizing intracranial pressure. Children with head trauma are best managed by moderate hyperventilation and hypocarbia ($Pco_2 = 30$ to 35 mm Hg) to reduce intracranial pressure.[6,9,11]

Tube thoracostomy is accomplished during this phase of resuscitation for symptomatic hemopneumothorax. A chest tube of adequate caliber to evacuate blood and air is inserted into the pleural cavity. The narrow intercostal space of a small child usually limits the size of the tube, but the largest caliber tube that can be placed is preferable (18° F to 20° F). The tube should be placed in the midaxillary line at the nipple level (fourth or fifth intercostal space) to avoid intra-abdominal

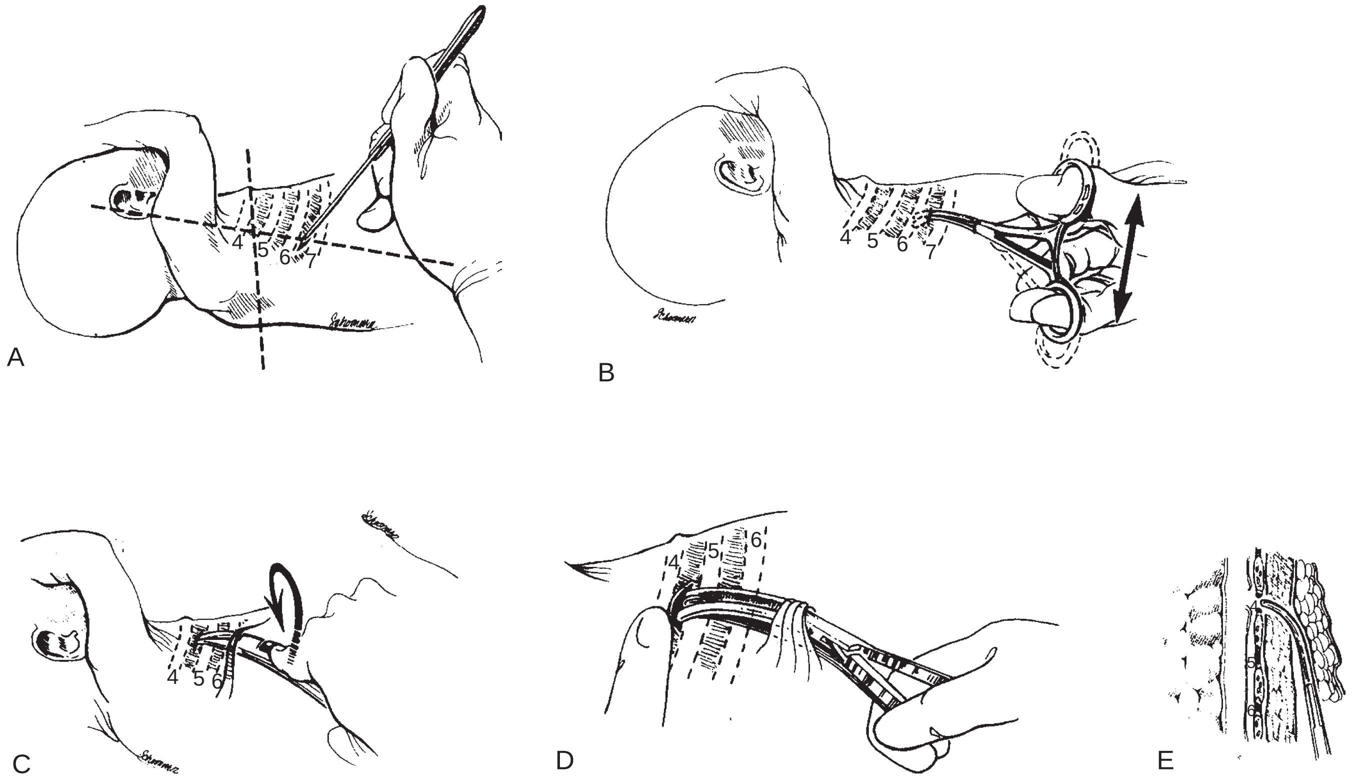

**FIGURE 18-5** Thoracostomy tube insertion. **A,** An incision is made in the midaxillary line just below the nipple in a male or inframammary fold in a female (fourth intercostals space). **B,** The dissection is carried out in a cephalad direction, subcutaneously over two ribs. A long subcutaneous track is preferable in a child to minimize air leak around the tube. **C,** The fourth intercostal space is the ideal place for thoracostomy tube placement. **D,** The entrance into the pleural space should be made just over and superior to the rib to avoid injury to intercostal vessels. **E,** Lateral view of the technique. (From Eichelberger MR: Pediatric Trauma, Prevention, Acute Care, Rehabilitation. St Louis, Mosby, 1993.)

placement through an elevated diaphragm. The tube should be directed posterior and cephalad to evacuate both blood and air. The tube is connected to a pleurovac closed-suction drainage system set at −15 cm $H_2O$. Persistent hemorrhage from a thoracostomy tube is uncommon in children; however, drainage of 1 to 2 mL/kg/hour is a sign of ongoing significant bleeding from a vascular or mediastinal injury that requires thoracotomy to identify the source of blood loss and to secure hemorrhage.

### Circulation and Vascular Access

The third priority in the sequence of the primary survey is the rapid assessment of circulation and the establishment of venous access. Seriously injured children often have normal vital signs, even with significantly decreased circulating volume as a result of a remarkable cardiovascular reserve. This compensation that occurs in the injured child delays the early hemodynamic signs of hypovolemia until relatively late in their physiologic decline. A high index of suspicion based on the mechanism of injury and continuous careful scrutiny of physiologic parameters and clinical signs is necessary to minimize morbidity.

A reliable sign of adequate perfusion is a normal mental status. As the child is resuscitated, clinical signs of the efficacy of resuscitation should be monitored. Improvement in the following parameters is consistent with hemodynamic stability and success of resuscitation:

- Slowing of the heart rate (<100 beats/min)
- Increased pulse pressure (>20 mm Hg)
- Return of normal skin color
- Increased warmth of extremities
- Clearing of the sensorioum (improving Glasgow Coma Scale [GCS] score)
- Increase in systolic blood pressure (>80 mm Hg)
- Urinary output of 1 to 2 mL/kg/hour in infants and 1 mL/kg/hour in adolescents

After establishing an adequate airway, provision of venous access in a hypovolemic child is often a challenge. Two functioning catheters are best in all cases of significant injury. Optimal circumstances would be to achieve venous access above and below the diaphragm, given the potential for extravasation of resuscitation fluids from occult intra-abdominal venous injuries. Nevertheless, in children any peripheral venous access is useful.

Two attempts should be made to place large-bore peripheral IVs in the upper extremities. If percutaneous placement is unsuccessful, insertion of an intraosseous (IO) line is useful in a child less than 6 years of age. If more than 6 years of age, a venous cutdown performed at the ankle is best. The greater saphenous vein is easily exposed through short transverse incisions, 0.5 to 1 cm proximal and anterior to the medial malleoli. The exposed vein can be suspended over a silk ligature, and the largest appropriate intravenous catheter is introduced into the vessel lumen under direct vision. Trans-section or ligation of the vein is not necessary (Fig. 18-6).

Because central venous catheterization can result in significant complications, such as laceration of the subclavian or

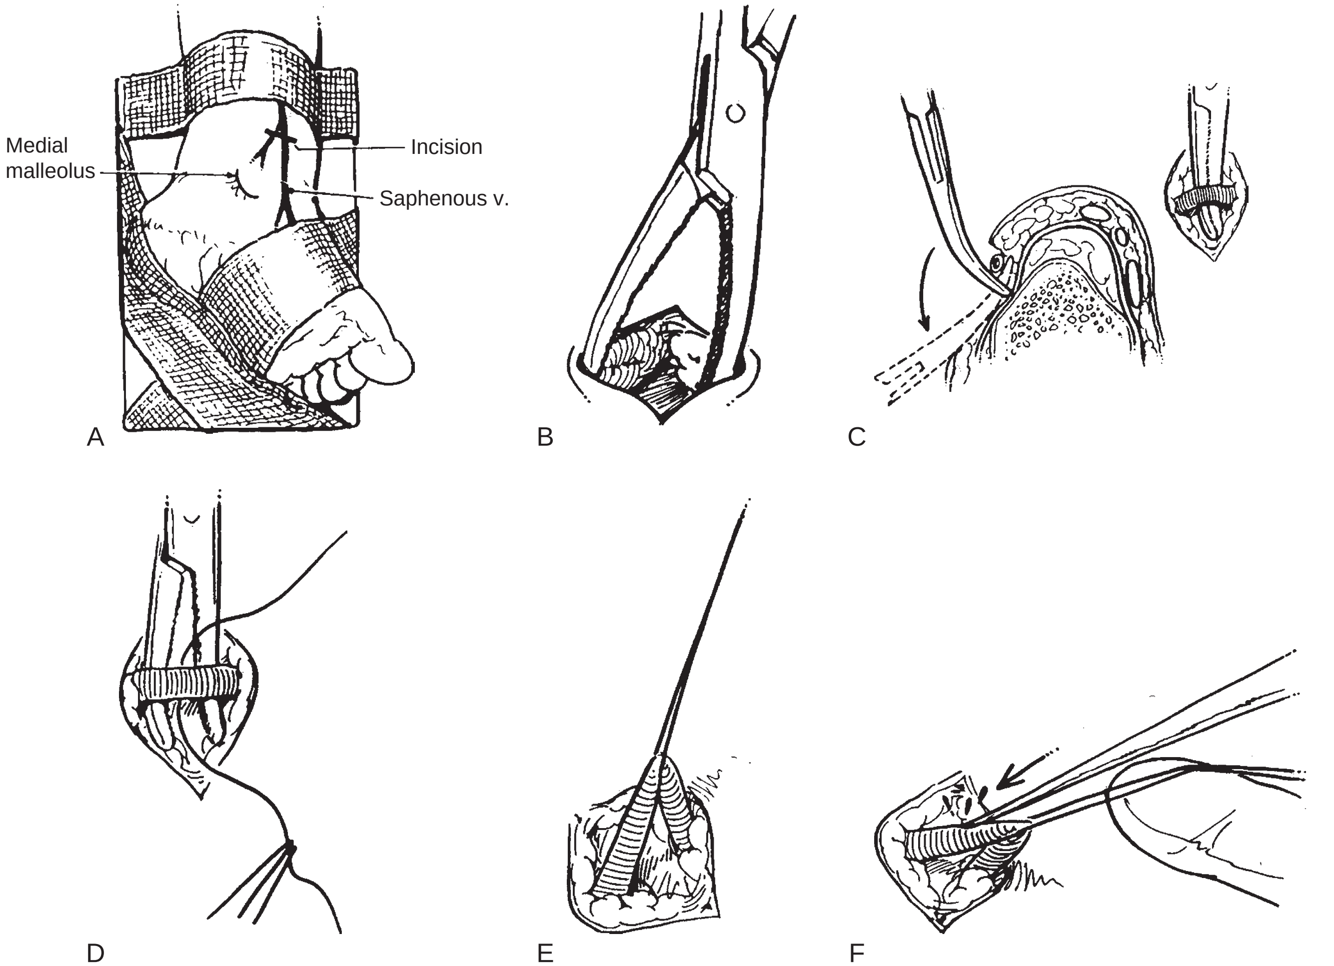

**FIGURE 18-6** Greater saphenous vein cannulation. **A,** Consistent emergency venous access is achieved at the ankle, anterior to the medial malleolus via the saphenous vein. **B,** A transverse incision is made anterior to the medial malleolus (1 cm anterior and 1 cm cephalad). Perpendicular dissection in the incision exposes the saphenous vein. **C,** The vein is dissected circumferentially. **D,** A suture ligature is passed around the vessel. **E** and **F,** Gentle traction on the suture facilitates catheterization of the vein. (From Eichelberger MR: Pediatric Trauma, Prevention, Acute Care, Rehabilitation. St Louis, Mosby, 1993.)

femoral artery, this technique is less useful. The femoral route is preferred because of ease of access. If subclavian venous access is necessary, the child should be positioned in the Trendelenberg position, with the head maintained in a neutral position without the placement of a posterior shoulder roll. This position provides optimal cross-sectional area of the subclavian vein in both children and adults.[12]

An intraosseous (IO) line is a simple, reliable, and a safe route for administration of fluids, blood products, and medication. The technique is applicable in children 6 years of age and younger, because of the well-perfused marrow of early childhood. The preferred site for IO insertion is through the flat anteromedial surface of the tibia, about 2 to 3 cm below the tibial plateau. The needle is angled 60 degrees from horizontal and pointed toward the foot. The cortex is penetrated and the marrow cavity detected by aspirating blood and particulate material. Alternative sites include the midline distal femur, 3 cm above the condyles directed cephalad in small children, and the distal tibia above the medial malleolus or the proximal humerus in the adolescent. Specially designed IO needles should be available in the pediatric resuscitation room to facilitate this maneuver; however, a 14- to 16-gauge needle can be used. The complication rate of IO is low but includes osteomyelitis, cellulitis, fracture, growth plate injury, fat embolism, and compartment syndrome.

As soon as vascular access is established, fluid resuscitation with a bolus of fluid is begun. Generally, isotonic crystalloid solution, such as lactated Ringer solution, is administered in 20 mL/kg increments. If evidence of hypovolemia persists after 40 mL/kg has been given, transfusion of ABO-matched packed red blood cells (RBCs) is initiated in a bolus of 10 mL/kg. Packed RBCs have the desirable qualities of raising colloid oncotic pressure and effecting a more rapid and sustained intravascular expansion than crystalloid. In addition, the red blood cell provides hemoglobin to increase oxygen-carrying capacity. All fluids (crystalloid, colloid, and blood) should be warmed during infusion. This is accomplished by use of a microwave to heat crystalloid solutions and use of a warming device.

It is important to reassess the child's response to resuscitation continually to characterize the nature and extent of the injuries and to avoid the complications of excessive fluid resuscitation. As perfusion is restored, the rate of fluid infusion is gradually reduced to avoid unnecessary fluid administration. Pulmonary edema rarely occurs in normal lungs, but considerable morbidity results from fluid

sequestration in a region of pulmonary and cerebral contusion. If hemodynamic stabilization does not occur with crystalloid and blood resuscitation, hemorrhage is likely from an intra-abdominal or pelvic source, cardiac dysfunction because of tamponade, contusion, or tension hemopneumothorax; cerebrospinal injury, such as atlantooccipital disassociation; and profound hypothermia.[9,13]

### Disability

A rapid neurologic evaluation is included in the primary survey to identify serious injuries that may have immediate consequences for airway management. A rapid method for describing gross cerebral function is the AVPU pneumonic: alert, voice responsive, pain responsive, or unresponsive. An assessment of pupillary responsiveness and symmetry is also useful. Transtentorial herniation secondary to an expanding intracranial hematoma causes ipsilateral pupillary dilation and loss of light reflex. Direct trauma to the eye is an equally common cause of unilateral anisocoria. Characterization of extremity posturing as decorticate or decerebrate indicates the loss of cortical or global brain function, respectively. In the comatose child with a unilateral fixed and dilated pupil, measures to reduce intracranial pressure (ICP) are imperative. These include early controlled endotracheal intubation to keep the $Pco_2$ regulated (30 to 35 mm Hg) with moderate hyperventilation, which causes cerebral vasoconstriction and decreases cerebral blood flow. This lowers brain volume and ICP with resulting increase in cerebral perfusion pressure (CPP). The reverse Trendelenburg position, in which the head is slightly elevated by 30 degrees, can also reduce intracranial hypertension but should be employed in children with normal cardiac function.

### Exposure

Complete exposure of the child is essential to facilitate a thorough examination and identification of injury. A conscious child does not understand the need for such action, so exposure must be done carefully. A thorough primary survey on a stable child with a normal GCS score can be performed without removing all items of clothing simultaneously. Children are particularly apprehensive about exposing an injury that had previously been covered. Attention to the special sensitivities of the child in this regard frequently results in a more efficient resuscitation.

In a child, hypothermia affects physiologic parameters, such as cognitive function, cardiac activity, and coagulation. It is important to maintain core temperature above 35 to 36 degrees Celsius. A warm resuscitation room preserves core body temperature and minimizes heat loss. Similarly, resuscitation fluid and inhaled gases should be warmed and humidified. Overhead and bed warmers are essential but a radiant warmer is best for the injured infant.

## RESUSCITATION PHASE

The cornerstone of resuscitation is continuous reappraisal of the child's response to therapeutic intervention. Deterioration at any point requires repetition of the primary survey. After the ABCs are completed and life-threatening injuries are stable, place a gastric tube and urinary catheter, followed by removal of blood for analysis and establishment of a cardiac monitor.

In children, acute gastric dilation can cause both respiratory compromise and vagus-mediated bradycardia. Gastric decompression to evacuate the stomach and reduce the risk of vomiting and aspiration is important in all injured children, especially those with a decreased level of consciousness. Assessment for a stable midface and for presence of cerebrospinal fluid (CSF) rhinorrhea are important before placement of nasogastric tube for decompression. If abnormal, gastric tube placement is contradicted.

A urinary catheter is also placed following a thorough perineal assessment, including a rectal exam prior to placement. In instances of a high-riding prostate, meatal bleeding, perineal or scrotal ecchymosis, or unstable anterior pelvic fracture, a retrograde urethrogram is indicated before insertion of the catheter.

An electrocardiogram (ECG) is essential to monitor cardiac rhythm, which is rarely abnormal. Secondary abnormalities are occasionally seen and include sinus bradycardia because of advanced shock; or electromechanical dissociation from hypovolemia, tension pneumothorax, or pericardial tamponade; and ventricular fibrillation because of hypothermia or acidosis. Ventricular ectopy, low voltages, and signs of ischemia can accompany myocardial contusion. Beyond evaluating the actual rhythm, diffuse low voltage may be the first indication of hemopericardium.

After vascular access, blood and urine is obtained for laboratory analysis, hemoglobin, urinalysis, and arterial blood gas analysis. Blood alcohol level and a toxicology screen are not routine in children but reasonable in adolescents. Blood should be drawn for typing and crossmatching for possible transfusion.[13,14]

## NEURORESUSCITATION

Brain injury is the most common cause of acquired disability and mortality during childhood. It is estimated that 1 in 500 children in the United States sustains a brain injury, 7000 children die from head injury, and 28,000 children become permanently disabled.[15,16] Largely a result of prevention strategy and of regional trauma systems, the overall mortality from severe traumatic brain injury has decreased from approximately 50% in the 1970s to 36% in 2006. In children, the current overall mortality from injury is 3%; the primary cause of death in 70% of the cases is CNS injury. Overall, the outcome for children older than 3 years of age is better than for adults with comparable injuries; however, outcome in young children (<3 years) is often poor.[6,9,17]

Traumatic brain injury can be defined as either primary or secondary. Primary brain injury is the structural derangement of cerebral architecture that occurs from direct, mechanical impact, resulting in cellular and vascular disruption, infarction, or tissues loss. The child's brain is susceptible to injury of deep white matter shear, punctate hemorrhage, brain swelling, and linear, nondepressed skull fractures rather than a mass lesion, such as subdural, epidural, intracerebral hematoma, and depressed skull fractures, which are more frequently encountered in adults. Children, however, have a higher incidence of epidural hematoma, perhaps because the thinner, less rigid skull is more apt to fracture and lacerate the meningeal artery. The proportionately larger size of the cranium in children, along with a less muscular and more flexible ligamentous cervical spine, may account for the increased incidence of diffuse axonal injury in the injured child.

Primary brain injury responds only to prevention efforts, while the secondary brain injury is the target of clinical neuroresuscitation. Secondary brain injury occurs as a result of decreased cerebral perfusion after the traumatic event. Both diffuse and regional brain swelling impair oxygen and substrate delivery largely as a result of increasing intracranial pressure (ICP) and its effect upon cerebral perfusion pressure (CPP). CPP, ICP, and mean arterial pressure (MAP) are related by the following formula: $CPP = MAP - ICP$. Resuscitation should optimize CPP by controlling ICP and maintaining MAP. When ICP exceeds venous outflow pressure (as a result of brain swelling), it acts as a Starling resistor and determines the pressure gradient for cerebral blood flow. Normal CPP values and the ideal range of ICP in children with severe brain injury are not clear.[17] Favorable outcomes in children are possible by maintaining the ICP less than 20 mm Hg in all ages and a CPP greater than 45 mm Hg in children younger than 8 years of age and 70 to 80 mm Hg in older childen.[18]

Efforts to reduce secondary brain injury focus upon maintaining a therapeutic ICP and CPP and the normalization of MAP. The most expeditious method is intubation and controlled hyperventilation—initially, by reducing $Pco_2$ to a range of 30 to 35 mm Hg, while maintaining $Po_2$ greater than 100 mm Hg, and pH to $7.40 \pm 0.05$. Hypocarbia and alkalosis promote cerebral vasoconstriction, limiting cerebral blood volume and lowering ICP. The effect is rapid but can be limited in duration by re-equilibration of cerebrospinal fluid (CSF) pH balance. The maximal duration of the effect is unknown but may range from several hours to several days. Current therapy maintains the $Pco_2$ in the range of $35 \pm 5$ mm Hg. This regimen avoids excessive hyperventilation, which has been found to be deleterious in severe brain injury by converting borderline regions of cerebral ischemia into infarction.[17] A ventriculostomy is usually placed to allow CSF to drain to further optimize CPP. Repeat computed tomography (CT) of the head is indicated 24 to 48 hours after injury to assess the extent of brain edema, to identify new infarcts, or to demonstrate the development of a new hematoma or large contusion, which may require evacuation. The ventilation and fluid hydration status are reassessed and optimized.

If measures fail to control ICP, then osmotherapy with 20% mannitol rapid bolus intravenous infusion is administered: 0.25 gm/kg to 0.5 gm/kg/dose every 4 to 6 hours. Mannitol is withheld if the serum sodium concentration is greater than 145 meq/L, serum osmolarity is greater than 310 mOsm, urine output is less than 0.5 mL/kg/hour, or blood pressure is low. Mannitol exerts a therapeutic effect by creating a hyperosmolar environment in the cerebral microcirculation; this improves brain oxygen delivery by exerting a diuresis of free water from the cerebral interstitium, which improves red blood cell rheology.[17]

The induction of mild to moderate hypertension may reverse abnormal ICP and raise CPP by improving brainstem microvascular perfusion.[19] Therapy is begun with dopamine 5 to 20 μg/kg/min intravenous infusion with avoidance of cerebral edema.

Hyperthermia and seizures are common after traumatic brain injury and adversely affect efforts to normalize ICP and CPP. Both fever and seizures promote further secondary brain injury by increasing metabolic demand of the compromised brain. Therefore core temperature in children is maintained in the normal range (35° to 36° C) with acetaminophen, 10 mg/kg/dose every 4 to 6 hours. Cooling blankets may be necessary for recalcitrant fever. A single seizure in a child after the injury and resultant normal neurologic assessment does not require treatment. Seizures that occur within 1 week after injury is treated with phenobarbital in children less than 1 year of age, and with dilantin in children greater than 1 year of age. Either drug is administered by one-time intravenous therapy of 10 to 20 mg/kg, followed by daily dosage of 5 mg/kg/day. Treatment is discontinued after 7 days. Children who develop a late seizure require long-term anticonvulsant medication. Whether the comatose child who has not demonstrated seizure activity requires anticonvulsant prophylaxis during the resuscitation process is controversial.[20]

## COAGULOPATHY

Dysfunctional coagulation related to injury occurs in several circumstances: extreme hypothermia, massive transfusion, and severe brain injury. Hypothermia causes excessive bleeding by reducing the efficiency of enzymatic processes that cause coagulation. Massive transfusion, defined as the acute administration of blood products equal to or greater than one blood volume (65 to 80 mL/kg) causes coagulopathy by hypothermia. Another mechanism results from storage of blood in anticoagulants containing ethylenediaminetetraacetic acid or citrate (citrate-phosphate-dextrose), both of which chelate calcium and inhibit the calcium-dependent steps of the coagulation cascade. Acute hypocalcemia is another consequence of massive transfusion.

The most common mechanism by which massive transfusion causes coagulopathy, is dilutional thrombocytopenia. Coagulopathy resulting from dilution of clotting factors is much less common because of a much greater functional reserve of these components. As continued hemorrhage depletes circulating platelets and blood is replaced with RBCs, a progressive reduction in the platelet count ensues. With acute injury, a decrease of platelet count to 50,000 can produce surgical bleeding. Such drastic reductions in platelet levels requires a massive transfusion of at least two blood volumes. Platelet levels less than 100,000 signify impending coagulopathy, and levels of 50,000 or less require platelet transfusion. Administration of ABO-matched platelets at an initial dose of 0.1 U/kg raises the platelet level by about 40,000.

Severe head injury is also associated with a coagulopathy unrelated to platelet dilution. Presumably, large concentrations of procoagulant tissue thromboplastin are released from cerebral laceration. These thromboplastins initiate disseminated intravascular coagulation, resulting in a consumptive coagulopathy in which clotting factors and fibrinogen are depleted as well as platelets. Coagulopathy after head injury is a grim prognostic sign. Treatment requires administration of matched fresh frozen plasma at a dose of 15 to 30 mL/kg. Cryoprecipitate contains large amounts of fibrinogen, factor VIII, factor X111, and von Willebrand factor and can be given at a dose of 0.1 U/kg in addition to fresh frozen plasma. Administration of fresh frozen plasma, cryoprecipitate, or both may also be required in the setting of preexisting coagulopathies, such as hemophilia, von Willebrand disease, and advanced liver disease.[9]

It is clear that the coagulopathy associated with traumatic injury is a result of multiple independent but interacting

mechanisms. Early coagulopathy is driven by shock and requires thrombin generation from tissue injury as an initiator. Following initiation and further activation of anticoagulant and fibrinolytic pathways, the acute coagulopathy of trauma-shock is propagated by events associated with the care of the traumatically injured child, specifically acidemia, hypothermia, and dilution.[21]

## Damage Control

The goal of "damage control" is to reverse the sequelae of shock. Severely traumatized children who require operative intervention are at risk for hypothermia, acidosis, and coagulopathy. In these circumstances, the child may require emergent completion of the surgical procedure using a process of damage control surgery. The fundamentals of damage control in children are the following:

1. Exposure and control of vascular or solid organ hemorrhage
2. Control of contamination from hollow-viscus injury
3. Packing of the abdomen
4. Temporary abdominal closure
5. Transport to the pediatric intensive care unit (PICU)

All measures available for core rewarming should be used in these children. Efficient and rapid abdominal closure is critical. Since the early descriptions of the wound vacuum-assisted closure (VAC) technique, commercially produced products have been developed for managing these open abdominal wounds by temporary abdominal closure.[22] The VAC allows for a rapid abdominal closure as well as minimizing the risk of abdominal compartment syndrome post-operatively in the PICU during the physiologic and biochemical restoration phase. The VAC has also been shown to be of benefit in children with head injury by optimizing cerebral blood flow.

During damage control, blood products should be used in a 1:1:1 ratio of RBC to plasma to platelets. The decision to return to the operating room for formal closure occurs when all aspects of physiology have been restored.[23]

## Pain Management

The primary goal of acute pain management is to reduce the stress of the injured child and to improve outcome. Acute pain serves as a noxious stimulus that leads to the activation of the physiologic stress response. The result is a disruption in the neuroendocrine response, which has a profound and deleterious effect upon metabolism, thermoregulation, wound healing, and immunity.

The following are critical elements in the pain management of injured children:

- An experienced interdisciplinary team, lead by a clinician devoted to pain management
- Ensuring the least possible pain
- Recognizing that effective pain management requires constant adjustment
- Recognizing that anxiety needs to be considered and treated, because it may alter the effectiveness of pain treatment
- The ability and knowledge to effectively use all pain therapy in real-time coordination with the rest of the child's supportive care and treatment plans

A team-oriented, protocol-based algorithm that attempts to control pain in this environment will further enhance the overall success of the emergency management of these children.[24]

## Conclusion

A systematic approach to the injured child saves lives. Nevertheless, prevention of injury is essential to children.

The unintentional childhood injury death rate has declined nearly 48% during the past 25 years.[4] Among the most notable advances in childhood injury prevention are the declines in death rates for unintentional firearm (94%) and bicycle-related injury (78%). The death rate from fire and burn injury declined 53%, while that of pedestrian injury dropped 64%. Unfortunately, the motor vehicle occupant death rate, particularly among children ages 5 to 9 years, has been slow to decline, and the death rate from airway obstruction injury among infants remains unchanged.

Many factors have contributed to the overall dramatic decline in the unintentional childhood injury death rate. It is clear that the highest priority should be on injury prevention with particular emphasis placed on minimizing injury risk to minorities, younger children, and motor vehicle occupants. Once injury occurs, proper resuscitation can save lives.

# CHAPTER 19

# Thoracic Injuries

David E. Wesson and Charles S. Cox, Jr.

## Epidemiology and Prevention

Injuries to the chest wall, diaphragm, lungs, and mediastinal structures occur in about 25% of children treated in level I pediatric trauma centers, usually after high-energy blunt or penetrating trauma. Change in velocity, $\Delta V$, is a strong predictor of significant injury for children in motor vehicle crashes.[1] Low-energy mechanisms, such as simple falls from playground equipment, seldom cause chest injury. Thoracic injuries range in severity from minor to rapidly fatal, but virtually all chest injuries can be treated successfully if they are promptly diagnosed and appropriately treated. Although chest injuries are less common than injuries to the abdomen, soft tissues, and extraaxial skeleton, they are more lethal. Because of the impact required, patients who have sustained such injuries have a significant risk of mortality. In fact, thoracic injuries account for a high proportion of all trauma deaths not caused by central nervous system (CNS) injury.

As with most types of pediatric trauma, the male-to-female ratio is between 2:1 and 3:1. Thoracic injuries can be classified by anatomic site (e.g., rib fracture, pulmonary contusion, bronchial laceration), mechanism (blunt or penetrating), or threat to life (immediate or potential). Although most serious blunt injuries to the chest are motor vehicle–related in all age groups, the proportion of children injured as pedestrians is much higher than in adults. The causes of penetrating thoracic injuries in teenagers mimic those in adults—mostly knife and gunshot wounds. BBs or pellets fired from air guns, although often considered to be relatively innocuous, may also be life threatening.[2] The causes of penetrating injuries in preadolescent children include a number of other unusual mechanisms, such as impalement by shards of broken glass or metal rods.[3]

The most common thoracic injuries seen clinically are listed in Table 19-1. Autopsy series, which include prehospital and emergency department deaths, reveal a higher proportion of rapidly fatal, major vascular and cardiac injuries.[4] In adults, rib fractures are by far the most common type of blunt trauma to the chest. In children, pulmonary contusions are the most frequent.[5,6] Tracheobronchial lacerations are more common in children than in adults, whereas the opposite is true for traumatic rupture of the aorta.[7]

The most common thoracic injuries are lung contusion, pneumothorax, hemothorax, and fractures to the ribs, sternum, or scapula. Injuries to the heart, aorta, trachea, bronchi, and diaphragm are much less common but potentially more dangerous. The most common *immediately* life-threatening injuries to the chest are airway obstruction, tension pneumothorax, massive hemothorax, and cardiac tamponade. Open pneumothorax and massive flail chest are rare. The most common *potentially* life-threatening injuries of the chest are myocardial contusion, aortic disruption, ruptured diaphragm, and tracheobronchial disruption. Esophageal rupture is rare.

The relative incidence of blunt and penetrating thoracic trauma varies widely, depending on the amount of violence in the community. Peterson and colleagues[3] reported a large series of adults and children with thoracic trauma. Blunt injuries comprised 81% of thoracic injuries in children 12 years of age or younger; penetrating injuries accounted for 58% of chest injuries in adolescents. In Nakayama's series, 97% of thoracic injuries in children up to 17 years of age were blunt.[6] Meller[8] reported a series in which nearly all wounded teenagers had penetrating injuries. The National Pediatric Trauma Registry reflects the combined experience of many pediatric trauma centers across North America. From 1985 to 1991, more than 25,000 cases were reported to the National Pediatric Trauma Registry, including 1553 cases with thoracic injury.[5] Eighty-six percent of injuries were blunt (mostly motor vehicle related). The remaining 14% were penetrating (mostly stab or gunshot wounds).

The overall mortality rates for blunt and penetrating cases were almost identical at 15% and 14%, respectively.[5] Mortality increases with the number of associated injuries. Most of the deaths in the group that had blunt trauma were caused by associated head injuries, whereas most of the deaths in the group with penetrating injuries resulted from the chest injuries themselves. Overall, thoracic injuries were second only to CNS injuries as the cause of death in the National Pediatric Trauma Registry. Most deaths from chest injuries occur at the scene of the accident or in transit to the hospital and result from fatal injuries to vital organs. Patients with thoracic injuries who reach the hospital alive are potentially salvageable.

Although the ratio of blunt-to-penetrating injuries varies in adults and children, the spectrum of chest injuries and the basic principles of diagnosis and treatment are the same for all ages. The most common injuries—pulmonary contusion, rib fracture, pneumothorax, and hemothorax—can be treated with simple measures, such as tube thoracostomy, oxygen, and analgesia. Approximately 20% of patients with these injuries also require endotracheal intubation and

mechanical ventilation, often for the management of associated head injuries.

Several thoracic injuries virtually always require operation: major airway lacerations, aortic injuries, structural cardiac and pericardial injuries, and esophageal perforations. One of the greatest challenges in thoracic trauma is to recognize the rare cases that need an operation as early as possible during the course of treatment. In Nakayama's series, 2 of 3 patients with penetrating injuries and only 3 of 83 patients with blunt injuries had chest operations.[6] In Peterson's report, 15% of the children with blunt injuries required thoracotomy (about the same as in adult series). Forty percent of those with penetrating injuries required surgery (far higher than in adult series).[3]

Although clinicians are naturally concerned with the needs of individual patients, no consideration of chest injuries in children would be complete without mentioning prevention. Motor vehicle accidents and gunshot wounds cause the vast majority of severe pediatric thoracic injuries. These injuries are all preventable. Increasing the use of seat belts and child restraints would substantially reduce the risk for injury to motor vehicle occupants. Reducing the illegal use of firearms would also have major benefits, especially for teenagers. Chest protectors may be effective in reducing the incidence of chest injuries, including *commotio cordis* in young athletes.[9,10] In combination, these measures would substantially reduce the incidence and severity of pediatric thoracic trauma and the deaths and disabilities which result from it.

## Clinical Presentation

The pathophysiology of thoracic trauma and the anatomy and physiology on which management strategies are based differ significantly between children and adults. The most important anatomic factors that distinguish children are the relatively narrow airway, which is prone to obstruction, the anterior and superior position of the glottis, which makes nasotracheal intubation difficult and therefore inappropriate in an emergency, and the short trachea, which increases the risk of endobronchial intubation. The increased oxygen consumption and low functional residual capacity of children predispose them to hypoxia. Because young children rely largely on their diaphragm to breathe, any increase in intra-abdominal pressure compounds the problem by restricting diaphragmatic excursion.

Children with significant thoracic injuries may present with minimal signs and symptoms. A large adult series from the Maryland Institute of Emergency Medical Services Systems (MIEMSS) found that two thirds of patients with thoracic injuries arrived with stable vital signs.[11] This same finding was reported in children.[8] About 25% of the patients with significant intrathoracic injuries in the MIEMSS series did not have a rib fracture. These "occult" injuries included pneumothorax, hemothorax, myocardial contusion, cardiac rupture, tracheobronchial injury, pulmonary laceration, ruptured diaphragm, and ruptured aorta.

The ribs of a child are more pliable than those of an adult. Consequently, rib fractures are much less common in children. However, it is important to note that because of the elasticity of the chest wall in childhood, severe thoracic injuries may occur without injury to the chest wall or external signs of injury. In Nakayama's series, less than half of the children with significant thoracic injuries had rib fractures.[6] The compressibility of the chest wall may also explain why traumatic asphyxia is almost unique to children and why major airway trauma is so much more common in children than in adults.

The mediastinal structures are more mobile in children than in adults. Therefore tension pneumothorax is more likely to shift the mediastinum, compromising ventilation of the contralateral lung and impairing return of venous blood to the heart.

## Diagnosis and Initial Resuscitation

Diagnosis and initial treatment of patients with traumatic chest injury must proceed simultaneously. Although the manifestations of thoracic injury may be immediate or delayed by hours or days, the initial goal should be to rule out injuries that are immediately life threatening, such as airway obstruction, tension pneumothorax, massive hemothorax, and cardiac tamponade.

All injury victims should be managed according to the principles of the Advanced Trauma Life Support (ATLS) Program of the American College of Surgeons.[12] The overall plan is as follows:

1. Primary survey
2. Resuscitation of vital functions
3. Detailed secondary survey
4. Definitive care

All children with thoracic trauma must have supplemental oxygen, two large-bore intravenous lines, and a nasogastric (NG) tube to prevent gastric distention. A NG tube may also reveal an abnormal position of the esophagus or stomach, thereby indicating aortic injury or a ruptured diaphragm. Children with thoracic trauma should be observed closely. Vital signs and oxygen saturation in arterial blood ($SaO_2$) should be continuously monitored. If the child is intubated, end-tidal carbon dioxide should be monitored continuously or checked frequently. Blood should be available for transfusion. The equipment and skilled personnel needed to address

breathing problems and to manage the airway with suction, oral airways, endotracheal tubes, laryngoscopes, and a bag-valve-mask apparatus must always be on hand, especially during transport and diagnostic procedures.

Life-threatening injuries should be identified *and* treated during the initial resuscitation phase of the ATLS protocol. The first priority is to clear and secure the airway. Endotracheal intubation may be required. After intubation, the position of the endotracheal tube must be checked by observing chest excursion, listening for bilateral air entry, monitoring end-tidal carbon dioxide, and obtaining a chest radiograph. A colorimetric carbon dioxide detector may be used to verify endotracheal tube position, especially in the prehospital setting.[13]

The second priority is to ensure adequate ventilation. Tension pneumothorax, if present, should be treated before a radiograph is obtained. Occasionally, open pneumothorax or massive flail chest requires intubation and assisted ventilation during the initial resuscitation. Persistent shock despite adequate fluid administration usually indicates ongoing (most likely abdominal) blood loss. However, if no obvious cause of hypovolemia can be found, the possibility of acute pericardial tamponade should be considered; this disorder can be relieved, at least temporarily, by pericardiocentesis.

The indications for urgent thoracotomy may become obvious at any stage (Table 19-2). The most common indications are massive bleeding, massive air leak, and cardiac tamponade. Emergency room (ER) or resuscitative thoracotomy is a controversial technique that does not seem to have clear indications or contraindications. In the report from MIEMSS,[11] none of 39 adult patients who presented without vital signs in the ER survived after emergency thoracotomy. However, emergency thoracotomy may be lifesaving in children, especially those with penetrating cardiac injuries. Powell and colleagues reported a 26% survival rate in a series of children and adolescents who had ER thoracotomy.[14] These authors recommended thoracotomy in the ER for post-traumatic arrest, or near arrest, in the following three situations:

1. All cases of penetrating thoracic trauma
2. Blunt trauma with acute deterioration but signs of life in the ER
3. Blunt trauma with signs of life at the scene when the scene is in proximity to the hospital

The incision for emergency thoracotomy should be on the left anterolateral chest wall in the fifth interspace. A rib spreader should be used. If evidence of pericardial tamponade exists, the pericardium should be opened longitudinally, anterior to the phrenic nerve. Cardiac wounds should be controlled by direct pressure and simple suture. If cardiac tamponade is not present, the descending aorta should be cross-clamped. If the patient has massive lung injury, the hilum should be clamped or twisted off (see Treatment later). Patients who respond to these measures should then have definitive repair performed in the operating room.

**TABLE 19-2**
**Indications for Emergency Thoracotomy**

1. Penetrating wound of the heart or great vessels
2. Massive or continuous intrathoracic bleeding
3. Open pneumothorax with major chest wall defect
4. Aortogram indicating injury to aorta or major branch
5. Massive or continuing air leak, indicating injury to a major airway
6. Cardiac tamponade
7. Esophageal perforation
8. Diaphragmatic rupture
9. Impalpable pulse with cardiac massage

In most cases of thoracic trauma, the child is physiologically stable. After initial resuscitation, the next step is the detailed secondary survey. To avoid missing a significant injury, a complete and careful assessment is essential. In nearly all cases, a history that suggests significant impact to the chest can be elicited. Therefore it is crucial to obtain as much information as possible regarding the details of the accident. Children involved in motor vehicle accidents, occupants and pedestrians alike, demand especially careful assessment. A history of difficulty breathing also indicates significant thoracic injury.

A systematic physical examination of the chest by inspection, percussion, palpation, and auscultation is the next step of the secondary survey. Tachypnea and tenderness and abrasions of the chest wall are predictive of intrathoracic injury.[15,16] One should look for cyanosis, dyspnea, noisy breathing, tracheal deviation, hoarseness or stridor, subcutaneous emphysema, open or sucking chest wounds, reduced or absent breath sounds, venous engorgement, pulsus paradoxus, and hypotension. Dyspnea and cyanosis suggest inadequate oxygenation. Noisy breathing may result from an injury to the airway or the presence of foreign material, such as blood, mucus, or vomitus. Tracheal deviation implies tension pneumothorax or massive hemothorax. Hoarseness, stridor, or other difficulty with phonation suggests direct laryngeal or tracheal injury. Surgical emphysema suggests a tracheal or bronchial laceration or, on rare occasions, an esophageal perforation. Jugular venous engorgement, hypotension, and pulsus paradoxus greater than 10 mm Hg imply cardiac tamponade. The patient should also be checked for signs of acute aortic coarctation, which can be caused by injury to the thoracic aorta. The most sensitive sign of a significant cardiac injury is hypotension or a large fluid requirement that is not explained by bleeding. A cardiac injury may also cause a loud systolic murmur. Acute congestive heart failure may result from valvular injury or a traumatic ventricular septal defect.

Holmes and colleagues developed a set of clinical predictors for the presence of chest injuries in a group of children less than 16 years old with blunt torso trauma.[17] The strongest predictors were hypotension, increased respiratory rate, abnormal physical examination of the thorax, associated femur fracture, and Glasgow Coma Scale (GCS) less than 15. Ninety-eight percent of proven cases had at least one of these predictors. Inspection and palpation were the most sensitive, but abnormalities detected on auscultation had the highest positive predictive value. This confirms the importance of clinical assessment in children with blunt trauma. The most common injuries were lung contusion, pneumothorax, and rib fracture, in that order.

In recent years, bedside surgeon–performed ultrasonography (US) has proven helpful in assessing abdominal trauma, and US is now a routine part of the clinical assessment of all major trauma cases.[18] US also has a role in chest trauma. It is sufficiently accurate to be clinically useful in diagnosing

pneumothoraces, hemothoraces, and pericardial effusions.[18–20] Recent reports document that surgeon-performed ultrasonography in the emergency department (ED) is an accurate screening test for the presence of a pneumothorax.[19,21]

Because it lacks sensitivity and specificity, clinical assessment is routinely supplemented by diagnostic imaging, usually the key step in identifying those children who need an operation.[22] Plain chest radiographs are routine, although Bokhari suggests that they are not necessary in blunt trauma cases with a completely normal chest physical examination.[15,23] A standard posteroanterior and lateral examination is best, but a supine anteroposterior film will suffice. The chest radiograph should be repeated on arrival at the trauma center even if the patient has been transferred from another hospital. The important signs of chest injury on plain chest radiographs include subcutaneous emphysema, fractures to the rib or other bony structures, hemothorax, pneumothorax, contusion or other parenchymal lesion (e.g., aspiration pneumonia), mediastinal shift or widening, and diaphragmatic rupture.

Computed tomography (CT) gives greater detail than plain radiographs and is more sensitive in the diagnosis of pneumothorax, rib fracture, and pulmonary contusion. It may also help in the diagnosis of ruptured diaphragm. Because chest films are not 100% sensitive, some groups have recommended that CT be used to screen all patients suspected of having a chest injury. However, this is not proven, and plain chest radiographs are still the standard screening tool for chest trauma.[24] The most common injuries identified by CT are pulmonary contusions and lacerations.[25] Many pneumothoraces revealed by CT are either not evident or underestimated on plain films. CT gives greater detail than plain radiographs in pulmonary contusions.[25] Manson concluded that plain radiographs, especially those obtained in the trauma resuscitation room, are only “a gross screening examination” for thoracic injury and recommended dynamically enhanced CT in all cases of significant thoracic trauma diagnosed clinically or by plain radiograph. In such cases, CT will give better definition of the injuries already recognized and may well reveal occult injuries not visible on plain radiographs. Exadaktylos and colleagues support this view.[26] In their experience, CT revealed potentially life-threatening aortic injuries, even when the plain chest radiographs were normal. They recommended routine chest CT in all patients with major chest trauma. Renton and colleagues studied the question of whether CT should replace routine chest radiograph as the initial diagnostic imaging test of choice.[27] They concluded that it should not, mainly because the increased cost was not justified by the relatively few changes in management that resulted from the use of CT scans. They estimated that 200 CTs would have to be done for each clinically significant change in management. In summary, CT should not be used liberally in cases of suspected chest injury.

Occasionally, other diagnostic tests, including ultrasonography, transthoracic or transesophageal echocardiography, bronchoscopy, radionuclide bone scan, angiography, and even video-assisted thoracic surgery are also helpful. Ultrasonography is more sensitive than supine anteroposterior (AP) chest radiographs and equally sensitive to CT in the diagnosis of traumatic pneumothorax.[28] Recent case reports document the use of video-assisted thoracic surgery to diagnose pericardial rupture and herniation of the heart.[29] In cases of suspected child abuse, a radionuclide bone scan helps to detect recent and long-standing rib fractures. Although impractical in most emergencies, MR is very helpful in defining injuries to the thoracic spine, especially when spinal cord involvement is suspected. It may also help identify diaphragmatic injuries in equivocal cases.[30]

For many years angiography has been the gold standard for the diagnosis of injuries to the aorta and its main branches. However, there is a clear trend to use helical CT as the initial test for suspected aortic injury, reserving aortography for proven cases to guide the repair, or, in some reports, eliminating aortography entirely.

Transthoracic echocardiography is a very useful way to diagnose all types of structural heart injury and ventricular dysfunction caused by contusion. Transthoracic echocardiography may reveal intracardiac injuries or pericardial tamponade. Transesophageal echocardiography is a useful screening test for traumatic rupture of the aorta. It can identify the cause of mediastinal hematomas seen on plain radiographs or CT scan.[31]

Pericardiocentesis may be used for diagnosis when cardiac tamponade is suspected and echocardiography is unavailable. All patients with thoracic trauma should have continuous echocardiographic monitoring during assessment in the ER. A full 12-lead echocardiogram should be obtained in cases of suspected cardiac contusion to rule out an arrhythmia. Bronchoscopy should be done in the operating room under general anesthesia in cases of suspected major airway trauma.

## Treatment

The treatment of thoracic injuries varies from supportive only (oxygen, analgesia), to simple interventions (endotracheal intubation, ventilation, tube thoracostomy) to operation (minimally invasive, open thoracotomy), depending on the specific structures injured and the severity of the injuries. However, most patients do not require an operation and can be managed with supportive measures, with or without tube thoracostomy.[32]

The ideal location for the incision when an operation is indicated varies depending on the preoperative diagnosis. An anterolateral incision in the fifth interspace, which can be extended across the midline, is best in an emergency. A trapdoor incision, which may be best, has been described for vascular injuries in the upper mediastinum. For esophageal injuries, a right posterolateral thoracotomy gives adequate exposure, except for the most distal thoracic esophagus, which is best viewed from the left. Median sternotomy is best for cardiac injuries. Heart–lung bypass is only rarely needed emergently for such injuries as coronary artery laceration and laceration of the thoracic aorta. Intracardiac injuries to the atrioventricular valves or the atrial or ventricular septae do require bypass, but they can be repaired semielectively. Injuries to the root of the neck or shoulder can be approached through a supraclavicular extension of a median sternotomy.

The concept of damage control, which is now well established for intra-abdominal trauma, can also be applied in selected cases of intrathoracic injury. Nonanatomic resection of the lung to control bleeding and massive air leak, pulmonary tractotomy with a gastrointestinal anastomosis (GIA) stapler

for through and through wounds of the lung, en masse pneumonectomy, and hilar twist[33] all may be lifesaving. The latter has been reported in cases of uncontrollable bleeding or air leak from the lung. The inferior pulmonary ligament is divided, and the lower lobe is twisted anteriorly over the upper lobe. This controls the situation so that the patient can be taken back to the intensive care unit (ICU) for stabilization and returned to the operating room (OR) later for definitive control, usually by pneumonectomy. The EndoGIA stapler (Covidien, Mansfield, MA) with vascular staples is very useful for rapid control of major pulmonary vessels in damage control.

## BLUNT INJURIES

### Chest Wall

***Soft Tissue*** Although seldom clinically important, injuries to the soft tissue of the chest wall suggest the possibility of more serious associated intrathoracic injuries. Soft tissue injuries to the chest wall should be managed according to accepted principles of wound care.

***Rib Fractures*** In childhood, the ribs are strong and pliable. Therefore rib fractures are less common than in adults and flail chest is quite rare. Because rib fractures require a great deal of force, they are an indication of severe injury. Fractures of the first rib suggest the possibility of a major vascular injury, especially to the subclavian artery.[34] First rib fractures may also be complicated by Horner syndrome and thoracic outlet syndrome.

The goal of treatment is to prevent atelectasis and pneumonia while optimizing patient comfort. The treatment of rib fractures includes rest and analgesia. Oral or intravenous narcotics are usually sufficient for pain control. Intercostal nerve blocks may also be helpful. Children rarely experience pulmonary atelectasis from splinting of the chest wall. Rib fractures usually heal spontaneously within 6 weeks. The overall mortality rate for children with rib fractures in the National Pediatric Trauma Registry was 10%.[5]

Rib fractures in infants and toddlers less than 3 years old are often caused by child abuse.[35,36] The likelihood of nonaccidental injury in children with one or more rib fractures decreases with increasing age.[36] In cases of child abuse, the typical site of fracture is the neck of the rib near the costotransverse process articulation. Kleinman and colleagues[37] described fractures of the head of the rib in abused infants, which are usually undetectable on radiographs because the head is cartilaginous. Cystic lesions of the ribs that are located posteriorly are another indication of child abuse,[38] as are multiple rib fractures at varying stages of healing.

***Flail Chest*** Flail chest is relatively uncommon in children. It occurs when a segment of the chest wall is destabilized when several adjacent ribs are fractured. The injured chest wall moves paradoxically—*in* during inspiration and *out* during expiration. Ventilation is inefficient because of the paradoxical movement. Flail chest is usually associated with a lung contusion. Chest wall splinting and ineffective coughing often compound the primary injury. This leads to consolidation and collapse of the affected lung, which, in turn, result in a ventilation/perfusion (V/Q) mismatch and hypoxia.

Initial treatment of flail chest includes supplemental oxygen, pain relief (intercostal nerve blocks, oral or intravenous narcotics, or an epidural blockade given as a continuous infusion), and physiotherapy. Fluid therapy must be carefully monitored to avoid pulmonary edema, and intensive care monitoring is advisable. Children with isolated flail chest and no other significant injuries seldom require ventilation. If respiratory failure develops, endotracheal intubation and positive-pressure ventilation with positive end-expiratory pressure may be required for several days. Tracheotomy is rarely necessary. In the National Pediatric Trauma Registry, the overall mortality rate for patients with flail chest was 40%.[5]

***Sternal Fractures*** Sternal fractures are less common in young children than in adults, because the sternum is cartilaginous.

### Lung and Airway

***Pneumothorax*** Pneumothorax can result from an injury to the chest wall, the lung parenchyma, the tracheobronchial tree, or the esophagus. High energy is required to produce a pneumothorax; so, it must be considered a marker for other occult injuries.

**Simple Pneumothorax** Simple pneumothorax may cause chest pain, respiratory distress, tachypnea, decreased air entry on the affected side, and oxygen desaturation. Careful examination may reveal an abrasion of the chest wall, crepitus, or tracheal shift. However, many patients show no clinical signs or symptoms. This underscores the importance of routine chest radiographs for all trauma cases. The radiographic signs include unilateral or asymmetric lucency, a sharp outline of the mediastinum, mediastinal shift, and a visible visceral pleural border away from the chest wall. The diagnosis of simple pneumothorax should be confirmed by chest radiography before treatment.

Simple pneumothoraces should be treated by intercostal chest tube drainage (Fig. 19-1). The best location for chest tube insertion is the fourth or fifth intercostal space (nipple level) in the anterior axillary line. The recommended chest tube sizes are as follows: newborns, 12 to 16 Fr; infants, 16 to 18 Fr; school-age children, 18 to 24 Fr; and adolescents, 28 to 32 Fr. Safe chest tube insertion requires training and experience to minimize complications.[39,40] The chest tube should be connected to an underwater seal on gentle suction and removed when the air leak stops. For most cases, this is the only treatment necessary. A continued or massive air leak suggests injury to the tracheobronchial tree.

A small, asymptomatic pneumothorax may be observed in carefully selected cases. If the patient is to be transferred to another hospital or intubated and ventilated for any reason, or if the pneumothorax exceeds 15%, it should be drained. When in doubt, a chest tube should be inserted.

**Open Pneumothorax** Open pneumothorax is rare in children. In cases of open pneumothorax, the intrapleural pressure is equal to that of the atmosphere. As a result, the lung collapses and alveolar ventilation decreases. Sucking wounds should be recognized clinically. They may be treated by insertion of a Heimlich valve or applying an occlusive dressing to the wound, taping the dressing on three sides only so that it can act as a flutter valve, and inserting a chest tube in the usual location.

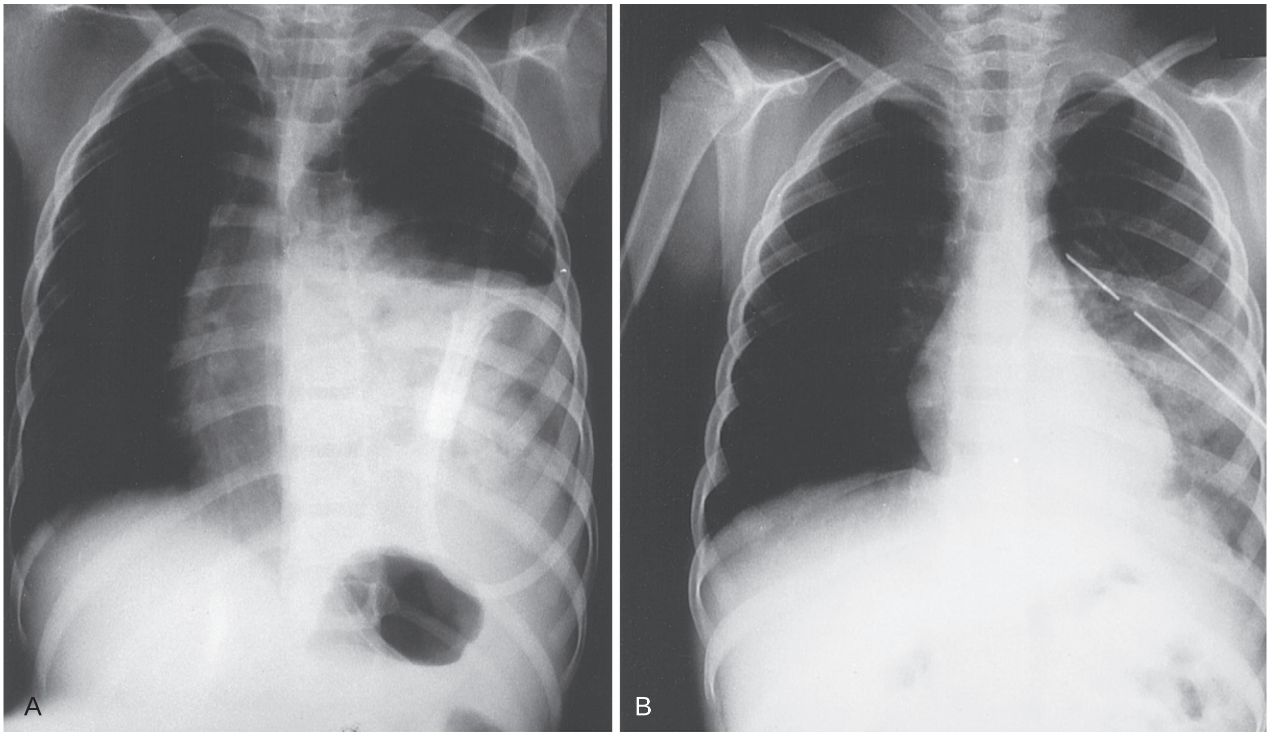

FIGURE 19-1 **A,** Left hemopneumothorax; note the nasogastric tube in situ. **B,** Same patient after insertion of intercostal drain; no other treatment was required. (From Wesson DE: Trauma of the chest in children. Chest Clin North Am 1993;3:423-441. Used with permission.)

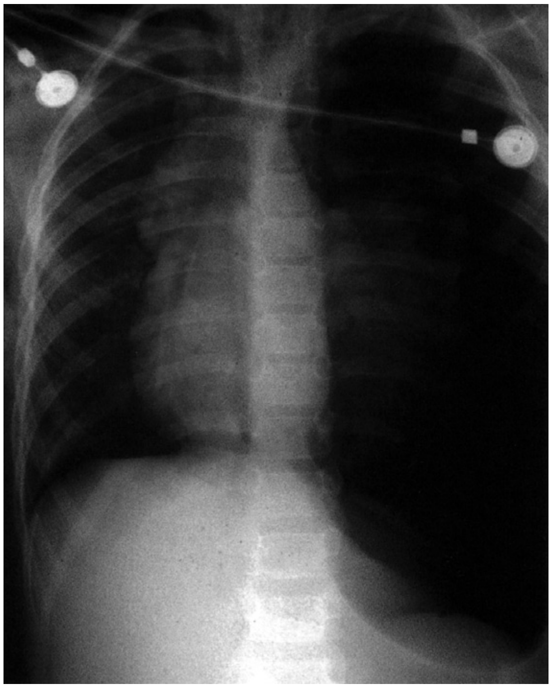

FIGURE 19-2 Tension pneumothorax. Pneumothorax resulting from blunt thoracic trauma in a 4-year-old boy run over by a school bus. He was unconscious when seen in the emergency department, and no breath sounds could be heard in the right chest. The trachea was shifted toward the left. The suspected pneumothorax on the right was treated initially with needle aspiration and then a chest tube inserted. (From Haller JA Jr, Shermeta DW: Acute thoracic injuries in children, Pediatr Ann 1976;5:71-79. Used with permission.)

**Tension Pneumothorax** Tension pneumothorax may develop when a one-way valve effect occurs, allowing air to enter the pleural space but not to escape (Fig. 19-2). The underlying cause is usually a pulmonary laceration or an injury to the trachea or a large bronchus. The intrapleural air pressure exceeds that of the atmosphere, collapses the ipsilateral lung, pushes the mediastinum to the opposite side, flattens the diaphragm, impairs ventilation of the opposite lung, and reduces return of venous blood to the heart. The pulse and respiratory rate increase, and the patient becomes severely distressed. The trachea is usually deviated away from the involved side, and the neck veins may become engorged. The ipsilateral side of the chest is hyperresonant to percussion with diminished breath sounds. Frank cyanosis is a late sign. The most important differential diagnosis is pericardial tamponade. However, this disorder can be distinguished from tension pneumothorax, because the trachea is not displaced and the chest is normal to percussion. Tension pneumothorax should be considered when an injured patient, especially one on a mechanical ventilator, suddenly deteriorates for no apparent reason. Both acute gastric dilation and right mainstem intubation may result in diminished breath sounds on the left, and should not be confused with a tension pneumothorax.

The treatment for tension pneumothorax is immediate needle-catheter drainage (without waiting for chest radiographs) through either the second intercostal space in the midclavicular line or the fourth or fifth interspace in the axilla, followed by insertion of a chest tube.

***Hemothorax*** When enough blood is lost into the thorax to cause shock, the term massive hemothorax is used. Massive hemothorax is more common after penetrating than blunt trauma.

Hemothorax may result from a laceration of an intercostal or internal mammary artery, the lung, or a mediastinal blood vessel. Free bleeding into the pleural space from a major vessel, such as the aorta or one of the pulmonary hilar vessels, is usually rapidly fatal. Most bleeding from the lung stops spontaneously because of the low pressure in the pulmonary circulation. Bleeding from a systemic vessel, such as an intercostal artery, is more likely to cause massive hemothorax producing signs of hypovolemia, mediastinal shift, diminished breath sounds, and dullness to percussion on the affected side. Hemothorax is often associated with pneumothorax (see Fig. 19-1). The treatment is intercostal drainage to prevent a clotted hemothorax and to monitor the rate and total volume of blood loss. It is wise to establish two large-bore intravenous catheters, begin treatment for shock, if present, and obtain blood for transfusion before draining a massive hemothorax, because it may precipitate further bleeding. However, drainage and reexpansion of the lung usually stop the bleeding.

In most cases, intercostal drainage is the only treatment needed. However, thoracotomy may be indicated for the following reasons:

1. Initial drainage exceeds 20% to 25% of estimated blood volume
2. Continued bleeding exceeds 2 to 4 mL/kg/hour
3. Bleeding is increasing
4. The pleural space cannot be drained of blood and clots

Hoth and colleagues reported an increased likelihood of nontherapeutic exploration when thoracotomy is performed for increased chest tube output of blood in blunt trauma.[41] Auto-transfusion may be helpful during surgery for massive intrathoracic bleeding.

### Lung

***Hematoma and Contusion*** Pulmonary contusion is the most common type of blunt injury to the chest in children. Direct force to the lung causes disruption of the parenchyma, bleeding, and edema in a nonanatomic distribution, often without obvious injury to the chest wall. Specific clinical signs or symptoms are seldom evident at presentation, although rib fractures and abrasions over the chest may be present.

Because of the lack of specific physical features, routine chest radiographs are the key to the diagnosis of hematoma and contusion. Pulmonary contusions are usually obvious on plain radiographs taken at admission (Fig. 19-3) and are even more striking on CT, which has shown that they usually lie posteriorly or posteromedially.[25] However, there is no need for a CT when a contusion is obvious on plain films. Pulmonary contusions may be progressive, especially when compounded by edema and atelectasis. Children with pulmonary contusions seldom require mechanical ventilation and almost never develop adult respiratory distress syndrome. The differential diagnosis includes aspiration pneumonia, which can result from aspiration at the scene, en route, during intubation, or with vomiting after admission. It affects the right lower lobe most frequently.

Patients with extensive lung hematomas or contusions should be monitored carefully with continuous $SaO_2$ measurements, preferably in an intensive care unit. The treatment for these disorders is supportive, with analgesia, physiotherapy, supplemental oxygen, and fluid restriction. Endotracheal intubation and mechanical ventilation are less likely to be needed for children than for adults. Deterioration after admission is unusual.[42] It is important to guard against overhydration and aspiration of gastric content. The most common complication is infection of the lung. Most pulmonary hematomas and contusions clear within 10 days, unless the lung becomes infected.

Pulmonary contusions may be complicated by pneumothorax, hemothorax, or pleural effusion, all of which may require intercostal drainage. These secondary phenomena are much more common in the presence of concomitant fractures of the bones of the chest wall and may be delayed as long as 48 hours. Therefore serial chest radiographs should be obtained in cases of pulmonary contusion (see Fig. 19-3).

Occasionally, a post-traumatic pneumatocele forms when the injured lung cavitates during healing. Because pneumatoceles usually resolve spontaneously in a few months, treatment is seldom necessary.

### Laceration

Pulmonary lacerations are most often seen after penetrating injuries and usually result in a pneumothorax or hemothorax. They may also be caused by rib fractures.

Air embolus is the most serious complication of pulmonary laceration. This diagnosis should be suspected in all children with thoracic trauma who suddenly deteriorate, especially while receiving positive-pressure ventilation in the absence of a pneumothorax. Air embolus may cause focal neurologic deficits. Frothy blood aspirated from an arterial cannula is a telltale sign. Emergency thoracotomy, clamping of the pulmonary hilum, and aspiration of the air from the heart or right ventricular outflow tract may be lifesaving.[43]

***Trachea and Bronchi*** Injuries to the major airways are uncommon in children. Nearly all are caused by blunt trauma.[5] The most common specific lesions are partial or complete transections of one of the main bronchi and tears of the membranous trachea. Airway injuries usually occur within 2 to 3 cm of the carina and may be rapidly fatal if not recognized and treated promptly.

Some patients with major airway injuries die from respiratory failure before reaching the hospital or shortly thereafter. Most present with dyspnea, which is often caused by tension pneumothorax. Other characteristics of patients with major airway injuries are voice disturbance, cyanosis, hemoptysis, massive subcutaneous and mediastinal emphysema, and failure of expansion of the lung or continuing large-volume air leak despite properly functioning chest tubes. Failure of the lung to expand or a continuous massive air leak after intercostal drainage strongly suggests a major airway injury (Fig. 19-4). Although not common, "dropped lung," in which the lung actually falls to the lower half of the pleural cavity below the level of the injured bronchus, is virtually diagnostic of a major airway injury. Finally, some patients present late with chronic collapse and infection of the involved lung from bronchial obstruction.

Initial management in the trauma room depends on the clinical situation. The initial treatment of airway injuries is to control the airway and breathing according to the ATLS protocol. This may require endotracheal intubation and intercostal drainage. If the patient has a good airway and is well oxygenated, it is prudent not to manipulate the airway by attempting intubation before taking the patient to the OR. Flexible bronchoscopy may facilitate endotracheal intubation

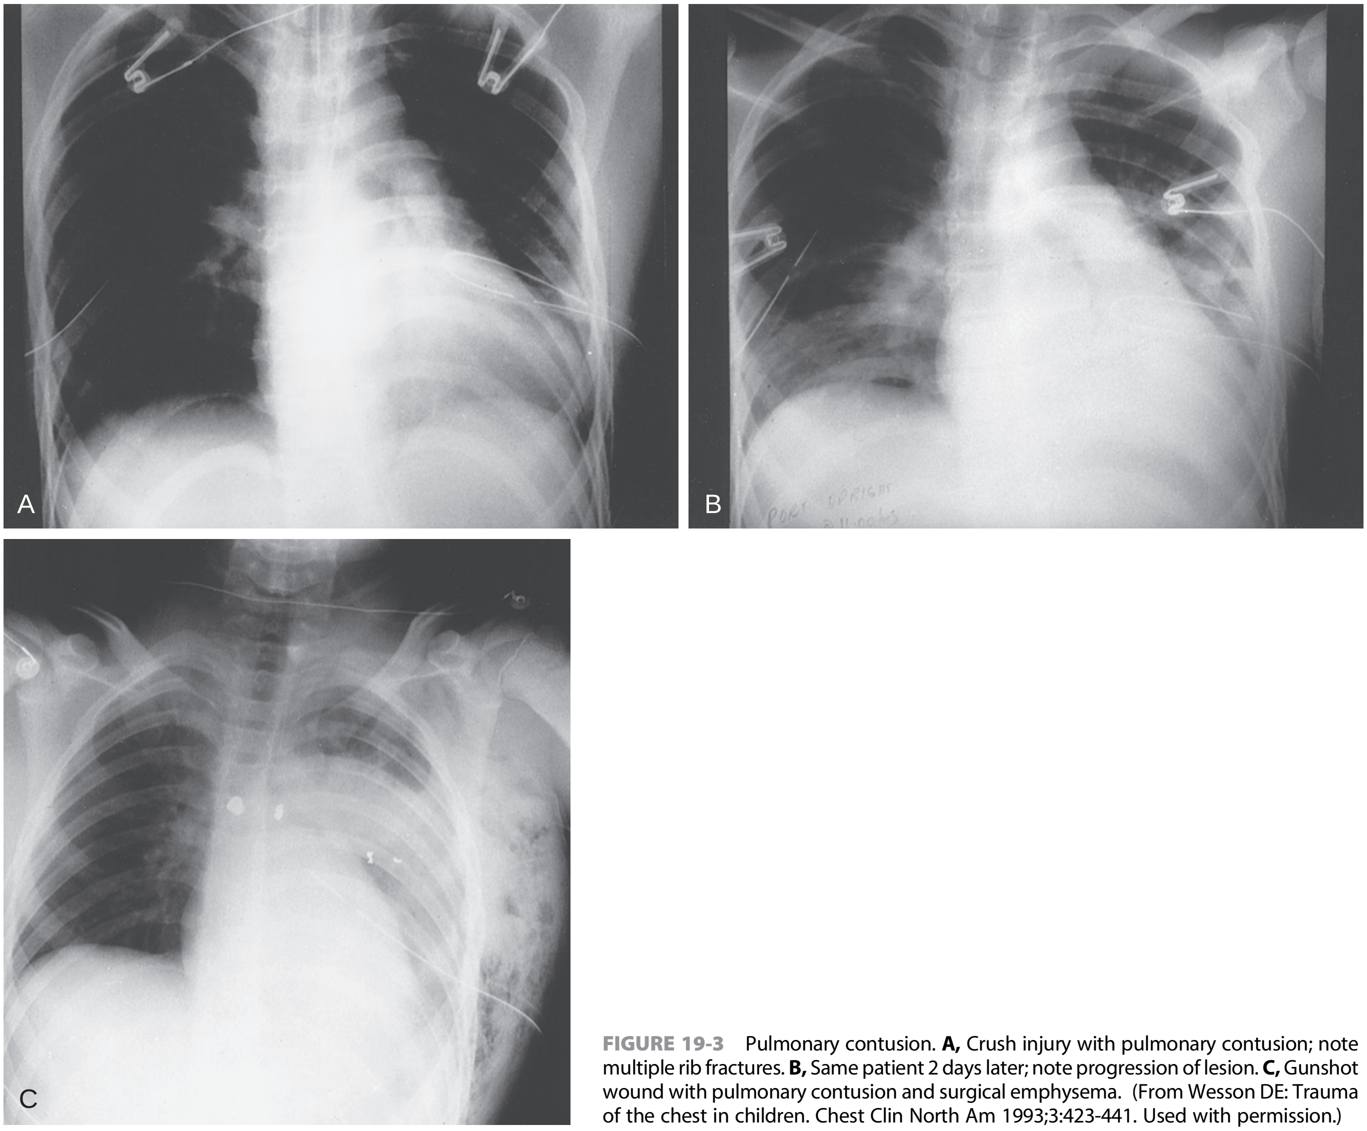

**FIGURE 19-3** Pulmonary contusion. **A,** Crush injury with pulmonary contusion; note multiple rib fractures. **B,** Same patient 2 days later; note progression of lesion. **C,** Gunshot wound with pulmonary contusion and surgical emphysema. (From Wesson DE: Trauma of the chest in children. Chest Clin North Am 1993;3:423-441. Used with permission.)

beyond the site of the injury or selective intubation of the uninjured bronchus. High-frequency ventilation may be more effective than conventional methods in the presence of a massive air leak and may facilitate stabilizing the patient for surgical repair.[44]

Helical CT may be a good initial test in stable patients with suspected major airway injuries, but bronchoscopy is more reliable. Bronchoscopy is indicated whenever the lung fails to expand or a massive air leak continues after intercostal drainage. It should be done in the operating room under general anesthesia; a rigid, ventilating bronchoscope should be used. If possible, the patient should be allowed to breathe spontaneously during induction of anesthesia and passage of the bronchoscope. Staff and equipment for thoracotomy must be at hand. In unstable patients or those with possible or confirmed cervical spine injuries, flexible bronchoscopy with the patient awake or through an endotracheal tube may also reveal the lesion. At bronchoscopy, a defect in the wall of the airway may be visible. Other bronchoscopic signs of injury include mucosal disruption or exposed cartilage.

Spontaneous healing is the rule for small lacerations in the membranous trachea and some partial bronchial tears involving up to one third of the circumference.[45] These may be treated nonoperatively. For larger lacerations of the trachea or bronchi, primary surgical repair through a posterolateral thoracotomy is the best way to ensure good long-term results. Distal injuries to a lobar or segmental bronchus may be treated by lung resection rather than direct repair. The right side of the chest allows the best exposure of the trachea, carina, and right main bronchus; the left side gives better exposure for injuries to the distal left main bronchus. In the presence of a massive air leak, it may be necessary to clamp the hilum before attempting to repair the airway. Advancing the endotracheal tube or passing a sterile tube across the surgical field into the distal airway may also be helpful during the repair. Simple, interrupted sutures after debridement of the margins work best. Although lobectomy or pulmonary segmentectomy may be necessary, pulmonary resection is done only as a last resort in unstable patients or when the lung is extensively damaged. The late functional results of pulmonary resection or bronchial repair are usually excellent.[46]

**FIGURE 19-4** This patient had a sustained air leak associated with blunt thoracic injury despite adequate chest tube drainage. Blood was noted in the right upper lobe bronchus, and contrast injection demonstrated the location and extent of the leak, which was controlled by the injection of fibrin glue and chest tube drainage. Operative closure or resection is sometimes required.

Asymptomatic pneumomediastinum is often detected on chest CT during the evaluation of the multiple injury patient. Recent studies have demonstrated that there is an exceedingly low incidence of aerodigestive tract injuries presenting with pneumomediastinum alone.[47–49]

Bronchial injuries that are missed initially may seal spontaneously, but there is a risk of stenosis. After months or years, children with spontaneously sealed bronchial injuries may have persistent atelectasis often with pneumonia or frank bronchiectasis in the involved lung caused by a bronchial stricture. The diagnosis can be confirmed by bronchography or bronchoscopy. This type of stricture can be dilated in some cases. Open repair or even resection of the involved lung is usually necessary. One report illustrates that late repair of a completely transected main stem bronchus with preservation of the lung is possible.[50]

***Esophagus*** The most common causes of esophageal injury are ingestion of caustic liquids and penetrating trauma, which includes iatrogenic instrumentation. Forceful vomiting and retching rarely cause esophageal tears in childhood. External blunt trauma rarely causes esophageal injury. The mechanism of esophageal injury from blunt trauma is believed to be a sudden increase in intraesophageal pressure caused by expulsion of gas from the stomach through the gastroesophageal (GE) junction.

Esophageal perforations cause fever, chest pain, and tachycardia. Occasionally, subcutaneous emphysema develops in the neck. Mediastinal or intrapleural air may be visible on routine chest radiographs or CT. If esophageal injury is suspected, a water-soluble contrast swallow, endoscopy, or both should be done.

When diagnosed within the first 12 hours, esophageal injuries are best treated by primary closure, and drainage. When diagnosed later and for more destructive lesions, they may require salivary diversion by means of a cervical esophagostomy and gastrostomy in addition to thoracic drainage. Alternatively, the repair can be buttressed by a neurovascular intercostal muscle pedicle flap. The flap can be secured akin to a modified Graham closure after primary repair, or it can be used to augment the extramucosal repair.[51] There has been a growing, favorable experience with endoscopic stenting of esophageal perforations/leaks in adults, and this may be an alternative to standard approaches in some circumstances.[52]

***Diaphragm*** Although rare in children, diaphragmatic injuries can be caused by a forceful impact to the abdomen or by a penetrating missile. It is important to recognize these injuries, because the stomach and bowel may herniate through the defect and strangulate. Ninety percent of diaphragmatic injuries occur on the left side. In blunt trauma, tears are usually in or near the central tendon and oriented radially.

Diaphragmatic injuries are easily missed at initial presentation, especially because they are often associated with other severe injuries. They may be asymptomatic or cause abdominal, thoracic, or ipsilateral shoulder tip pain. Physical examination is rarely helpful in the diagnosis of diaphragmatic injuries. The diagnosis is usually based on the plain chest radiograph, which is the most important diagnostic test (Fig. 19-5). Table 19-3 summarizes the radiographic signs of diaphragmatic injury. Basically, any abnormality of the diaphragm or near the diaphragm on plain chest radiography should arouse suspicion. Chest radiographs are initially normal in 30% to 50% of cases.[53] Therefore repeat radiographs should be obtained if a diaphragmatic injury is suspected.

Because other injuries often dominate the clinical picture, delayed diagnosis of a diaphragmatic injury is common. At first, herniation of abdominal viscera into the chest may not have occurred, especially in patients receiving mechanical ventilation. However, the negative intrathoracic pressure of normal breathing may gradually draw the stomach and bowel up into the chest. This can be recognized on plain radiographs, especially if the stomach herniates with a nasogastric (NG) tube in place. In the absence of an NG tube, acute dilation of the herniated stomach may develop leading to severe respiratory distress.

The diagnosis may be confirmed, if necessary, by contrast upper- or lower-intestinal studies. However, these studies may not be possible in patients with multiple acute injuries. Here, CT with multiplanar reconstruction may be helpful. The signs of diaphragmatic injury on CT include discontinuity of the diaphragm, herniation of intra-abdominal viscera into the chest, and constriction of the stomach as it passes through the defect.[54] In stable patients, MR may also help to establish the diagnosis.

Some patients present late with obstruction or strangulation of the herniated gut. This causes severe abdominal or chest pain (or both), nausea, and vomiting. Primary repair through an abdominal incision is indicated. The usual repair is by open laparotomy, but several recent reports of laparoscopic repair demonstrate the feasibility of this approach.[55,56]

5. Atypical pneumothorax
6. Platelike atelectasis adjacent to the diaphragm

## Heart and Pericardium

Blunt trauma to the heart can produce several types of injury: concussion, contusion, or frank rupture of the myocardium, a valve, or septum.[57,57a] Although rare, disruption or thrombosis of a coronary artery may also occur. A tear of the pericardium may allow herniation of the heart into the pleural space, thereby impairing cardiac function and causing a low output state. Occasionally, blunt trauma to the chest produces occult structural cardiac injuries without gross impairment of cardiac function, bleeding, or cardiac tamponade.[58] These injuries include atrial or ventricular septal defects, mitral or tricuspid insufficiency, and ventricular aneurysm formation. Often, the only sign is a new murmur or a change on the electrocardiogram. The diagnosis can be confirmed by echocardiography or cardiac catheterization. These injuries may be repaired electively once the patient is stable.[58] Follow-up echocardiography should be arranged in all cases of known or suspected injury to the heart.

Several case reports have appeared documenting sudden cardiac arrest in children after a direct blow to the chest. The term *commotio cordis* has been applied to this entity.[9,10] *Commotio cordis* occurs most often during organized sporting events such as baseball. No contusion or other sign of injury can be found at autopsy, and death has usually been attributed to ventricular fibrillation.

When performing emergency surgery for cardiac trauma, the surgeon should bear in mind a few simple rules:

1. Prepare and drape the entire chest.
2. Place the incision in the left fourth or fifth interspace in an anterolateral direction (except for stable patients undergoing elective repair of known cardiac injuries, which should be repaired through a median sternotomy).
3. Avoid the phrenic nerve when opening the pericardium.
4. Apply direct pressure to control the bleeding.
5. Suture the heart using pledgets as required, avoiding the main coronary arteries.
6. Leave the pericardium open.

Some authors have reported the use of skin staples to control cardiac wounds. Direct suture is preferable. A Foley catheter may be introduced through the defect to control the bleeding during repair.

Although most cardiac injuries can be repaired without cardiopulmonary bypass, this option should be available. During the operation, the surgeon should always check for a thrill, which might indicate a ruptured valve or traumatic ventricular septal defect. Intraoperative trans-esophageal echocardiography may be a useful adjunct to diagnose traumatic septal and valve injuries as well as monitor the integrity of any repair. It is also important to check for intracardiac lesions by listening for new murmurs and performing

echocardiography in the postoperative period. Follow-up echocardiography should also be done after discharge.

***Myocardial Contusion*** Myocardial contusion is the most common type of blunt cardiac injury. It produces focal damage to the heart that can be identified histologically. It can cause life-threatening arrhythmias and cardiac failure. Treatment is aimed primarily at these complications.

Contusion can be distinguished from concussion and *commotio cordis* because the latter do not produce any structural change, even at the microscopic level. Contusions are usually, but not always, associated with an injury to the chest wall. Myocardial contusions may be completely silent or cause an arrhythmia (supraventricular tachycardia or ventricular fibrillation) or hypotension secondary to reduced cardiac output.

Unfortunately, although many tests have been proposed, including electrocardiography, echocardiography, myocardial enzyme determinations (creatine kinase–myocardial band [CKMB], cardiac troponin I, and troponin T), and radionuclide scans, there is no definitive diagnostic test for cardiac contusion. This makes it difficult to define the indications for any of the currently available diagnostic tests and even more difficult to decide on treatment. Tellez and colleagues concluded that a "comprehensive diagnostic evaluation of the heart in all children sustaining multiple injuries from blunt trauma cannot be justified."[59] The simplest test is a 12-lead electrocardiogram, which may reveal reversible changes to ST segments and T waves. Echocardiography may show reduced ejection fraction, localized systolic wall motion abnormality, or an area of increased end-diastolic wall thickness and echogenicity. Swaanenburg and colleagues found that cardiac troponin I and T levels were more accurate and reliable than any of the other diagnostic tests in selecting patients for ICU monitoring.[60–62] They recommended a repeat analysis after admission for patients suspected of having myocardial contusion who have normal values at admission.

A prospective study of 41 children with blunt thoracic trauma, which used a battery of tests that included serum enzyme levels, electrocardiography, echocardiography, and pyrophosphate myocardial scanning, revealed a high incidence of abnormal tests. However, there was little correlation among the tests or between any of the tests and the clinical course.[63] The authors concluded that myocardial contusion is rarely clinically significant in pediatric thoracic trauma. For practical purposes, significant myocardial contusion can be ruled out when findings on 12-lead electrocardiography and echocardiography are normal.

Treatment of myocardial contusion includes electrocardiographic monitoring for 12 to 24 hours, frequent blood pressure determinations and inotropic support as indicated. Complications tend to occur early in the disorder or not at all.[64] Tellez and colleagues recommended cardiac monitoring in the emergency room and intensive care unit to identify arrhythmias and, in patients with arrhythmias and obvious thoracic injuries, serial electrocardiograms and cardiac enzyme tests.[59] Rarely, patients may suffer profound myocardial dysfunction after myocardial contusion. Extracorporeal circulatory support has been useful in isolated cases with marked cardiac dysfunction after blunt trauma.[65] Consideration must be given to left ventricular decompression at the time of circulatory support to prevent distention and subendocardial ischemia.

***Myocardial Rupture*** Rupture of the heart is usually rapidly fatal. In fact, myocardial rupture is the most common cause of death from thoracic injury. In a population-based autopsy series, Bergman and colleagues found that two thirds of these patients died at the scene of the accident, and one third died in the emergency room.[4] Most cases of cardiac rupture result from high-energy impacts, such as those sustained in motor vehicle accidents or falls from great heights. The atria tend to rupture from impact occurring during late systole; ventricles rupture from impact during late diastole. The right ventricle is the most commonly ruptured site.

Children with myocardial rupture usually present with pericardial tamponade (discussed later). Myocardial necrosis, aneurysm formation, and delayed rupture may also occur.[66] Those with a traumatic atrial septal defect or ventricular septal defect may present with a new murmur without obvious cardiac failure. All patients with chest trauma should be checked carefully for a new murmur before discharge. Any new murmur is an indication for echocardiography. Occasionally, with early diagnosis and repair, patients can survive myocardial rupture.

***Valve Injury*** Valve injuries are rare but well recognized after blunt trauma.[67,68] Atrioventricular valves are most commonly injured, causing incompetence by damage of the annulus or rupture of the chordae tendinae or papillary muscle (Fig. 19-6). A diastolic murmur, and worsening pulmonary failure out of proportion to the initial pulmonary injury should prompt echocardiography and/or pulmonary artery catheterization to investigate the possibility of a valve injury. This is one type of blunt cardiac injury that can be repaired semielectively.

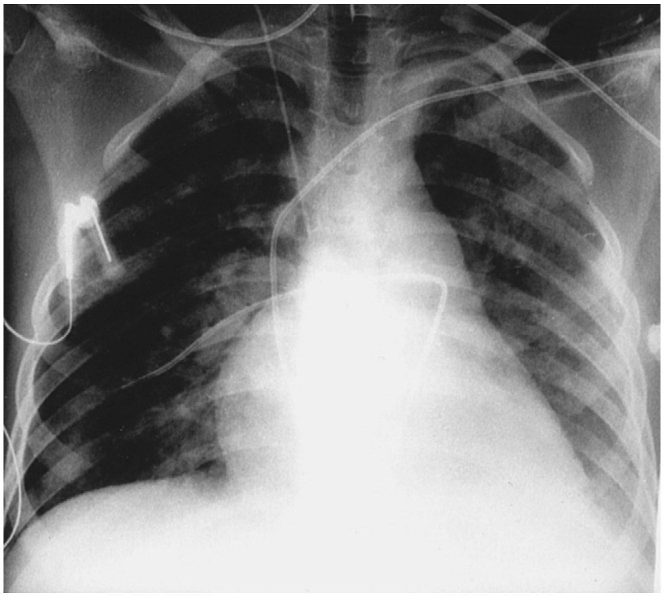

**FIGURE 19-6** Cardiomegaly and pulmonary edema 2 days after blunt chest trauma; note Swan-Ganz catheter. Torn mitral valve annulus and chordae tendinae were successfully repaired. (From Wesson DE: Trauma of the chest in children. Chest Clin North Am 1993;3:423-441. Used with permission.)

***Pericardial Tamponade*** Pericardial tamponade can result from an accumulation of blood in the pericardial sac after blunt trauma. The full spectrum of pericardial tamponade—pulsus paradoxus and the Beck triad (elevated jugular venous pressure, systemic hypotension, and muffled heart sounds)—rarely develops in patients with acute trauma. Pericardial tamponade is usually associated with tachycardia, peripheral vasoconstriction, jugular venous distention, and persistent hypotension, regardless of aggressive fluid resuscitation. In fact, pericardial tamponade should be suspected in all cases of unexplained hypotension, especially when it is associated with elevated jugular venous pressure. The best way to confirm the diagnosis is by transthoracic echocardiography, which can be performed by the surgeon at the bedside in conjunction with the FAST (focused abdominal sonography trauma) examination.[20,69]

Treatment of suspected pericardial tamponade begins with control of the airway and breathing plus restoration and expansion of the circulating blood volume. The diagnosis should be confirmed by echocardiography, which is the single best diagnostic tool. However, if the patient is in severe shock, needle-catheter drainage of the pericardial space may be lifesaving (Fig. 19-7). Therefore, in emergency situations or when echocardiography is not available, immediate pericardiocentesis is indicated. The needle should be inserted by the subxiphoid approach at a 45-degree angle upward and toward the left shoulder. A successful tap is confirmed by aspiration of nonclotting blood. A catheter should be inserted and left for repeated aspirations, if necessary, pending definitive treatment. Pericardiocentesis may be complicated by bleeding or damage to the left anterior descending coronary artery. If pericardiocentesis is positive, and does not stabilize the patient, immediate thoracotomy should be performed to relieve the tamponade and control the bleeding.

***Pericardial Laceration*** The pericardium may be torn by blunt trauma. The most common site is on the left, anterior to the phrenic nerve. The heart may herniate through the defect, impairing its function and reducing cardiac output. This type of injury may be recognized on CT or by video-assisted thoracic surgery.[54,70,71]

## Aorta and Great Vessels

Traumatic rupture of the aorta and its major branches is uncommon in children.[72] Eddy and colleagues reported that aortic injuries caused 2.1% of all traumatic deaths in children in King County, Washington.[73] Traumatic rupture of the aorta causes a higher proportion of traumatic deaths in adults (approximately 10%) than in children, probably because adult aortas are more brittle and easily torn. Predictors of aortic injury include hypotension, head injury, unrestrained motor vehicle occupant, pelvic fracture, extremity fracture, and other chest injuries. However, it is not clear which mechanism is a reliable predictor. Dyer found mechanism of injury to be "imperfect" and "subjective."[74] Horton found that $\Delta V$ greater than or equal to 20 mph and near-side passenger compartment intrusion of greater than or equal to 15 inches correlated strongly with aortic injury.[75]

Traumatic rupture of the aorta occurs with rapid deceleration, which applies shear stress to the wall of the aorta. The most common sites of injury are near the ligamentum arteriosum, the root of the aorta or one of the other main branch points, such as the take-off of the innominate, vertebral or carotid artery. Tears of the distal arch are usually located on the anteromedial aspect of the aorta and oriented horizontally. Children with Marfan syndrome are at risk for aortic dissection following blunt torso trauma.

Although it is usually rapidly fatal, in some cases, the adventitia and pleura contain the blood and prevent

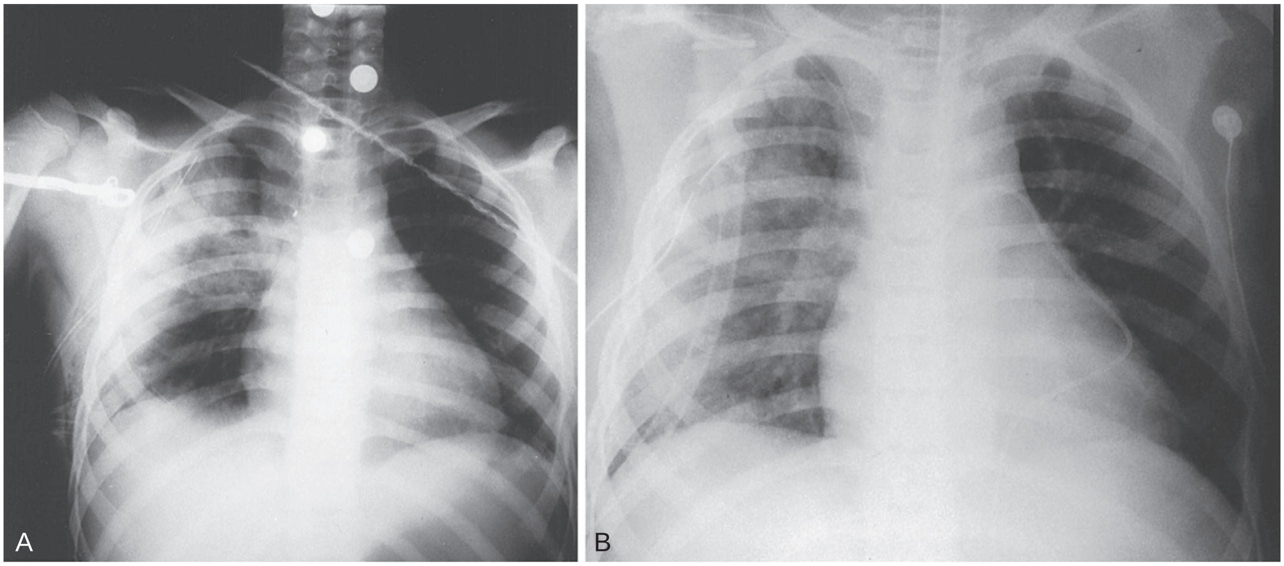

**FIGURE 19-7** Pericardial tamponade from blunt chest trauma. The patient was a rear seat passenger in a high-speed frontal collision. Seat belt mark over lower sternum. Shock unresponsive to fluid. Pericardial effusion on transthoracic echocardiography. **A,** Normal heart on plain chest radiograph with evidence of pulmonary contusion. **B,** Chest radiograph after catheter drainage of bloody pericardial effusion. No further treatment was required. (From Wesson DE: Trauma of the chest in children. Chest Clin North Am 1993;3:423-441. Used with permission.)

exsanguination. The natural history of patients who do not exsanguinate immediately is unknown, but imminent rupture in these patients is unlikely. Therefore it is unnecessary to rush them to the OR before stabilization, a full diagnostic workup, and treatment of other injuries. This may require laparotomy, craniotomy, or both before repair of the aorta.

The management of aortic injuries in children is essentially the same as in the adult.[76,77] Diagnosis is difficult, because there may be no clinical evidence of thoracic injury. The acute coarctation syndrome—upper limb hypertension, a difference in blood pressure between the upper and lower limbs, and a loud murmur over the precordium or back—is rare. DelRossi and colleagues reported a series of 27 cases of aortic injury without a single case of coarctation syndrome.[78]

The diagnosis is most often suggested by plain chest radiography, which is sensitive (false negatives, 2% to 7%) but not specific (false positives, 80%). The radiographic signs of traumatic rupture of the aorta are the same as described for adults (Table 19-4 and Fig. 19-8). Nearly all reported cases demonstrate widening of the mediastinum (mediastinum: chest ratio $> 0.25$) and an abnormal aortic contour.

Until recently, most authors referred to aortography as the gold standard diagnostic test. Many now believe that contrast-enhanced multislice helical CT, which is equally sensitive to aortography, has become the definitive test for diagnosing aortic injury (Fig. 19-9).[74,79–81] If the helical CT is normal, an aortogram is unnecessary. This has substantially reduced the number of negative aortograms done for patients with blunt chest trauma and suspicious plain radiographs. The techniques of helical CT and CT angiography have been reviewed by Melton and Rubin.[79,82] Timing of the contrast injection, as well as the volume and rate of infusion must be carefully controlled to yield optimal results. Helical CT costs about half as much as aortography.[80]

There is still a role for aortography in equivocal cases or to provide more anatomic detail before repair in proven cases.[83] However, many authorities now argue that helical CT alone is sufficient for management of aortic injuries.[79]

Transesophageal echocardiography (TEE) also has a role in the diagnosis of injuries to the descending thoracic aorta, especially for unstable patients in the ICU not able to go to radiology. It is not useful for injuries to the ascending aorta or its branches. Unfortunately, TEE is operator dependent and not universally available. Le Bret and colleagues noted three signs on TEE that are sensitive enough to screen patients for aortic injury.[31] These are increased distance (>3 mm) between the probe and the aorta, double contour of the aortic wall, and an ultrasonographic signal between the aorta and the visceral pleura. The sensitivity for diagnosing traumatic rupture of the aorta by transesophageal echocardiography in this report was 100%; the specificity was 75%. Le Bret proposed that TEE should be done in all cases of severe chest trauma. TEE is also useful in cases with equivocal findings on CT or aortography to avoid an unnecessary thoracotomy.[84]

**TABLE 19-4**

**Radiographic Signs of Aortic Injury**

1. Widened mediastinum (mediastinum:chest ratio $> 0.25$)
2. Loss or abnormal contour of aortic knob
3. Depression of left main bronchus (>40 degrees below horizontal)
4. Deviation of trachea (left margin to right of T4 spinous process)
5. Deviation of esophagus (nasogastric tube to right of T4 spinous process)
6. Left pleural cap
7. Left hemothorax

Once the diagnosis is proven the treatment options include open repair, endovascular stent graft, or even nonoperative observation in some cases. Aortic surgery carries a significant risk of complications, including intracranial hypertension, which may exacerbate bleeding, left ventricular strain, renal failure, and spinal cord ischemia. When used, heparin may increase the likelihood of bleeding at remote sites of injury.

A small intimal flap may heal spontaneously, but surgical repair after the patient has been stabilized (the bleeding at other locations should be repaired first) through a left posterolateral thoracotomy is the treatment of choice. Surgery may be safely delayed pending repair or control of associated severe injuries to the CNS, extensive burns, septic or contaminated wounds, solid organ injuries likely to bleed with heparinization, and respiratory failure.[85] In such cases, beta blockade to control mean arterial blood pressure and ICU monitoring are essential until repair can be safely accomplished. Esmolol is the preferred beta blocker.

Cardiopulmonary bypass (CPB) should always be available during repair in the event that the injury extends to the aortic root. The left lung should be collapsed and retracted. Care is required when dissecting the aorta for cross-clamping to avoid injury to the branches of the aorta that supply the spinal cord and to the vagus nerve and its recurrent branch. Some partial tears can be repaired primarily; however, repair usually requires placement of a woven Dacron graft, especially when the tear is circumferential. There are three basic ways to perform the operation:

Clamp and sew
Intraoperative shunt
Mechanical circulatory support

The simplest is to “clamp and sew” without a shunt or CPB. This is the fastest method and requires the shortest cross-clamp time; it is adequate if the injury is not too extensive. Razzouk and colleagues reported that the “clamp and sew” technique “is feasible in the majority of patients without increased mortality or spinal cord injury.”[86,87] Kwon and colleagues also believe that the clamp technique does not increase mortality or morbidity.[88] However, others strongly disagree. Hochheiser and colleagues reported a lower incidence of postoperative paraplegia after repair with mechanical circulatory support.[89]

Another option is intraoperative shunting with a heparin-bonded shunt. This may reduce the risk of ischemic damage to the spinal cord without the risks of systemic heparinization. However, no controlled studies to prove this exist. The third method is to use mechanical circulatory support during the repair. The most common choice is CPB from the left superior pulmonary vein or left atrium to the femoral artery.[90] Femoral–femoral bypass with direct perfusion of the distal descending thoracic aorta has also been used. CPB is thought by some authorities to reduce the risk of paraplegia, but conventional circuits require systemic heparinization, which can increase the incidence of intracranial hemorrhage; heparin-bonded circuits (including cannulas) are available, and short-term use at higher flows does not require anticoagulation.[91]

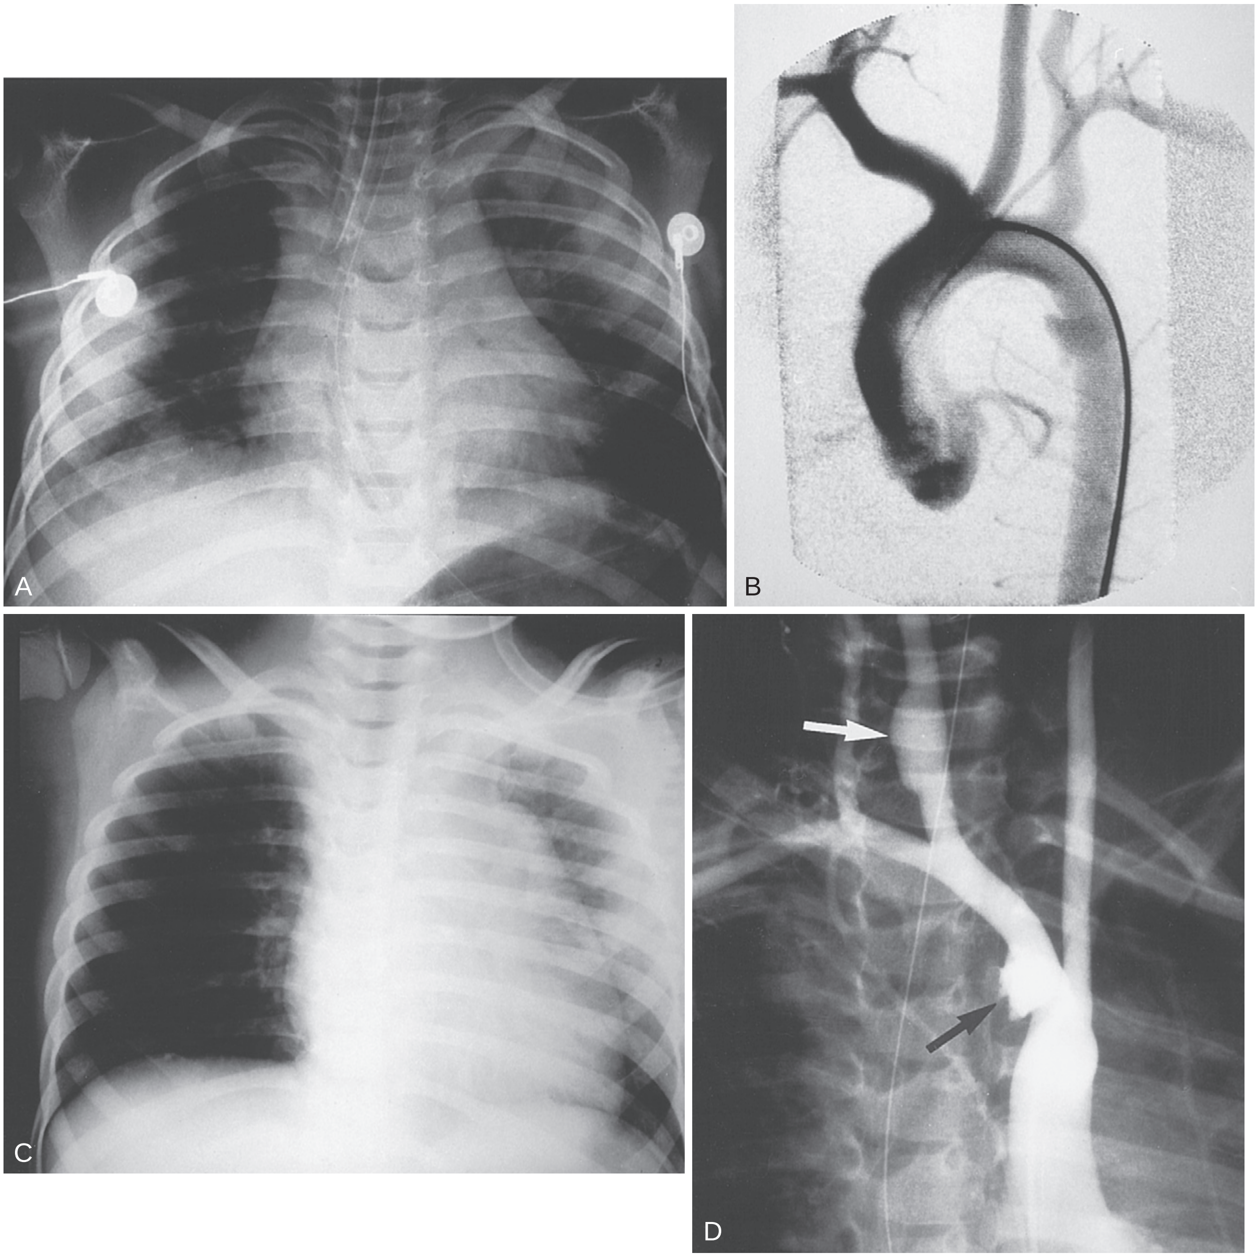

**FIGURE 19-8** Traumatic rupture of the aorta and branches. **A,** Widened mediastinum with deviation of the endotracheal and nasogastric tubes to the right. **B,** Same patient as in **A.** Aortic injury was confirmed by aortogram. **C,** Widened mediastinum in a patient who sustained blunt trauma to the chest. **D,** Same patient as in **C.** Innominate artery laceration at its origin (*arrow*). (From Wesson DE: Trauma of the chest in children. Chest Clin North Am 1993;3:423-441. Used with permission.)

The rate of paraplegia after repair of traumatic rupture of the aorta is about 5% to 10%. Individual variations in spinal cord blood supply, cross-clamp time, and intraoperative hypotension are important determinants of spinal cord injury.

There have been several recent reports of transfemoral stent insertion (endovascular stent grafting–thoracic endovascular aortic repair [EVSG–TEVAR]) for injuries to the thoracic aorta in adults. Early results indicate that the results may be better than with standard open repair. Three case series have appeared with remarkably low incidences of paraplegia.[92–94] EVSG–TEVAR has been reported in a small series of children, but there are no reports of long-term results.[77]

Only 1 of 13 patients in Eddy's report, a population-based study that included prehospital deaths, survived traumatic rupture of the aorta.[73] In contrast, DelRossi reported a 75% survival rate in a clinical series.[78] Three of the 21 survivors in Del Rossi's series were paraplegic after repair, but two recovered later. DelRossi found no evidence to support one technique of repair versus the others. However, Fabian and colleagues reported that the clamp and sew technique is more likely to result in paraplegia than repair with bypass, especially if the cross-clamp time is greater than 30 minutes.[95] As is true for many types of injury, outcome also depends on associated injuries.[91] Hormuth reported excellent overall

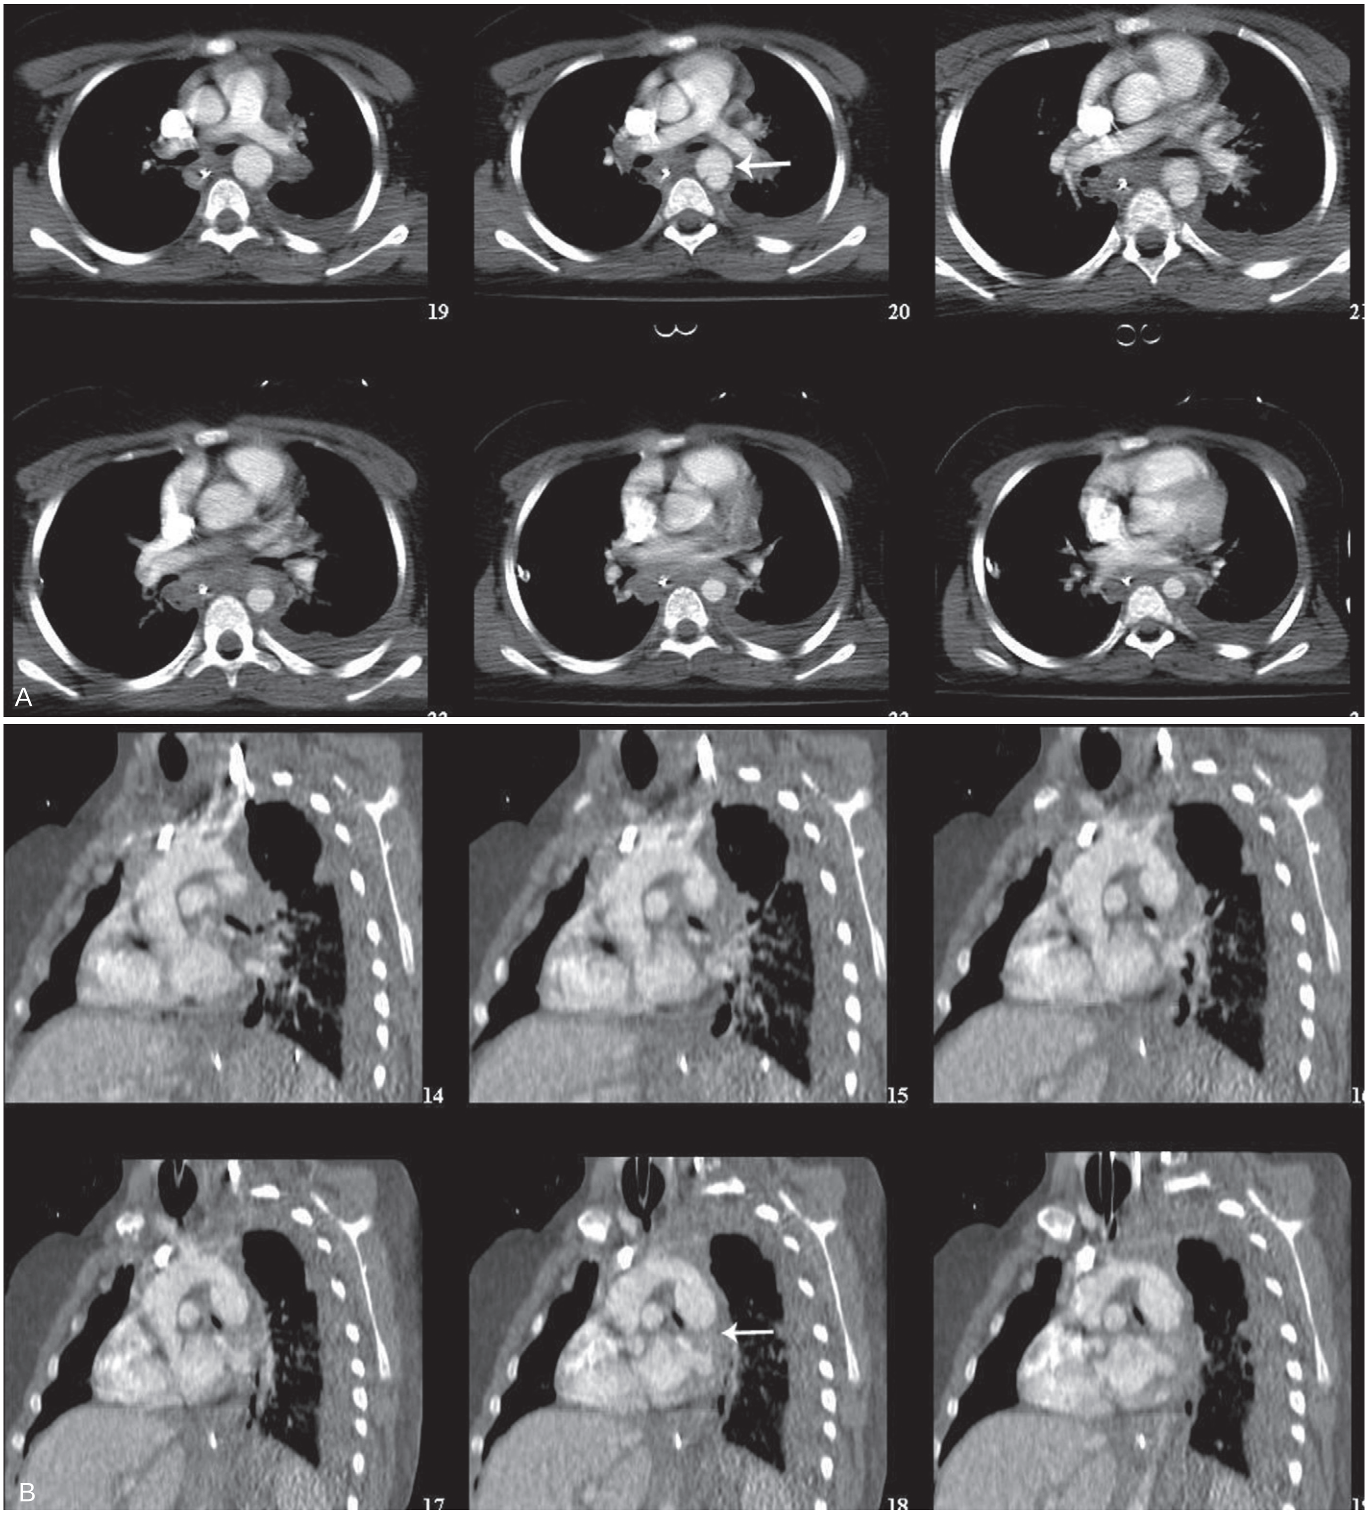

FIGURE 19-9 Helical computed tomography (CT) scan reconstruction showing traumatic rupture of the aorta in a 14-year-old boy. **A,** Transaxial view. Note periaortic hematoma at the isthmus. **B,** Three-dimensional reconstruction. Note interruption of flow at the isthmus.

results in a series of 11 children with thoracic aortic injuries.[76] They repaired isthmus injuries with left heart bypass with direct perfusion of the distal thoracic aorta and arch injuries with hypothermic arrest.

Other thoracic vascular injuries in children are rare, and the majority of injuries are in older children, resulting from penetrating mechanisms.[87] The standard vascular exposure for right subclavian vessel/innominate vessel injuries is a median sternotomy with a supraclavicular or anterior sternocleidomastoid-type neck extension. The choice depends on the injury complex and the potential need for extension distally toward the axilla on more distal injuries. Traditionally,

the left subclavian artery was approached through an anterior third intercostal space thoracotomy for proximal control with a supraclavicular approach for exposure of the middle-distal vessel. The proximal left subclavian artery can be controlled by a sternotomy as well, with a type of extension similar to that of right-sided injuries. Alternatively, hemodynamically stable patients have had thoracoscopic proximal control and direct repair performed. More recently, adolescents have undergone endovascular repair/stenting of these injuries. Caution must be exercised in considering the site of injury, because most grafts are not suitable for crossing joints because of an increased risk of thrombosis.

### Chylothorax

Injury to the thoracic duct, although rare, causes chylothorax. Most cases resolve spontaneously with nutritional support (total parenteral nutrition or elemental diet with medium-chain triglycerides). Occasionally, ligation of the thoracic duct is necessary.

### Traumatic Asphyxia

Traumatic asphyxia, a clinical syndrome that is unique to children, occurs with sudden compression of the abdomen or chest (or both) against a closed glottis.[96] This event causes a rapid rise in intrathoracic pressure, which is transmitted to all the veins that drain into the valveless superior vena cava. Extravasation of blood occurs into the skin of the upper half of the body, sclerae, and possibly the brain. The brain may also be damaged by hypoxia during and after the injury. The clinical features of this disorder include seizures, disorientation, petechiae in the upper half of the body and conjunctivae, and respiratory failure (Fig. 19-10). The treatment is supportive. Most patients recover uneventfully.

**FIGURE 19-10** Traumatic asphyxia. Two-year-old boy who was run over by truck wheel, causing typical plethoric appearance of "traumatic asphyxia." (From Haller JA: Thoracic injuries. ## PENETRATING INJURIES

The initial management of penetrating injuries is the same as for blunt trauma: Clear the airway, give oxygen and intravenous fluids, carefully assess the patient, and obtain a plain chest radiograph in every case. An attempt should be made to determine the path of the injury by marking the entry and exit wounds on the plain films. Endotracheal intubation and chest tube insertion should be done as needed during the initial resuscitation. It is important to remember the possibility of a concomitant abdominal injury with any wound below the nipple line. Bronchoscopy is indicated for suspected injury to the major airways; esophagoscopy and water-soluble contrast studies are indicated for suspected esophageal wounds. Echocardiography can be used in stable patients to diagnose suspected heart injuries.

Treatment is also the same as described for blunt trauma. Most of these patients do not require thoracotomy. The most common indications for surgery are massive bleeding, massive air leak, and pericardial tamponade.

Penetrating injuries are more likely to involve the heart, especially with anterior wounds medial to the midclavicular line. These injuries may cause pericardial tamponade or, if the pericardium has a defect, exsanguinating hemorrhage into the chest. Shock is a clear indication for urgent thoracotomy in cases of penetrating wounds to the chest. However, the management of patients who present with normal physiologic parameters and with wounds near the heart is problematic. The most conservative and safest approach is to take all such patients to the operating room for a subxiphoid pericardial window followed by thoracotomy through a median sternotomy, if necessary. Recent reports suggest that early echocardiography may be a very sensitive test for occult cardiac injuries and that this technique may be used to select patients who require a pericardial window, thereby minimizing unnecessary invasive procedures.[20,57,69] In this report, only patients with pericardial effusions on echocardiography underwent subxiphoid pericardial window; if blood was found, a median sternotomy followed. Patients with normal echocardiographs were observed clinically. Harris and colleagues reported a large experience with penetrating cardiac injuries and recommended cardiac ultrasonography in the diagnosis of these injuries in stable patients.[34]

When an operation is required for a penetrating cardiac injury, a Foley catheter placed through the defect may control the bleeding temporarily to facilitate suture of the defect. Median sternotomy is best for known cardiac injuries.

## THORACOABDOMINAL INJURIES

Thoracoabdominal injuries can be vexing because of the high mortality from multiple injuries and the need for combined procedures with appropriate sequencing for optimal results. Inappropriate sequencing of thoracic versus abdominal exploration occurs 20% to 40% of the time. The pitfalls are related to the unreliability of abdominal examination, inaccuracy of chest tube output as an indicator of ongoing thoracic bleeding, miscalculation of bullet/knife trajectory, and unreliability of central venous pressure as an index of preload. All of these pitfalls are managed by maintaining a high index of suspicion

of occult or underappreciated blood loss in the nonexplored cavity. Prompt changes in initial approaches minimizes delayed intervention, despite initial exploration of the less critical cavity.[97,98]

### TRANSMEDIASTINAL INJURIES

Transmediastinal injuries are initially managed according to hemodynamic status. Unstable patients are explored without extensive imaging or diagnostic studies. Stable patients should undergo initial chest radiography; then subsequent imaging or diagnostics depend on those findings/trajectory of the missile. CT imaging of the chest using helical scanners can diagnose most vascular injuries and give high-resolution images of potential aerodigestive tract injuries. Further localization depends on the findings and degree of certainty of the imaging studies.

## Complications

Very little information can be found in the literature on the morbidity of chest injuries or the complications after surgery for thoracic injuries in children. The two most common complications of thoracic surgery are pulmonary atelectasis and pneumonia. The most serious is paraplegia, which occurs in 5% to 10% of cases of injury to the thoracic aorta.

## Outcome

The risk for death from thoracic injury varies with the type of injury and the number and severity of associated injuries, particularly to the central nervous system. Roux and Fisher reported a series of 100 consecutive children with motor vehicle–related chest trauma in South Africa.[99] Ninety-one pedestrians comprised the largest subgroup. Eight died with a mean Injury Severity Score of 34 compared with 25 among the survivors. Seven of the 8 children who died had fatal head injuries. Thus in blunt injuries to the chest in children, the level of injury reflected in the Injury Severity Score and the presence of concomitant head injuries are the main determinants of survival. Deaths from thoracic injury in children tend to occur in the first few days after the injury, usually from other injuries and not from respiratory failure or sepsis, as is the case in adults.

The overall mortality for chest injuries was 15% in the National Pediatric Trauma Registry—virtually identical to most adult series.[5] Mortality increases with each individual chest injury: 30% for a ruptured diaphragm, 40% for cardiac injury, and 50% for injury to a major vessel.

The morbidity among survivors is remarkably low. DiScala[100] reported that 90% of survivors in the National Pediatric Trauma Registry had no impairment at the time of discharge.

## Summary

The following points summarize the management of thoracic injuries in children:

1. Most thoracic injuries can be diagnosed by a combination of clinical assessment and plain chest radiographs.
2. Most heal with medical (not surgical) treatment.
3. Life-threatening thoracic injuries are relatively uncommon.
4. A few thoracic injuries require surgery, but even the most severe can be managed successfully if recognized and treated expeditiously.

CHAPTER 20

# Abdominal Trauma

Steven Stylianos and Richard H. Pearl

Who could have imagined the influence of Simpson's 1968 publication on the successful nonoperative treatment of select children presumed to have splenic injury?[1] Initially suggested in the early 1950s by Warnsborough, then chief of general surgery at the Hospital for Sick Children in Toronto, the era of nonoperative management of splenic injury began with the report of 12 children treated between 1956 and 1965. The diagnosis of splenic injury in this select group was made by clinical findings, along with routine laboratory and plain radiographic findings. Keep in mind that this report predated ultrasonography (US), computed tomography (CT), or isotope imaging. Subsequent confirmation of splenic injury was made in one child who required laparotomy years later for an unrelated condition, when it was found that the spleen had healed in two separate pieces. Nearly half a century later, the standard treatment of hemodynamically stable children with splenic injury is nonoperative, and this concept has been successfully applied to most blunt injuries of the liver, kidney, and pancreas as well. Surgical restraint is now the norm, based on an increased awareness of the anatomic patterns and physiologic responses of injured children. Our colleagues in adult trauma care have slowly acknowledged this success and are applying many of the principles learned in pediatric trauma to their patients.[2]

Review of multiple large trauma databases indicates that 8% to 12% of children suffering blunt trauma have an abdominal injury.[3] Fortunately, more than 90% of them survive. Although abdominal injuries are 30% more common than thoracic injuries, they are 40% less likely to be fatal. The infrequent need for laparotomy in children with blunt abdominal injury has created a debate regarding the role of pediatric trauma surgeons in their treatment. Recent analyses of the National Pediatric Trauma Registry (NPTR) and the National Trauma Data Bank emphasize the overall "surgical" nature of pediatric trauma patients, with more than 25% of injured children requiring operative intervention.[4,5] Clearly, a qualified pediatric trauma surgeon would be the ideal coordinator of such care.

Few surgeons have extensive experience with massive abdominal solid organ injuries requiring immediate surgery. It is imperative that surgeons familiarize themselves with current treatment algorithms for life-threatening abdominal trauma. Important contributions have been made in the diagnosis and treatment of children with abdominal injury by radiologists and endoscopists. The resolution and speed of computed tomography (CT), the screening capabilities of focused abdominal sonography for trauma (FAST), and the percutaneous, angiographic, and endoscopic interventions of nonsurgeon members of the pediatric trauma team have all enhanced patient care and improved outcomes. This chapter focuses on the more common blunt injuries and unique aspects of care in children. Renal and genitourinary injuries are covered separately in Chapter 21.

## Diagnostic Modalities

The initial evaluation of an acutely injured child is similar to that of an adult. Plain radiographs of the cervical spine, chest, and pelvis are obtained after the initial survey and evaluation of the ABCs (airway, breathing, and circulation). Other plain abdominal films add little to the acute evaluation of pediatric trauma patients. As imaging modalities have improved, treatment algorithms have changed significantly in children with suspected intra-abdominal injuries. Prompt identification of potentially life-threatening injuries is now possible in the vast majority of children.

### COMPUTED TOMOGRAPHY

CT has become the imaging study of choice for the evaluation of injured children owing to several advantages. CT is now readily accessible in most health care facilities; it is a noninvasive, accurate method of identifying and qualifying the extent of abdominal injury, and it has reduced the incidence of nontherapeutic exploratory laparotomy. CT can be particularly helpful in diagnosing abdominal injuries in intubated, multi-injured children.[6]

Use of intravenous contrast is essential, and "dynamic" methods of scanning have optimized vascular and parenchymal enhancement. The importance of a contrast "blush" in children with blunt spleen and liver injury continues to be debated and is discussed later in the chapter (Fig. 20-1).[7] Head CT, if indicated, should be performed first without contrast, to avoid concealing a hemorrhagic brain injury. Controversy remains regarding the benefits of enteral contrast for diagnosis of gastrointestinal (GI) tract injuries. Many authors conclude that CT with enteral contrast does not

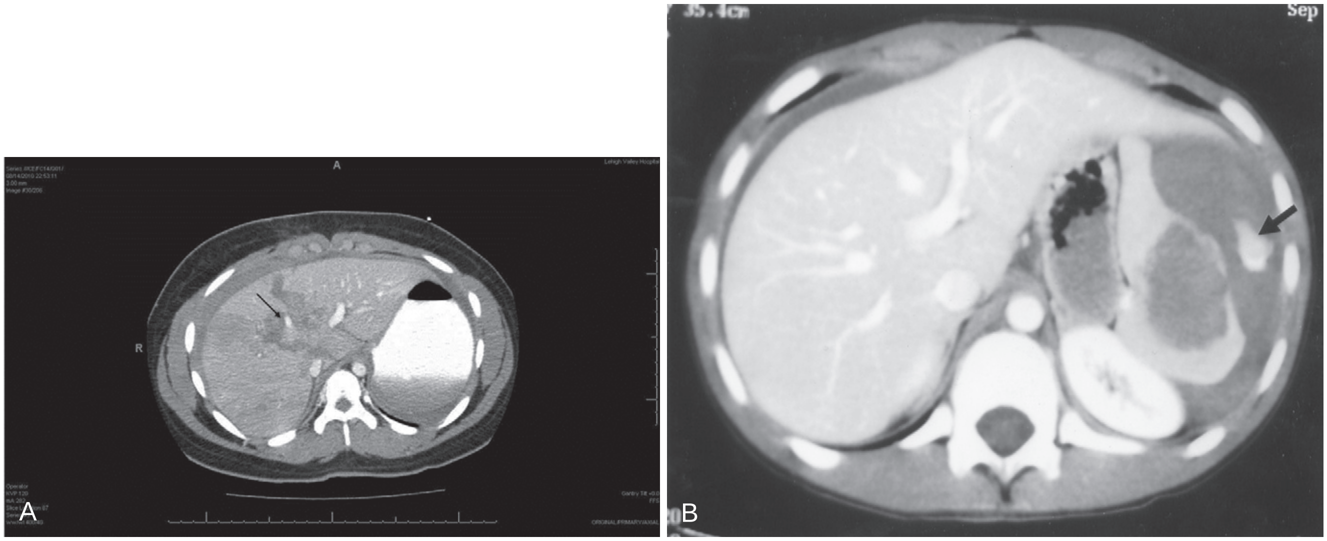

FIGURE 20-1 **A,** Abdominal computed tomography scan demonstrating a significant injury to the right hepatic lobe with intravenous contrast "blush" (*arrow*). This patient had successful angiographic embolization and avoided operation. **B,** Abdominal computed tomography scan demonstrating a significant injury to the spleen with intravenous contrast blush (*arrow*). The patient remained hemodynamically stable and avoided operation.

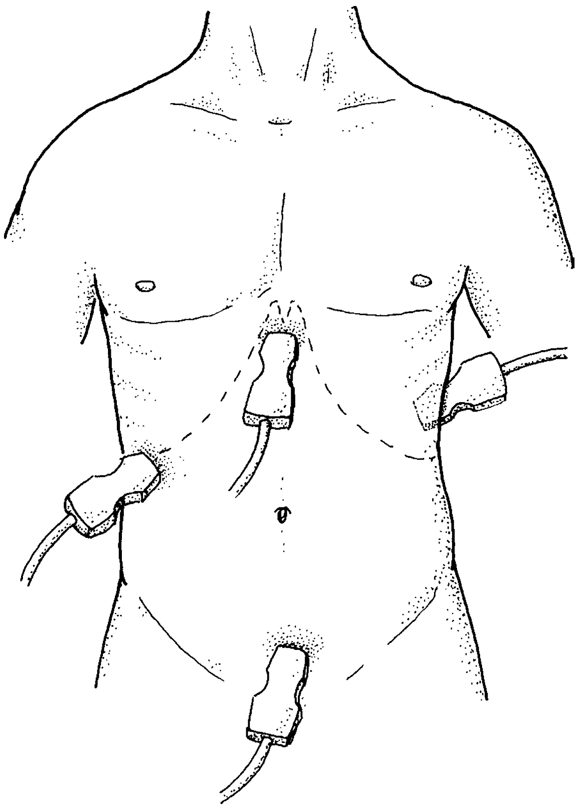

FIGURE 20-2 Schematic of a focused abdominal sonography for trauma (FAST) examination, with emphasis on views of the subxiphoid, right upper quadrant and pouch of Morrison, left upper quadrant and left paracolic region, and pelvic region and pouch of Douglas. (Original illustration by Mark Mazziotti, MD.)

improve diagnosis of GI injuries in the acute trauma setting and can lead to delays in diagnosis and aspiration.[8–12]

Not all children with potential abdominal injuries are candidates for CT evaluation. Obvious penetrating injury often necessitates immediate operative intervention. A hemodynamically unstable child should not be taken out of an appropriate resuscitation room for the performance of CT. These children may benefit from an alternative diagnostic study, such as peritoneal lavage or FAST, or urgent operative intervention. The greatest limitation of abdominal CT in trauma is the inability to reliably identify intestinal rupture.[13] Findings suggestive but not diagnostic of intestinal perforation are pneumoperitoneum, bowel wall thickening, free intraperitoneal fluid, bowel wall enhancement, and dilated bowel.[14] A high index of suspicion should exist for the presence of bowel injury in a child with intraperitoneal fluid and no identifiable solid organ injury on CT.[10] The diagnosis and treatment of bowel injury are reviewed in detail later.

## FOCUSED ABDOMINAL SONOGRAPHY FOR TRAUMA

Clinician-performed sonography for the early evaluation of an injured child is currently being evaluated to determine its optimal use. Examination of the pouch of Morrison; the pouch of Douglas; the left flank, including the perisplenic anatomy; and a subxiphoid view to visualize the pericardium is the standard four-view FAST examination (Fig. 20-2). This bedside examination may be a good rapid screening study, particularly in patients too unstable to undergo an abdominal CT scan. Early reports have found FAST to be a helpful screening tool in children, with a high specificity (95%) but low sensitivity (33%) in identifying intestinal injury. However, a lack of identifiable free fluid does not exclude a significant injury.[15] FAST may be useful in decreasing the number of CT scans performed for "low-likelihood" injuries. Repetition of the study may be necessary, depending on clinical correlation, and the finding of free fluid by itself is not an indication for surgical intervention. A recent meta-analysis of FAST in pediatric blunt trauma patients revealed modest sensitivity for hemoperitoneum.[16] The authors concluded that a negative FAST may have questionable utility as the sole diagnostic test to rule out the presence of an intra-abdominal injury. A hemodynamically stable child with a positive FAST should undergo CT.

## DIAGNOSTIC PERITONEAL LAVAGE AND LAPAROSCOPY

Diagnostic peritoneal lavage (DPL) has been a mainstay in trauma evaluation for more than 3 decades. However, its utility in pediatric trauma is limited. Because up to 90% of solid organ injuries do not require surgical intervention, the finding of free blood in the abdomen by DPL has limited clinical significance. Hemodynamic instability and the need for ongoing blood replacement are the determinants for operation in patients with solid organ injury in the absence of blood in the abdominal cavity. Additionally, the speed and accuracy of CT have further decreased the indications for DPL in pediatric trauma. The sensitivity of CT in diagnosing solid organ injuries and more subtle injuries to the duodenum, pancreas, and intestines continues to improve. This has relegated DPL to the evaluation of patients with clinical findings suggestive of bowel injury and no definitive diagnosis on CT. In this setting, the presence of bile, food particles, or other evidence of GI tract perforation is diagnostic. Recent literature has suggested that laparoscopy can both diagnose and, in some cases, allow definitive surgical management without laparotomy, further limiting the usefulness of DPL.[17]

Large series using laparoscopy in adults have demonstrated increased diagnostic accuracy, definitive management of related injuries, decreased nontherapeutic laparotomy rates, and a significant decrease in hospital length of stay, with an attendant reduction in costs.[18,19] The extent of feasible operations is directly related to the surgeon's skill with advanced laparoscopic techniques and the patient's overall stability. At the Children's Hospital of Illinois, our two most recent handlebar injuries causing bowel perforation were successfully treated laparoscopically. As with elective abdominal surgery, the role of laparoscopy in trauma will increase substantially as trauma centers redirect their training of residents to this modality and as more pediatric centers report outcome studies for laparoscopic trauma management in children.[20–22]

# Solid Organ Injuries

## SPLEEN AND LIVER

The spleen and liver are the organs most commonly injured in blunt abdominal trauma, with each accounting for one third of the injuries. Nonoperative treatment of isolated splenic and hepatic injuries in stable children has been universally successful and is now standard practice; however, there is great variation in the management algorithms used by individual pediatric surgeons.[23]

Controversy exists regarding the utility of CT grading and the finding of contrast blush as a predictor of outcome in liver and spleen injury.[24–26] Several recent studies reported contrast blush in 7% to 12% of children with blunt spleen injury (see Fig. 20-1).[27–29] The rate of operation in the blush group approached or exceeded 20%. The authors emphasized that CT blush was worrisome but that most patients could still be managed successfully without operation. The role and impact of angiographic embolization in adults is still debated and has yet to be determined in pediatric spleen injury.[30,31] Initial retrospective studies have found angiographic embolization to be safe and effective in children; however, selection criteria remain undefined.[32]

The American Pediatric Surgical Association (APSA) Trauma Committee analyzed a contemporary multi-institution database of 832 children treated nonoperatively at 32 centers in North America from 1995 to 1997 (Table 20-1).[33] Consensus guidelines on intensive care unit (ICU) stay, length of hospital stay, use of follow-up imaging, and physical activity restriction for clinically stable children with isolated spleen or liver injuries (CT grades I to IV) were defined based on this analysis (Table 20-2). The guidelines were then applied prospectively in 312 children with liver or spleen injuries treated nonoperatively at 16 centers from 1998 to 2000.[34] Patients with other minor injuries, such as nondisplaced, noncomminuted fractures or soft tissue injuries, were included as long as the associated injuries did not influence the variables in the study. The patients were grouped by severity of injury defined by CT grade. Compliance with the proposed guidelines was analyzed for age, organ injured, and injury grade. All patients were followed for 4 months after injury. It is imperative to emphasize that these proposed guidelines assume hemodynamic stability. The extremely low rates of transfusion and operation document the stability of the study patients.

Specific guideline compliance was 81% for ICU stay, 82% for length of hospital stay, 87% for follow-up imaging, and 78% for activity restriction. There was a significant improvement in compliance from year 1 to year 2 for ICU stay (77% versus 88%, $P < 0.02$) and activity restriction (73% vs. 87%, $P < 0.01$). There were no differences in compliance by age,

CT, Computed tomography; ICU, intensive care unit.

gender, or organ injured. Deviation from the guidelines was the surgeon's choice in 90% of cases and patient-related in 10%. Six patients (1.9%) were readmitted, although none required operation. Compared with the previously studied 832 patients, the 312 patients managed prospectively by the proposed guidelines had a significant reduction in ICU stay ($P < 0.0001$), hospital stay ($P < 0.0006$), follow-up imaging ($P < 0.0001$), and interval of physical activity restriction ($P < 0.04$) within each grade of injury.

From these data, it was concluded that prospective application of specific treatment guidelines based on injury severity resulted in conformity in patient management, improved use of resources, and validation of guideline safety. Significant reductions in ICU stay, hospital stay, follow-up imaging, and activity restriction were achieved without adverse sequelae when compared with the retrospective database. The pendulum continues to swing toward less hospitalization of stable children with solid liver or spleen injury. Retrospective and prospective studies suggest that the APSA guidelines for hospital length of stay can be reduced further.[35,36]

Authors from the Arkansas Children's Hospital reported on an abbreviated protocol based on hemodynamics while "throwing out" the CT grade of injury in 101 patients with isolated spleen or liver injury. Their protocol resulted in a significant reduction in length of stay (3.5 vs. 1.9 days, $P < 0.001$) from that predicted by APSA guidelines.

The attending surgeon's decision to operate for spleen or liver injury is best based on evidence of continued blood loss, such as low blood pressure, tachycardia, decreased urine output, and falling hematocrit unresponsive to crystalloid and blood transfusion. The rates of successful nonoperative treatment of isolated blunt splenic and hepatic injury now exceed 90% in most pediatric trauma centers and in adult trauma centers with a strong pediatric commitment.[35–37] A study of more than 100 patients from the NPTR indicated that nonoperative treatment of spleen or liver injury is indicated even in the presence of associated head injury if the patient is hemodynamically stable.[38] Rates of operative intervention for blunt spleen or liver injury were similar with and without an associated closed head injury.

Not surprisingly, adult trauma services have reported excellent survival rates for pediatric trauma patients; however, an analysis of treatment for spleen and liver injuries reveals alarmingly high rates of operative treatment.[39–41]

This discrepancy in operative rates emphasizes the importance of disseminating effective guidelines, because the majority of seriously injured children are treated outside of dedicated pediatric trauma centers. Mooney and Forbes[37] reviewed the New England Pediatric Trauma Database in the 1990s and identified 2500 children with spleen injuries. Two thirds were treated by nonpediatric trauma surgeons, and two thirds were treated in nontrauma centers. After allowing for multiple patient- and hospital-related variables, the authors found that the risk of operation was reduced by half when a surgeon with pediatric training provided care to children with splenic injuries. In a similar review using the Kids' Inpatient Database (KID) 2000 administrative data set, Mooney and Rothstein[42] found that despite adjustment for hospital- and patient-specific variables, children treated at an adult general hospital had a 2.8 greater chance ($P < 0.003$), and those treated at a general hospital with a pediatric unit had a 2.6 greater chance ($P < 0.013$), of undergoing splenectomy than those cared for at a freestanding pediatric hospital.

Several recent studies provide a basis for ongoing concern regarding disparity of treatment in children with blunt spleen injury.[37,40,42–45] Using large nonselected databases and adjusting for risk, these studies indicate that the disparity is substantial and continuing on a regional and national basis (see Table 20-5).

Todd and colleagues analyzed the Healthcare Cost and Utilization Project's National Inpatient Sample (HCUP-NIS), which contains a sample of discharges from 1300 hospitals in 28 states (representing 20% of all hospital discharges in the United States).[43] Children with splenic injury treated at rural hospitals had a risk-adjusted odds ratio for laparotomy of 1.64 (95% CI, 1.39 to 1.94) when compared with those treated at an urban teaching hospital. The APSA Center on Outcomes compared the treatment of pediatric splenic injury using discharge datasets from four states.[41] The authors found a risk-adjusted odds ratio for laparotomy of 2.1 (95% CI, 1.4 to 3.1) when comparing treatment at nontrauma centers versus centers with trauma expertise. Mooney and colleagues reviewed more than 2600 children with splenic injury from the New England Pediatric Trauma Database and found that similarly injured patients treated by nonpediatric surgeons had a risk-adjusted odds ratio for laparotomy of 3.1 (95% CI, 2.3 to 4.4) when compared with those treated by pediatric surgeons.[37] The last two studies found even greater disparity when comparing the treatment of children with isolated splenic injury as contrasted with those with multiple injuries. Bowman and colleagues used data from the Kids Inpatient Database (KID 2000) of the Healthcare Cost and Utilization Project, sponsored by the Agency for Healthcare Research and Quality.[44] This administrative database represents an

80% sample of non-newborn discharges from 2784 hospitals in 27 states (2.5 million pediatric discharges). The authors found a risk-adjusted odds ratio for laparotomy of 5.0 (95% CI, 2.2 to 11.4) when comparing treatment at general hospitals versus children's hospitals in pediatric patients with splenic injury. Davis and colleagues reviewed discharge data from 175 hospitals in Pennsylvania and found the risk-adjusted odds ratio for laparotomy to be 6.2 (95% CI, 4.4 to 8.6) when comparing treatment at adult trauma centers versus pediatric trauma centers.[45] Although these studies suggest marked differences in the processes of care, administrative datasets do not readily allow risk adjustment for differences in physiologic status at presentation, a potential major limitation (Table 20-3).

Sims and colleagues surveyed 281 surgeons (114 pediatric, 167 adult) regarding their treatment of children with solid organ injury (SOI).[40] For all clinical scenarios, adult surgeons were more likely to operate or pursue interventional radiologic procedures than their pediatric colleagues (relative risk [RR]: 8.6 with isolated SOI, $P < 0.05$; 14.8 SOI with multiple SOI, $P < 0.001$; 17.9 SOI with intracranial hemorrhage, $P < 0.0001$). Adult surgeons were also more likely to consider any transfusion a failure (13.3% vs. 1.2%, $P < 0.01$) and had a much lower transfusion threshold.

The importance of these data is further amplified by the fact that the overwhelming majority (68% to 87%) of pediatric patients were treated at the facilities or by physicians with the higher likelihood of operation.[37,44,45] In contrast, Stylianos and colleagues found that nearly two thirds of children with splenic injury were treated at institutions with trauma expertise.[41] Trauma centers had a significantly lower rate of operation for both multiple-injury patients (15.3% vs. 19.3%, $P < 0.001$) and those with isolated injury (9.2% vs. 18.5%, $P < 0.0001$) when compared to nontrauma centers (see Table 20-6). The operative rates at both trauma centers and nontrauma centers exceeded published APSA benchmarks (Tables 20-4 and 20-5) for all children with splenic injury (3% to 11%) and those with isolated splenic injury (0% to 3%).

Thus trauma centers and their corresponding state or regional trauma systems may represent rational targets for dissemination of current pediatric trauma guidelines and benchmarks. Broad application of existing APSA guidelines for splenic injury should

encourage conformity of care and result in reduced rates of operative intervention and diminished resource use.

Failure of nonoperative management (NOM) can have serious consequences; therefore patient selection is important.[47] Two recent multi-institutional reviews sought to evaluate the time line and the characteristics of patients who fail NOM.[48,49] There was operation in 120 of 1813 (6.6%) children with solid organ injury in a median time of 2.4 hours with 90% of patients having surgery within 24 hours. Pediatric patients who sustained pancreatic injuries were more likely to fail nonoperative management (odds ratio [OR] 7.49; 95% CI, 3.74 to 15.01) compared with those who suffered other injuries. The patients who failed had higher injury severity scores (ISS; $28 \pm 17$) than those who underwent successful NOM ($14 \pm 10$, $P < 0.001$). Severely head-injured patients (Glasgow Coma Scale [GCS] = 8) had a higher failure rate for NOM (OR 5.09; 95% CI, 3.04 to 8.52). Factors associated with increased failure rate include bicycle-related injury mechanism, isolated pancreatic injury, more than one solid organ injury, and an isolated grade 5 solid organ injury. The time to failure of NOM peaked at 4 hours and then declined over 36 hours from admission. Thus continued surgical evaluation and assessment during the entire hospital stay is required to limit morbidity and mortality of the pediatric trauma patient.

### Summary

If care is to be optimally provided at centers outside of the tertiary pediatric setting, health care providers in these environments need to reassess their approach to the management of pediatric splenic injury, recognizing that the operative rate is presently 4 to 6 times lower for children with splenic injury treated by pediatric surgeons at pediatric facilities than in other environments. It is incumbent upon pediatric trauma centers to do a better job of educating trauma colleagues in nonpediatric trauma centers regarding the optimal care of pediatric patients with splenic injury, so that these results are not limited to highly selected centers. Focusing educational programs and evidence-based management guidelines on centers with higher rates of splenectomy may be the next step to improve the rate of splenic conservation. Although the impact on in-hospital mortality might not be a relevant end point, because it is infrequent, these patients are at higher risk for overwhelming postsplenectomy sepsis and complications related to laparotomy, such as adhesive small bowel obstruction and incisional hernia.

Adult trauma surgeons caring for injured children must consider the anatomic, immunologic, and physiologic differences between pediatric and adult trauma patients and incorporate these differences into their treatment protocols.[50] The major concerns are related to the potential risks of increased transfusion requirements, missed associated injuries, and increased length of hospital stay. Each of these concerns has been shown to be without merit.[51–53]

## ASSOCIATED ABDOMINAL INJURIES

Advocates of surgical intervention for splenic trauma cite their concern about missing associated abdominal injuries if no operation is performed. Morse and Garcia reported successful nonoperative treatment in 110 of 120 children (91%) with blunt splenic trauma, of whom 22 (18%) had associated abdominal injuries.[51] Only 3 of these 120 patients (2.5%) had GI injuries, and each was discovered at early celiotomy done for a specific indication. There was no morbidity from missed injuries or delayed surgery. Similarly, a review of the NPTR from 1988 to 1998 revealed 2977 patients with solid abdominal visceral injuries; only 96 (3.2%) had an associated hollow visceral injury.[52] Higher rates of hollow visceral injury were observed in assaulted patients and in those with multiple solid visceral injuries or pancreatic injuries. Differences in mechanism of injury may account for the much lower incidence of associated abdominal injuries in children with splenic trauma. There is no justification for an exploratory celiotomy solely to avoid missing potential associated injuries in children.

## COMPLICATIONS OF NONOPERATIVE TREATMENT

Nonoperative treatment protocols have been the standard for most children with blunt liver and spleen injuries for the past 3 decades. This cumulative experience has allowed us to evaluate both the benefits and the risks of the nonoperative approach. Fundamental to the success of a nonoperative strategy is the early, spontaneous cessation of hemorrhage. Transfusion rates for children with isolated spleen or liver injuries have fallen below 10%, confirming the lack of continued blood loss in the majority of patients.[33,34,53] Rare anecdotal reports of significant delayed hemorrhage with adverse outcomes after solid organ injury continue to appear and cause concern.[47,54–56] Shilyansky and colleagues[56] reported two children with delayed hemorrhage 10 days after blunt liver injury. Both children had persistent right upper quadrant and right shoulder pain despite normal vital signs and stable hematocrits. The authors recommended continued in-house observation until symptoms resolve. The incidence of delayed bleeding after blunt splenic injury was 1 (0.33%) in 303 children reported from the Hospital for Sick Children in Toronto and resulted in a fatality.[47] These rare occurrences lead to caution when determining a minimum safe interval before the resumption of unrestricted activities.

Routine follow-up imaging studies have identified pseudocysts and pseudoaneurysms following splenic injury.[57] Splenic pseudoaneurysms often cause no symptoms and appear to resolve with time. The true incidence of self-limited, posttraumatic splenic pseudoaneurysms is unknown, because routine follow-up imaging after successful nonoperative treatment has been largely abandoned. Once identified, the actual risk of splenic pseudoaneurysm rupture is also unclear. Angiographic embolization techniques can successfully treat these lesions, obviating the need for open surgery and loss of splenic parenchyma (Fig. 20-3).[58] Splenic pseudocysts can achieve enormous size, leading to pain and GI disturbance (Fig. 20-4). Simple percutaneous aspiration leads to a high recurrence rate. Laparoscopic excision and marsupialization are highly effective (Fig. 20-5).

## SEQUELAE OF DAMAGE-CONTROL STRATEGIES

Even the most severe solid organ injuries can be treated without surgery, if there is a prompt response to resuscitation.[59,60] In contrast, emergency laparotomy, embolization, or both are

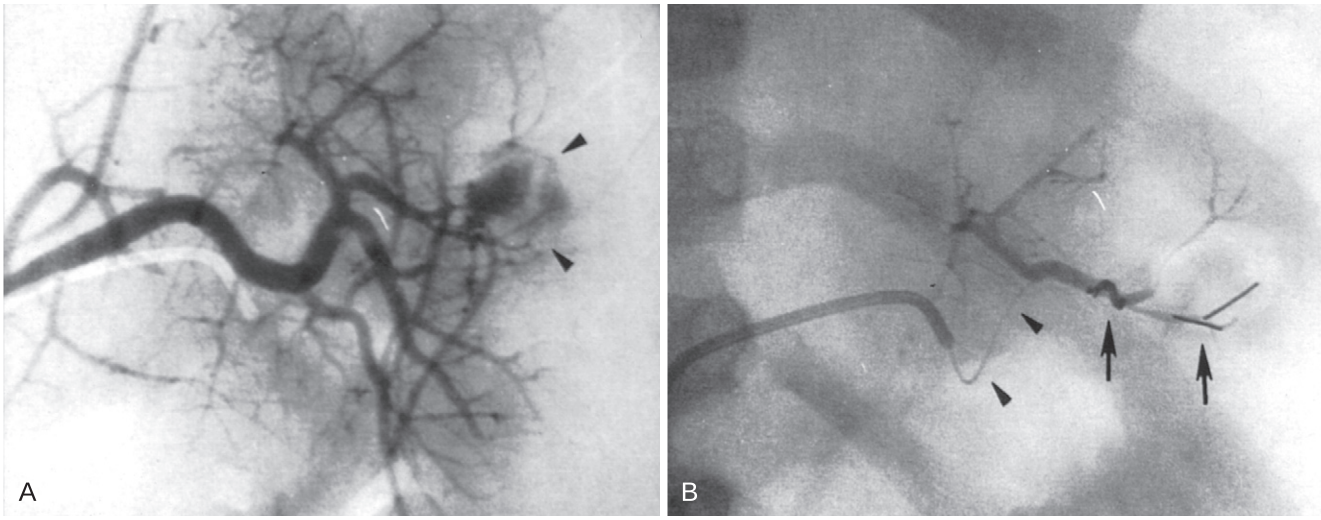

FIGURE 20-3 **A,** Splenic pseudoaneurysm (arrowheads indicate contrast within the pseudoaneurysm) after nonoperative treatment of blunt splenic injury. **B,** Successful angiographic embolization (*arrows* show occlusion of ruptured vessels).

indicated in patients who are hemodynamically unstable despite fluid and red blood cell transfusion (Fig. 20-6). Most spleen and liver injuries requiring operation are amenable to simple methods of hemostasis using a combination of manual compression, direct suture, topical hemostatic agents, and mesh wrapping. In young children with significant hepatic injury, the sternum can be divided rapidly to expose the suprahepatic or intrapericardial inferior vena cava, allowing for total hepatic vascular isolation (Fig. 20-7). Children can tolerate periods of vascular isolation for 30 minutes or longer, as long as their blood volume is replenished. Venovenous bypass may be useful but is rarely available for such rare injuries.[61] With this exposure, the liver and major perihepatic veins can be isolated and the bleeding controlled, permitting direct suture repair or ligation of the offending vessel. Although the cumbersome and dangerous technique of atriocaval shunting has been largely abandoned, newer endovascular balloon catheters can be useful

for temporary vascular occlusion to allow access to the juxtahepatic vena cava.[62]

The early morbidity and mortality of severe hepatic injuries are related to the effects of massive blood loss and replacement with large volumes of cold blood products. The consequences of prolonged operations with massive blood-product replacement include hypothermia, coagulopathy, and acidosis. Although the surgical team may keep pace with blood loss, life-threatening physiologic and metabolic consequences are inevitable, and many of these critically ill patients are unlikely to survive once their physiologic reserves have been

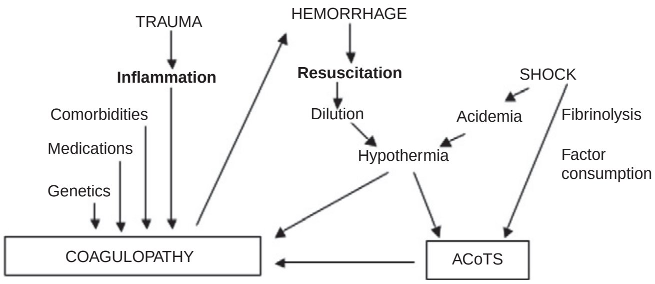

FIGURE 20-8 Acute coagulopathy of trauma and shock (ACoTS). (From Hess JR, Brohi K, Duton RP, et al: The coagulopathy of trauma: A review of mechanisms. J Trauma 2008;65:748-754.)

exhausted. A multi-institutional review identified exsanguination as the cause of intraoperative death in 82% of 537 patients at eight academic trauma centers.[63] The mean pH was 7.18, and the mean core temperature was 32° C before death. Moulton and colleagues reported survival in only 5 of 12 (42%) consecutive operative cases of retrohepatic vascular or severe parenchymal liver injury in children.[64]

Maintenance of physiologic stability during the struggle for surgical control of severe bleeding is a formidable challenge even for the most experienced surgical team, particularly when hypothermia, coagulopathy, and acidosis occur. This triad creates a vicious circle in which each derangement exacerbates the others, and the physiologic and metabolic consequences often preclude completion of the procedure. Lethal coagulopathy from a combination of tissue injury, dilution, hypothermia, and acidosis can rapidly occur (Fig. 20-8).[65] Experimental studies have defined the alterations in procoagulant and anticoagulant enzyme processes, platelet activation, and platelet adhesion defects with varying degrees of hypothermia.[66] The infusion of activated recombinant factor VII in children with massive hemorrhage has been promising in several case reports, and experimental studies suggest that recombinant factor VII maintains its effectiveness at hypothermic temperatures[67–70]

Increased emphasis on physiologic and metabolic stability in emergency abdominal operations has led to the development of staged, multidisciplinary treatment plans, including abbreviated laparotomy, perihepatic packing, temporary abdominal closure, angiographic embolization, and endoscopic biliary stenting.[71–74] Asensio and colleagues[75] reported on 103 patients with mostly penetrating grade IV or V hepatic injuries treated between 1991 and 1999. Mean blood loss was estimated at 9.4 L, and mean volume infusion in the operating room was 15 L. Packing of the hepatic injuries was used in 50% of patients at the first operation. Forty percent of patients who survived the initial operative control of hemorrhage had postoperative angiographic embolization (Fig. 20-9). Survival was 63% in grade IV patients and 24% in grade V patients, emphasizing the lethality of such injuries despite a well-choreographed, staged, multidisciplinary approach. Trauma surgeons treating critically injured children must familiarize themselves with these lifesaving techniques.

Hepatic angioembolization can clearly be an important adjunct in the treatment of patients with major liver injury. However, evidence of significant hepatic necrosis and biliary leaks occur in 30% to 40% of patients, thus emphasizing the need for cautious patient selection.[76,77]

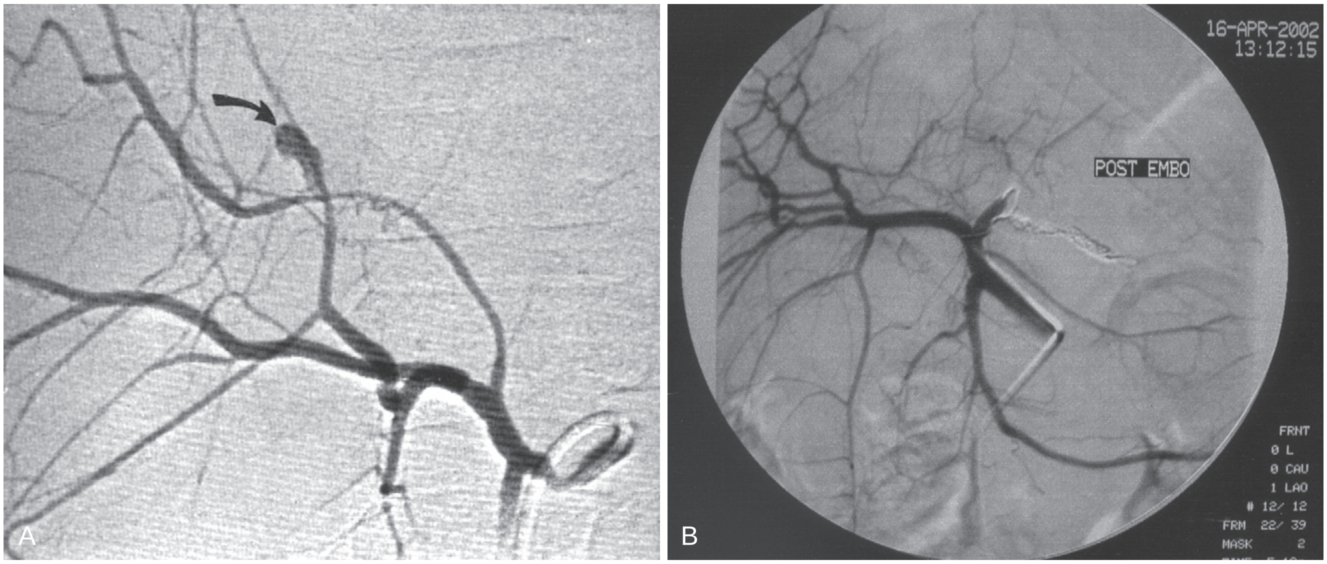

**FIGURE 20-9** **A,** Hepatic artery angiogram in a patient with persistent hemorrhage after initial damage-control laparotomy. The bleeding vessel is identified (*curved arrow*). **B,** Successful embolization was performed.

Abbreviated laparotomy with packing for hemostasis, allowing resuscitation before planned reoperation, is an alternative in unstable patients in whom further blood loss would be untenable. This damage-control philosophy is a systematic, phased approach to the management of exsanguinating trauma patients.[78–80] The three phases of damage control are detailed in Table 20-6. Although controversial, several resuscitative end points have been proposed beyond the conventional vital signs and urine output, including serum lactate, base deficit, mixed venous oxygen saturation, and gastric mucosal pH. Once a patient is rewarmed, coagulation factors are replaced, and oxygen delivery is optimized, he or she can be returned to the operating room for pack removal and definitive repair of injuries. A review of nearly 700 adult patients treated by abdominal packing from several institutions demonstrated hemostasis in 80%, survival of 32% to 73%, and abdominal abscess rates of 10% to 40%.[81,82] Although abdominal packing with planned reoperation has been used with increasing frequency in adults during the past 2 decades, there is little published experience in children.[61,83–88] Nevertheless, we believe that this technique has a place in the management of children with massive intra-abdominal bleeding, especially after blunt trauma. As an example, we reported a 3-year-old child who required abdominal packing for a severe liver injury, making closure of the abdomen impossible.[88] A Silastic silo was constructed to accommodate the bowel until the packing could be removed. The patient made a complete recovery. The combined technique of packing and a silo allowed time for correction of the hypothermia, acidosis, and coagulopathy without compromise of respiratory mechanics. One review reported 22 infants and children (age 6 days to 20 years) with refractory hemorrhage who were treated with abdominal packing.[87] The anatomic site of hemorrhage was the liver or hepatic veins in 14, retroperitoneum or pelvis in 7, and pancreatic bed in 1. Primary fascial closure was accomplished in 12 patients (55%), and temporary skin closure or prosthetic material was used in the other 10. Packing controlled hemorrhage in 21 of 22 patients (95%). Removal of the packing was possible within 72 hours in 18 patients (82%). No patient rebled after the packing was removed; however, 2 patients died with the packing in place. Seven patients (32%) developed an abdominal or pelvic abscess, and all were successfully drained by laparotomy (6 patients) or percutaneously (1 patient); 6 of the 7 patients with abdominal sepsis survived. Overall, 18 patients (82%) survived. Two deaths were due to multisystem organ failure, one to cardiac failure from complex cardiac anomalies, and one to exsanguination after blunt traumatic liver injury. There were no differences in the volume of intraoperative blood product transfusion, time to initiate packing, physiologic status, or type of abdominal closure between survivors and nonsurvivors.

ICU, Intensive care unit.

Preperitoneal pelvic packing for hemodynamically unstable patients with pelvic fracture is another unique use of pack tamponade in life-threatening hemorrhage.[89]

Although the success of abdominal packing is encouraging, it may contribute to significant morbidity, such as intra-abdominal sepsis, organ failure, and increased intra-abdominal pressure. Intra-abdominal packs are contaminated by skin and gut flora, but these organisms are not those implicated in

subsequent patient sepsis.[90] Adams and colleagues[91] evaluated fluid samples from 28 patients with abdominal packing and found peritoneal endotoxin and mediator accumulation even when cultures were sterile. The authors concluded that laparotomy pad fluid accumulating after damage-control laparotomy can contribute to neutrophil dysfunction by enhancing neutrophil respiratory burst and inhibiting neutrophil responses to specific chemotactic mediators needed to fight infection. Thus the known propensity of such patients to both intra-abdominal and systemic infection may be related to changes in neutrophil receptor status and effector function related to the accumulation of inflammatory mediators in the abdomen. Early washout, repetitive packing, and other efforts to minimize mediator accumulation deserve consideration.

It is essential to emphasize that the success of the abbreviated laparotomy and planned reoperation depends on an early decision to use this strategy before irreversible shock occurs. When used as a desperate, last-ditch resort after prolonged attempts at hemostasis have failed, abdominal packing has been uniformly unsuccessful. Physiologic and anatomic criteria have been identified as indications for abdominal packing. Most of these focus on intraoperative parameters, including pH ($\approx$7.2), core temperature ($<$35° C), and coagulation values (prothrombin time $>$16 seconds), in a patient with profuse hemorrhage requiring large volumes of blood product transfusion.

The optimal time for reexploration is controversial, because neither the physiologic end points of resuscitation nor the increased risk of infection with prolonged packing are well defined. The obvious benefits of hemostasis provided by packing are also balanced against the potential deleterious effects of increased intra-abdominal pressure on ventilation, cardiac output, renal function, mesenteric circulation, and intracranial pressure. Timely alleviation of the secondary abdominal compartment syndrome may be a critical salvage maneuver for patients. Temporary abdominal wall closure at the time of packing can prevent the abdominal compartment syndrome. We recommend temporary abdominal wall expansion in all patients requiring packing, until hemostasis is obtained and visceral edema subsides.

A staged operative strategy for unstable trauma patients represents advanced surgical care and requires sound judgment and technical expertise. Intra-abdominal packing for control of exsanguinating hemorrhage is a lifesaving maneuver in highly selected patients in whom coagulopathy, hypothermia, and acidosis render further surgical procedures unduly hazardous. Early identification of patients likely to benefit from abbreviated laparotomy techniques is crucial for success.

## ABDOMINAL COMPARTMENT SYNDROME

The abdominal compartment syndrome is a term used to describe the deleterious effects of increased intra-abdominal pressure.[92] The syndrome includes respiratory insufficiency from worsening ventilation-perfusion mismatch, hemodynamic compromise from preload reduction resulting from inferior vena cava compression, impaired renal function resulting from renal vein compression, decreased cardiac output, intracranial hypertension resulting from increased ventilator pressures, splanchnic hypoperfusion, and abdominal wall overdistention. The causes of intra-abdominal hypertension in trauma patients include hemoperitoneum, retroperitoneal or bowel edema, and use of abdominal or pelvic packing. The combination of tissue injury and hemodynamic shock creates a cascade of events, including capillary leak, ischemia-reperfusion, and release of vasoactive mediators and free radicals, which combine to increase extracellular volume and tissue edema. Experimental evidence indicates that there are significant alterations in cytokine levels in the presence of sustained intra-abdominal pressure elevation.[93,94] Once the combined effects of tissue edema and intra-abdominal fluid exceed a certain level, abdominal decompression must be considered.

The adverse effects of abdominal compartment syndrome have been acknowledged for decades; however, abdominal compartment syndrome has only recently been recognized as a life-threatening but potentially treatable entity.[95,96] The incidence of this complication has increased markedly in recent years due to high-volume resuscitation protocols. Measurement of intra-abdominal pressure can be useful in determining the contribution of abdominal compartment syndrome to altered physiologic and metabolic parameters.[97,98] Intra-abdominal pressure can be determined by measuring bladder pressure. This involves instilling 1 mL/kg of saline into the Foley catheter and connecting it to a pressure transducer or manometer through a three-way stopcock. The symphysis pubis is used as the zero reference point, and the pressure is measured in centimeters of water or millimeters of mercury. Intra-abdominal pressures in the range of 20 to 35 cm $H_2O$ or 15 to 25 mm Hg have been identified as an indication to decompress the abdomen. Many prefer to intervene according to alterations in other physiologic and metabolic parameters rather than a specific pressure measurement. Chang and colleagues[97] reported 11 adult trauma patients with abdominal compartment syndrome in whom abdominal decompression using pulmonary artery catheters and gastric tonometry improved preload, pulmonary function, and visceral perfusion. Anecdotally, decompressive laparotomy has been used successfully to reduce refractory intracranial hypertension in patients with isolated brain injury without overt signs of abdominal compartment syndrome.[99]

Experience with abdominal decompression for abdominal compartment syndrome in children is limited.[*] Nonspecific abdominal CT findings in children with abdominal compartment syndrome include narrowing of the inferior vena cava, direct renal compression or displacement, bowel wall thickening with enhancement, and a rounded appearance of the abdomen.[100] Neville and colleagues[101] reported the use of patch abdominoplasty in 23 infants and children, only 3 of whom were trauma patients. These authors found that patch abdominoplasty for abdominal compartment syndrome effectively decreased airway pressures and oxygen requirements. Failure to respond with a decrease in airway pressures or fraction of inspired oxygen was an ominous sign in their series. Several authors have found that abdominal decompression resulted in decreased airway pressures, increased oxygen tension, and increased urine output in children with abdominal compartment syndrome.[95,98,101]

Many materials have been suggested for use in temporary patch abdominoplasty, including Silastic sheeting, Gore-Tex sheeting, intravenous bags, cystoscopy bags, ostomy appliances, and various mesh materials. The vacuum-pack

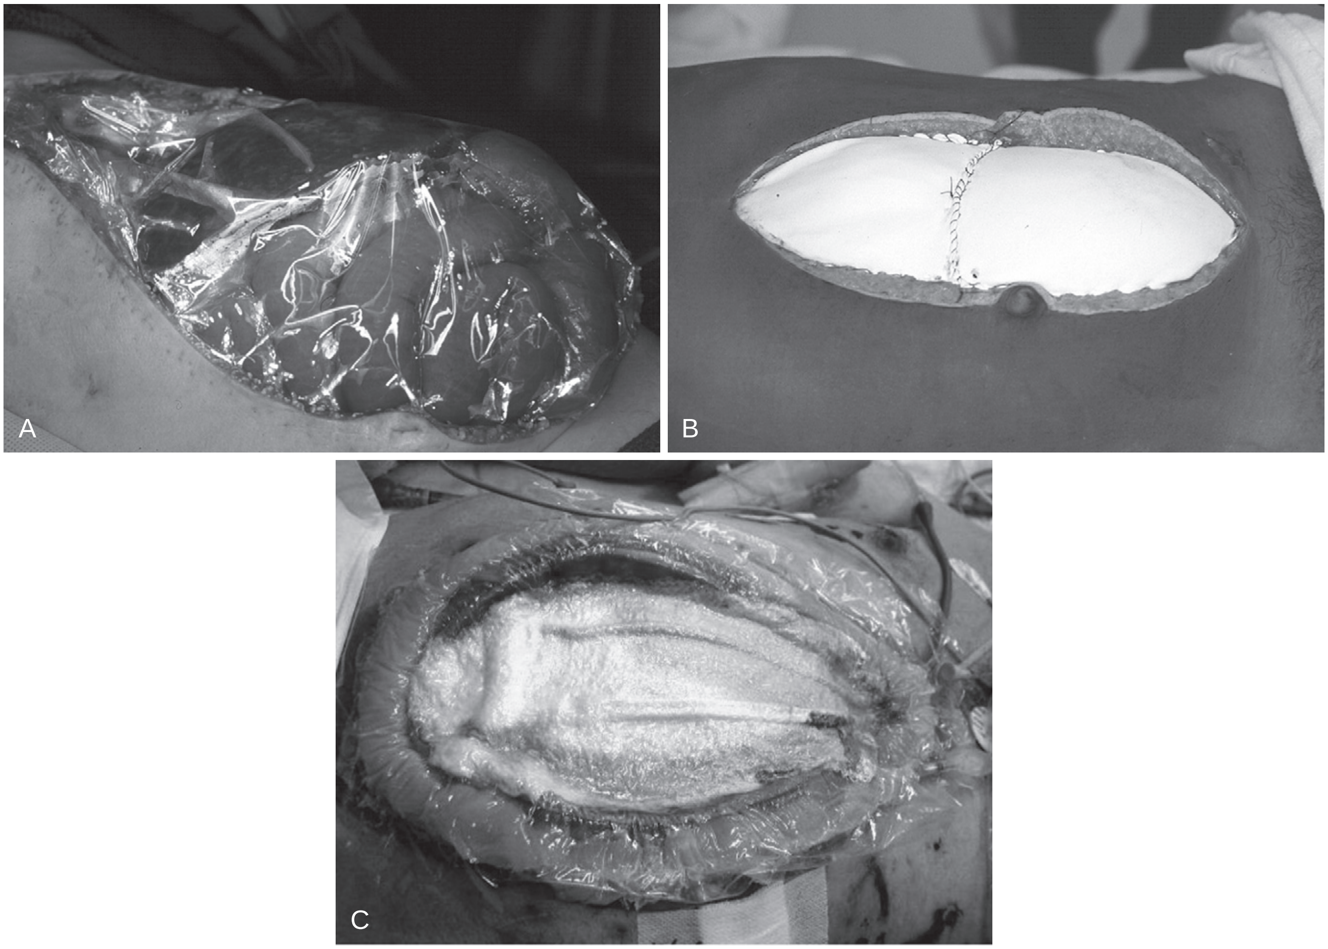

FIGURE 20-10 **A,** Abdominal wall expansion with Silastic sheeting. **B,** Abdominal wall expansion with a Gore-Tex patch. **C,** Vacuum-pack technique.

technique, used successfully in adults, has been an outstanding addition in children (Fig. 20-10).[78,85,102] Use of the vacuum-pack technique at the first trauma laparotomy may limit the early benefits of the open abdomen by resulting in a lower volume reserve capacity.[103]

### BILE DUCT INJURY

Nonoperative management of pediatric blunt liver injury is highly successful but is complicated by a 4% risk of persistent bile leakage.[104,105] Radionuclide scanning is recommended when biliary tree injury is suspected.[106] Delayed views may show a bile leak even if early views are normal. Several reports have highlighted the benefits of endoscopic retrograde cholangiopancreatography (ERCP) with placement of transampullary biliary stents for biliary duct injury following blunt hepatic trauma. Although ERCP is invasive and requires conscious sedation, it can pinpoint the site of injury and allow treatment of the injured ducts without open surgery (Fig. 20-11). Endoscopic transampullary biliary decompression is a recent addition to the treatment options for patients with persistent bile leakage. The addition of sphincterotomy during ERCP for persistent bile leakage following blunt liver injury has been advocated to decrease intrabiliary pressure and encourage internal decompression.[105–108] It is important to note that endoscopic biliary stents may migrate or become obstructed and require specific treatment.

## Injuries to the Duodenum and Pancreas

In contrast to the liver and spleen, injuries to the duodenum and pancreas are much less frequent, accounting for less than 10% of intra-abdominal injuries in children sustaining blunt trauma. Isolated duodenal and pancreatic injuries occur in approximately two thirds of cases, with combined injuries to both organs occurring in the remainder. The severity of the duodenal or pancreatic injury and associated injuries determines the necessity for operative versus nonoperative management. The “protected” retroperitoneum both limits the chance of injury and increases the difficulty of early diagnosis. Added to this diagnostic dilemma is the frequency of associated intra-abdominal or multisystem injuries, which can mask subtle physical and radiographic diagnostic signs of injury to the duodenum and pancreas.

### DUODENUM

In a report on blunt duodenal rupture, Ballard and colleagues[109] reviewed a 6-year statewide (Pennsylvania) experience. Of 103,864 patients registered from 28 trauma centers, blunt injury to the duodenum occurred in 206 (0.2%), of whom only 30 (14%) had full-thickness rupture. The mechanism of injury was car crash in 70%, which included both adults

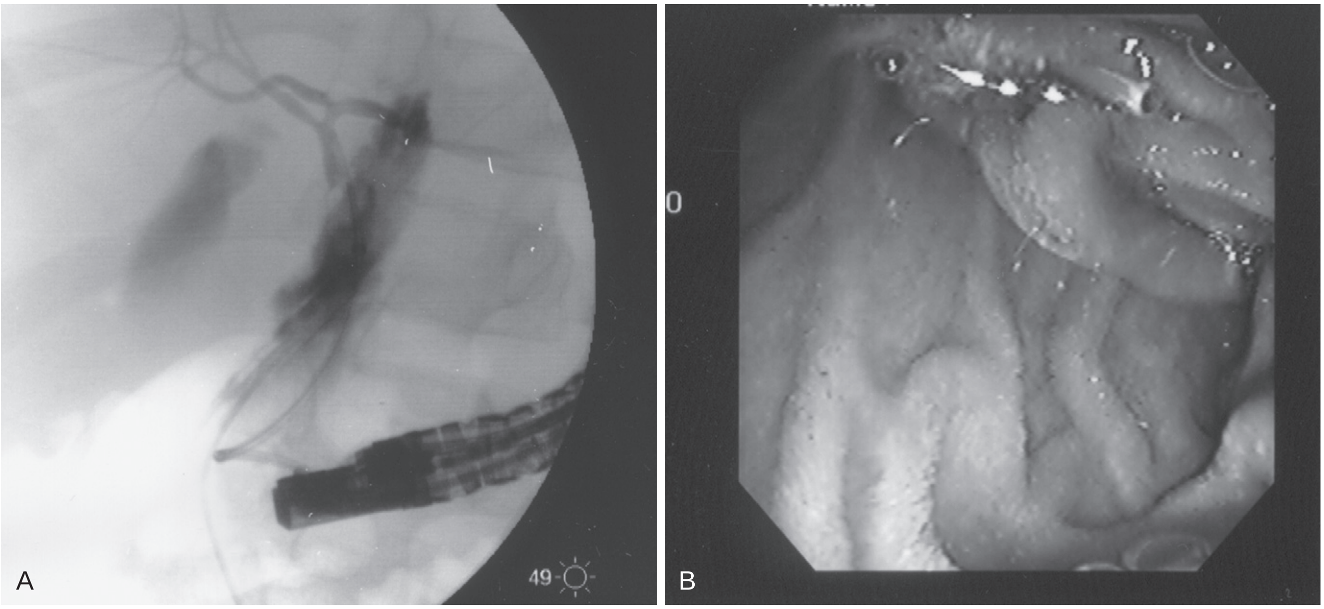

**FIGURE 20-11** **A,** Endoscopic retrograde cholangiopancreatography demonstrating several bile leaks after blunt liver injury. **B,** Endoscopic view of transampullary biliary stent.

and children. Of those without significant head injury (26 of 30), 92% either reported abdominal pain or had tenderness or rebound on physical examination. CT was performed in 18 patients; retroperitoneal air or extravasation of contrast was seen in only 26% of scans; an equal number were interpreted as normal. Mortality was 13% and was not affected by a delay in diagnosis or treatment. This study emphasizes the difficulty of analyzing this injury because of the low numbers reported by individual centers (and surgeons). Additionally, the investigators reviewed the range of repairs performed—from duodenal closure to the Whipple procedure—but commented that no definitive recommendations could be made because of the small number of patients and the many centers reporting.

In contrast, a group from Toronto reported a single-center experience in a series of 27 children (mean age, 7 years) sustaining blunt duodenal injuries and treated over a 10-year period.[110] Thirteen children had duodenal perforations (mean age, 9 years), and 14 sustained duodenal hematomas (mean age, 5 years). Associated injuries were seen in 19 patients (10 pancreas, 5 spleen, 4 liver, 2 long bone fracture, 1 central nervous system, 1 renal contusion, 1 jejunal perforation, and 1 gastric rupture). Seventeen patients were transferred from other facilities, with a 4-hour median time to transfer. The median interval from injury to surgery in those sustaining perforation was 6 hours. A comparison of the clinical presentation, laboratory evaluation, and radiographic findings in those with duodenal hematoma versus perforation is presented in Table 20-7. Most patients had abdominal CT scans performed with oral and intravenous contrast (Figs. 20-12 and 20-13). A comparison of CT findings in these patient groups is presented in Table 20-8. These data demonstrate that the clinical presentation is strikingly similar in both groups, with only age and injury severity score achieving statistical significance (but of little clinical relevance in individual patients). However, extravasation of air or enteral contrast into the retroperitoneal, periduodenal, or prerenal space was found in every child with a duodenal perforation (9 of 9) but in none of the 10 who had duodenal hematoma. The authors noted that few previous reports in the literature described these specific CT findings with duodenal injuries in general, and in particular, no previous series of pediatric patients had been reported. The CT scans (or upper GI contrast studies in equivocal cases) showing duodenal narrowing, corkscrewing, or obstruction without extravasation were diagnostic in all cases. In the current series of 14 patients treated nonoperatively, the duration of nasogastric decompression was 12 days (mean), and the length of total parenteral nutrition administration was 18 days (mean). Symptoms resolved in 13 of 14 patients an average of 16 days after injury. The remaining child developed a chronic fibrous stricture requiring operative duodenoplasty 49 days after injury. This child also had a pancreatic contusion.

Desai and colleagues,[111] from St. Louis Children's Hospital, reviewed their experience with 24 duodenal injuries from blunt abdominal trauma. There were 19 duodenal hematomas (15 diagnosed by CT, and 4 by upper GI studies), 17 of which were treated nonoperatively. In those with perforation, 4 of 5 were amenable to simple suture repair. The experiences from Salt Lake City and Pittsburgh emphasize an alarming finding that a common cause of duodenal trauma is child abuse, especially in younger patients.[112,113] Therefore isolated duodenal injures should raise suspicion if the history or mechanism of injury described is inconsistent with the actual injury.

In all these series, patients sustaining duodenal perforation were treated operatively in a variety of ways, depending on the injury severity and the surgeon's preference. We recommend primary closure of a duodenal perforation (whenever possible). Primary closure can be combined with duodenal drainage and either pyloric exclusion with gastrojejunostomy (Fig. 20-14) or gastric drainage with feeding jejunostomy. These surgical options decrease the incidence of duodenal fistula, reduce the time to GI tract alimentation, and shorten hospital stay. When faced with complicated

duodenal trauma, an effective combination is the three-tube technique: duodenal closure (primary repair, serosal patch, or anastomosis) with duodenal drainage tube for decompression (tube 1), pyloric exclusion with an absorbable suture through gastrotomy and gastric tube placement (tube 2), and feeding jejunostomy (tube 3). Several closed suction drains are placed adjacent to the repair. When the duodenum is excluded (by an absorbable suture for temporary closure of the pylorus), complete healing of the injury routinely occurs before the spontaneous reopening of the pyloric channel (Fig. 20-15). Bioprosthetic repair of complex duodenal injury in a porcine model has been reported and could add to operative strategies.[114]

*The child had an associated jejunal perforation.
†Enteral contrast was not administered in two children.

However, no matter what repair the surgeon selects, a summary of the literature demonstrates that protecting the duodenal closure (drain and exclusion) and a route for enteral feeding (gastrojejunostomy or feeding jejunostomy) reduces morbidity and hospital length of stay.[115,116]

The surgical options are listed in Table 20-9 and illustrated in Figures 20-14 and 20-16. Of note, pancreaticoduodenectomy (the Whipple procedure) is rarely required. Although occasionally reported in the literature, pancreaticoduodenectomy should be reserved for the most severe injuries to the duodenum and pancreas in which the common blood supply is destroyed and reconstruction is impossible.

## PANCREAS

Injuries to the pancreas are slightly more frequent than duodenal injuries, with estimated ranges from 3% to 12% in children sustaining blunt abdominal trauma. As with duodenal injuries, individual centers frequently have small patient numbers and thus are unable to evaluate their results

critically. Recently, two centers (Toronto and San Diego) reported their experience with divergent methods of managing blunt traumatic pancreatic injuries in a series of reports.[117–121] Here we compare these papers and excerpt other authors' experience to make management recommendations.

Canty and Weinman (San Diego)[118] reported 18 patients with major pancreatic injuries over a 14-year period. The mechanism of injury was car or bike crashes. Sixteen of the 18 patients had CT scans on admission. Of these, 11 suggested injury; in 5, the injury was missed. Distal pancreatectomy was performed in 8 patients (44%). In 5 of 6 patients with either proximal duct injuries or injuries missed on the initial CT scan, pseudocysts developed; pseudocysts also occurred in 2 other children who had minimal initial symptoms and no admission CT scans. Of these 7 pseudocysts, 2 resolved and 5 were treated by cystogastrostomy. Two patients, treated more recently, received endoscopic retrograde cholangiopancreatography (ERCP) with duct stenting and experienced resolution of symptoms and complete healing. The authors concluded that distal injuries should be treated with distal pancreatectomy, proximal injuries with observation, and pseudocysts with observation or cystogastrostomy. They also concluded that acute ERCP management with stent placement is safe and effective, and that CT is suggestive but not always diagnostic for the type and location of pancreatic injuries.[117,118]

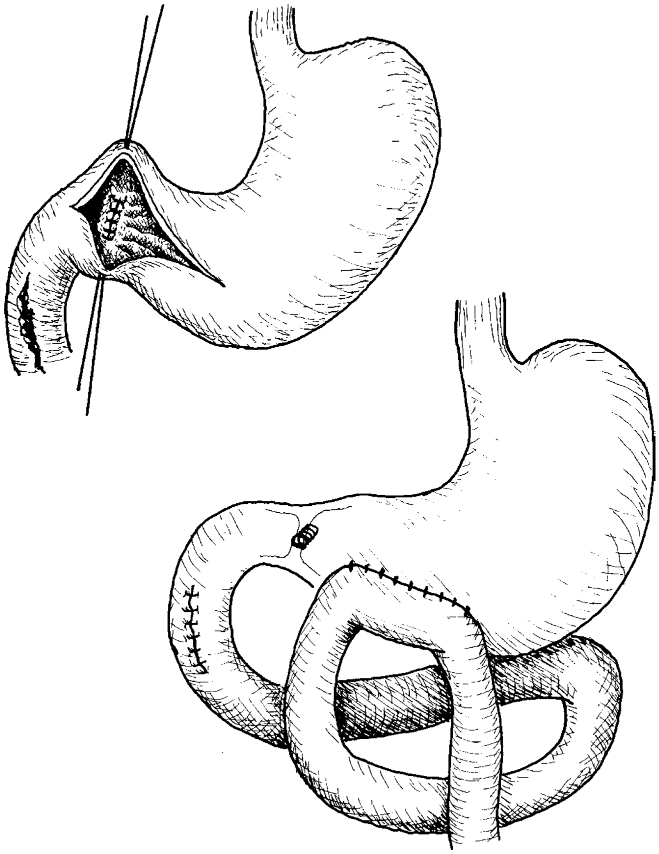

FIGURE 20-14 Lateral duodenal injury treated by primary duodenal repair and pyloric exclusion consisting of closing the pylorus with an absorbable suture and gastrojejunostomy. Closed suction drainage of the repair is not depicted. (Original illustration by Mark Mazziotti, MD.)

The experience summarized in three reports from Toronto is markedly different.[119–121] The extensive CT findings suggestive of pancreatic injury are detailed in Table 20-10. In the first brief report, 2 patients with documented duct disruption (by ERCP or cathetergram) had complete duct healing without operative intervention.[119] This was followed by a summary report of 35 consecutive children treated over 10 years (1987 to 1996).[120] Twenty-three had early diagnosis (<24 hours), whereas diagnosis was delayed (2 to 14 days) in 12 patients. Twenty-eight children were treated nonoperatively, and the other 7 had operations for other injuries. In the 28 cases treated nonoperatively, CT was diagnostic, revealing five patterns of injury: contusion, stellate fragmentation, partial fracture, complete transection, and pseudocyst (Fig. 20-17). The patients were placed in three clinical groups based on CT grade (Table 20-11). In these 28 patients, pseudocysts occurred in 10 (2 of 14 in group 1, 5 of 11 in group 2, and 3 of 3 in group 3). No patients in group 1 required drainage, whereas 4 in group 2, and all 3 in group 3 required intervention. These drainage procedures occurred 10 to 14 days after injury. Average time for the initiation of oral feeding was 15 days (11 days for group 1, 15 days for group 2, and 23 days for group 3). Mean hospital stay for all patients treated nonoperatively was 21 days.

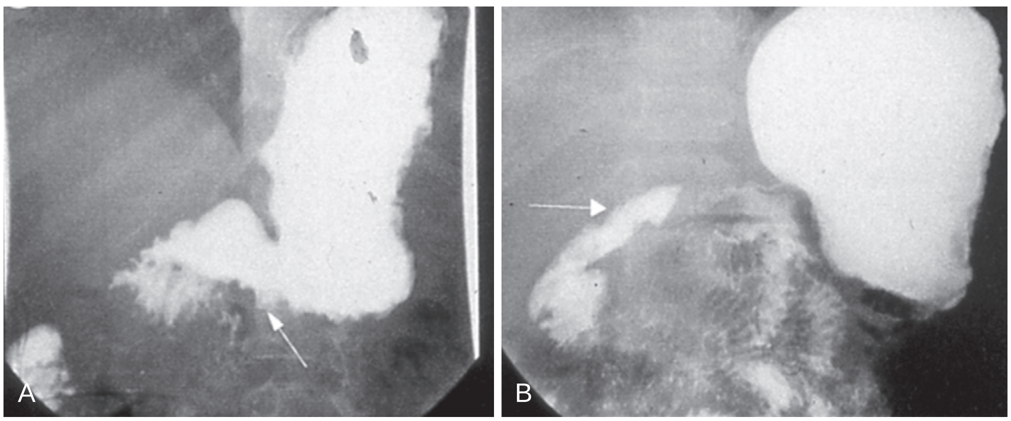

FIGURE 20-15 Upper gastrointestinal study of a 7-year-old girl with duodenal perforation resulting from a motor vehicle accident. Primary repair, pyloric exclusion, retrograde tube duodenostomy, gastrojejunostomy, and feeding gastrostomy were performed. The child tolerated jejunal feeds 6 days after the injury and oral feeds 12 days after the injury. **A,** Six weeks postinjury, an upper gastrointestinal study demonstrated spontaneous closure of the gastrojejunostomy (*arrow*). **B,** A patent pylorus is evident (*arrow*).

Resection and closure of the duodenal stump, tube duodenostomy, tube cholecystostomy, gastrojejunostomy, and multiple closed suction drains are depicted. A feeding jejunostomy should be strongly considered (not depicted). (Original illustration by Mark Mazziotti, MD.)

A comparison of the San Diego and Toronto protocols is depicted in Figure 20-18. The striking differences in these series are the 100% diagnostic sensitivity of CT in Toronto versus 69% in San Diego and the 44% operative rate in San Diego versus 0% in Toronto. A subsequent study from Toronto reviewed the follow-up on 10 patients with duct transections.[121] Four of these children (40%) developed pseudocysts, three of which were drained percutaneously (Fig. 20-19). The mean hospital stay was 24 days, and all recovered. Follow-up CT in eight of nine patients revealed atrophy of the distal pancreas in six and completely normal glands in two. There was no exocrine or endocrine dysfunction in a mean of 47 months of follow-up. The authors concluded that

following nonoperative management of pancreatic blunt trauma, atrophy (distal) or recanalization occurs in all cases with no long-term morbidity.

Reports from Dallas and Seattle favor early distal pancreatectomy for transection to the left of the spine to shorten hospital stay.[122,123] However, long-term sequelae of adhesive intestinal obstruction and endocrine and exocrine dysfunction were not assessed. Other reports document the efficacy of magnetic resonance pancreatography as a diagnostic tool, early ERCP intervention for diagnosis and treatment with ductal stenting, and the use of somatostatin to decrease pancreatic secretions and promote healing.[124–128] Of note, a large single-center series from Japan reported nonoperative management in 19 of 20 children with documented pancreatic injury (9 contusions, 6 lacerations, and 5 main duct disruptions).[129] In all cases, recovery was complete without surgery. That center's experience with pseudocyst formation and treatment and overall outcome virtually mirrors that of the Toronto report. A recent report from Denver documents their experience with pediatric pancreas injury over an 11-year period.[127] All ($n = 18$) with grade I injuries were treated nonoperatively. Children with grades II to IV received operative treatment in 14 and nonoperative in 11 cases. They concluded that children undergoing operative treatment had fewer pseudocysts but similar length of stay because of nonpancreatic complications.

These reports from major pediatric trauma centers are clearly in conflict. Some favor and document the efficacy and safety of observational care for virtually all pancreatic injuries, including duct disruption; others advocate aggressive surgical management with debridement or resection. Because proponents supply compelling data for each of these treatments, algorithms reflecting individual hospital or surgeon preference will probably determine which treatment plan is selected. However, it is clear that with simple transection of the pancreas at or to the left of the spine, spleen-sparing distal pancreatectomy can provide definitive care for this isolated injury, with short hospitalization and acceptable morbidity (Fig. 20-20). Laparoscopic techniques may limit perioperative morbidity.[128]

**TABLE 20-11**
**Proposed Classification of CT Findings in Children with Pancreatic Injuries**

| *Group (Clinical)* | *Grade (CT)* | *Pancreatic Injury* | *Description* | *Number of Children* |
|---|---|---|---|---|
| 1 | I | Contusion | Diffuse or focal swelling of the pancreas | 14 |
| 2 | II | Stellate fragmentation | Fluid or blood dissecting within pancreatic parenchyma | 2 |
| | III | Partial fracture | Incomplete separation of two portions of the pancreas | 1 |
| 3 | IV | Complete transection | Complete separation of two portions of the pancreas | 8 |
| | V | Pseudocyst | Persistent peripancreatic fluid collection | 3 |

Data from references 119-121.
CT, Computed tomography.

With this controversy in mind, we favor conservative therapy whenever possible, including the following:

1. Early spiral CT with oral and intravenous contrast in all patients who, by history, physical examination, or mechanism of injury, may have blunt trauma to the pancreas
2. Documentation of injuries and early ERCP to provide duct stenting in selected cases
3. Nonoperative management with total parenteral nutrition
4. Expectant management of pseudocyst formation
5. Percutaneous drainage for symptomatic, infected, or enlarging pseudocyst (Fig. 20-21)

# Injuries of the Stomach, Small Intestine, and Colon

Several different mechanisms cause distinct patterns of injury to these hollow organs. First is a crush injury that occurs as the stomach, jejunum, ileum, or transverse colon is compressed violently against the spine. Hematomas, lacerations, or partial or complete transections can occur with instantaneous or delayed perforation or obstruction. Second, burst injury occurs when rapid compressive forces are applied to a filled and distended hollow viscus, without direct mechanical compression. Shoulder-belt and seat-belt injuries to the GI tract can occur in this fashion. Third is shear injury caused by rapid acceleration–deceleration of an organ that is tethered at one end, such as the ligament of Treitz, ileocecal region, or rectosigmoid junction. With deceleration, the injury is caused by the tearing of tissue at the point of fixation.

Regardless of the mechanism of injury, a perforated viscus causes rapid contamination of the abdominal cavity. On the initial trauma assessment, virtually all neurologically intact patients have some symptoms (pain) and physical findings (tenderness, guarding, rebound). In fact, many reports have documented that the initial and serial physical examinations have a higher degree of diagnostic specificity than US or CT for these injuries.[130–132] In a series from New Mexico

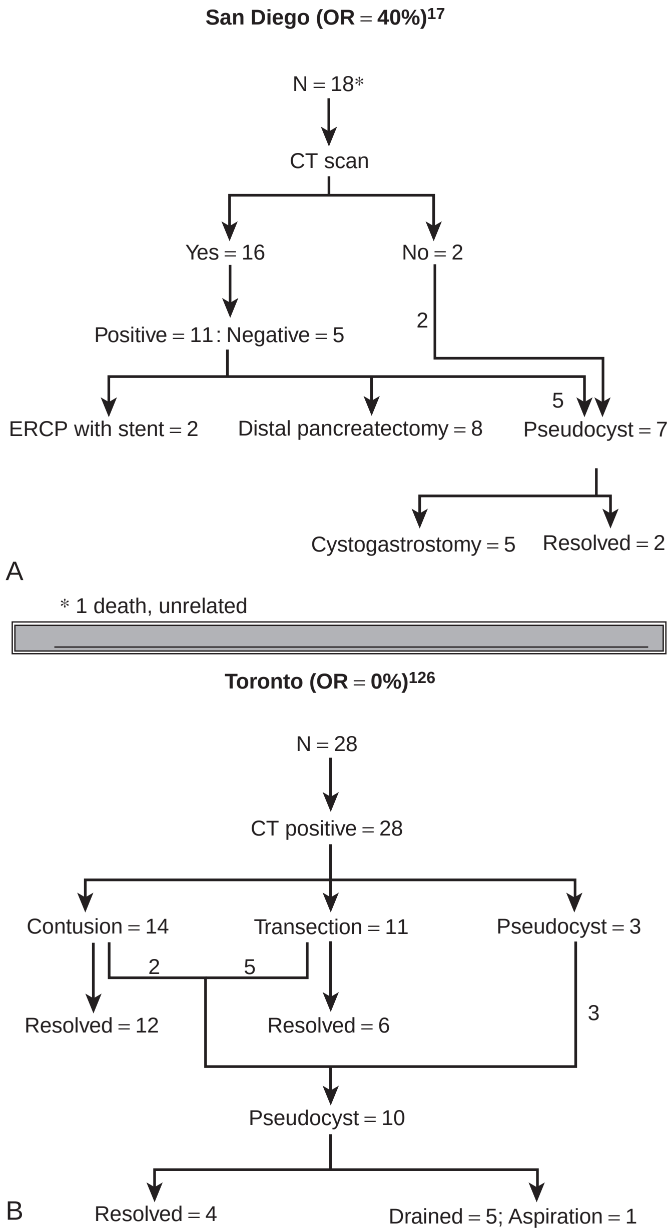

**FIGURE 20-18** Comparison of protocols in the management of blunt pancreas injury in children. **A,** San Diego. **B,** Toronto. reporting 48 patients with small bowel injury, all conscious patients had abnormal physical findings either on presentation or after serial physical examinations.[131] Other diagnostic tests (US, CT, DPL, laboratory tests) were of comparatively less value. These findings were confirmed by a similar series from North Carolina involving 32 children with intestinal injury confirmed at laparotomy; 94% had physical findings suggestive of intestinal injury on admission, with 84% having diffuse abdominal tenderness (peritoneal signs).[132] Prompt diagnosis of these injuries is possible when free air and GI contrast extravasates into the abdominal cavity at the time of the initial injury. However, when partial-thickness lacerations, hematomas, or avulsed

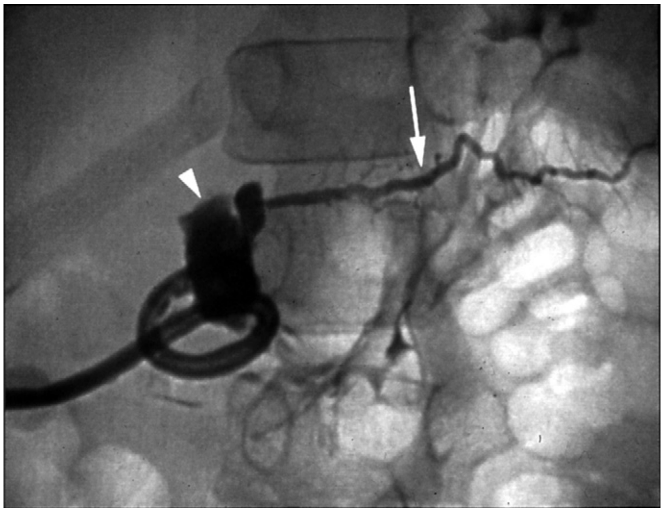

**FIGURE 20-19** Contrast study through a percutaneous drain placed into a pancreatic pseudocyst (*arrowhead*) after blunt trauma in a child. Communication with the main pancreatic duct (*arrow*) is demonstrated. The pseudocyst resolved without fistula formation or operative intervention.

FIGURE 20-22 Small bowel mesentery avulsion with ischemic bowel.

mesenteric blood vessels occur, progression to full-thickness defects with leakage can be delayed over hours to days (Fig. 20-22). A high index of suspicion is indicated, along with the liberal use of serial physical examinations.

The APSA Trauma Committee recently performed a multi-institutional, retrospective review to determine whether delay in treatment of blunt intestinal perforation adversely affected outcome.[133] Their data in 214 patients suggested that delay in operative treatment up to 24 hours did not have a significant effect on prognosis after pediatric blunt intestinal injury, even when there is peritoneal contamination secondary to perforation.

Injuries to the stomach and small intestine are straightforward to repair. A full stomach usually ruptures at the greater curvature with a blowout or stellate configuration. Debridement with direct repair is virtually always sufficient. Small intestinal injuries run the gamut from simple laceration to transection to complete avulsion with larger segments of compromised bowel. However, unless the contamination is massive (or other injuries require extensive repair), debridement or resection with anastomosis is usually sufficient. In colon injuries, particularly if there is a delay in diagnosis and significant fecal contamination, colostomy with a defunctionalized distal mucous fistula or a Hartmann pouch is in order. If isolated colon injuries occur and are repaired early, on-table bowel irrigation, bowel anastomosis, and perioperative antibiotic coverage are safe and effective and avoid the complications caused by stomas and reoperation. The critical factors with injuries to the intraperitoneal GI tract are early recognition of the injury; prompt resuscitation; expeditious surgery, with complete removal of contaminated and devitalized tissue; reconstruction or diversion of the GI tract, as clinically indicated; and broad-spectrum antibiotics, with the duration of therapy dependent on the degree of contamination and postoperative clinical course (e.g., normalization of white blood cell count, absence of fever, return of GI tract function). Laparoscopic techniques may limit perioperative morbidity.[17]

## SEAT-BELT SIGN

Seat belts, when compared with no restraint, reduce serious injury and death by 50%.[134] Frequent physical examinations and vigilance are required for the subset of injuries caused by lap-belt restraints when children are passengers in high-speed automobile crashes.[130] These children present with visible seat-belt signs on physical examination of the abdomen (Fig. 20-23). Multiple studies have documented increased abdominal injuries to both solid and hollow organs with this finding.[135–137] However, a large retrospective review of 331 child occupants in motor vehicle crashes found that the seat-belt sign had relative risk of only 1.7 for an abdominal injury.[138] An interesting triad of injuries has been noted: abdominal wall contusions or herniation, chance fractures of the lumbar spine, and isolated jejunal or ileal perforations. One report reviewed 95 patients admitted with abdominal trauma, all of whom were wearing seat belts at the time of injury; in 60 of 95, there was a seat-belt sign.[137] Nine (15%) of the 60 patients with the seat-belt sign had intestinal injuries, compared with none of the 35 without the seat-belt sign. The more common injuries described earlier can distract both the patient and the trauma team, causing delay in the diagnosis of serious vascular injuries involving the aorta and iliac vessels.[139–141]

FIGURE 20-23 Seat-belt sign across the lower abdomen.

In recent reports from Philadelphia, a database created by the State Farm Insurance Company was used to review 147,985 children who were passengers in motor vehicle crashes.[142,143] In that series, 1967 children (1.33%) had abdominal bruising from seat-belt restraints. Although abdominal wall bruising was infrequent, those with this finding were 232 times more likely to have a significant intra-abdominal injury than were those without a bruise. These data further revealed that 1 of 9 children with an abdominal seat-belt sign had a significant intra-abdominal injury. Therefore, although the seat-belt sign is rare, CT scanning (admission and serial) is mandated when it is present. Optimal ($n = 881$) and suboptimal ($n = 1086$) use of seat-belt restraints was noted. After adjusting for age and seating position, optimally restrained children were more than 3 times less likely (odds ratio 3.51) than suboptimally restrained children to suffer an abdominal injury.

Our recommendation is to admit all children involved in a motor vehicle crash who present with a seat-belt sign, even in the setting of a “normal” FAST and/or abdominal CT. Progression of an intestinal wall crush should be detected with serial examinations with or without repeat imaging.

## IMAGING FOR GASTROINTESTINAL INJURY

Imaging of the GI tract has evolved over the past decade, with spiral CT or FAST examinations done by surgeons in the emergency department directly impacting diagnostic accuracy and

decision making. Some of the strengths and weaknesses of CT diagnosis have already been discussed. However, the ability to diagnose and treat blunt abdominal trauma in children has clearly been enhanced by this modality. Two studies from Toronto examined these issues. The first, reviewed 12 patients with blunt abdominal trauma evaluated by CT and found that bowel wall enhancement was a sign of either global GI tract ischemia associated with fatal central nervous system injury or bowel perforation when seen with bowel wall thickening and free peritoneal fluid.[144] A follow-up study reviewed 43 patients evaluated over 10 years with surgically confirmed GI tract perforation.[14] Extraluminal air was seen in 47%, with one false-positive. Five CT findings were found to be suggestive but not diagnostic of GI tract perforation: extraluminal air, free intraperitoneal fluid, bowel wall thickening, bowel wall enhancement, and bowel dilation. In every patient who had all five of these findings, bowel perforation was confirmed. However, this occurred in only 18% of the study population. All patients had at least one of these five specific CT findings. There were no false-negative studies. As mentioned previously, although CT scanning is a reliable modality for assessing GI tract perforations, it should not replace and does not improve on diligent serial clinical evaluations. A similar study from Calgary reviewed 145 children with blunt abdominal trauma.[145] CT scans were interpreted as positive for GI tract injury in 20 and negative in 152 (several children had more than one study). The sensitivity of abdominal CT scan was determined to be 0.93 for mesenteric or intestinal injuries requiring surgery, with a negative predictive value of 0.99 in this study population. Therefore CT rarely misses significant mesenteric or intestinal injuries.

The significance of isolated free intraperitoneal fluid in the absence of solid organ injury has frequently been heralded as a sign of intestinal trauma. Hulka and colleagues[146] reported a series of 259 CT scans (all with oral and intravenous contrast) and found only 24 patients (9%) with isolated free intraperitoneal fluid. Among the 16 patients with only a “small amount” of isolated fluid, only 2 required laparotomy. However, 4 of 8 patients (50%) with fluid in more than one location had a bowel injury requiring exploration. These authors also noted that enteral contrast is rarely present to aid in the diagnosis of bowel injury. Similar findings were reported by Holmes and colleagues,[147] with small quantities of intraperitoneal fluid having little clinical significance. In their report, only 8% of abdominal CT scans were positive for isolated intraperitoneal fluid, and in only 17% of these cases was there an identifiable injury. This represented only 7 of the 542 children (1.3%) studied.

Finally, FAST was found to be useful as a screening tool, with high specificity (95%) but low sensitivity (33%), in evaluating intestinal injury.[15] In that study of 89 FAST-negative children, only 20 went on to have CT scans performed, all at the surgeon’s request. Without this finding, they all might have had abdominal CT scans. Clearly, FAST can decrease the number of unnecessary CT scans performed, but it cannot detect the specific abdominal organs injured. FAST is therefore of limited value in assessing these injuries. Finally, to come full circle, in a large study from Pittsburgh, 350 children with abdominal trauma were reviewed, with 30 requiring laparotomy (8.5%).[148] There were five false-negative CT scans (26%) in 19 patients who underwent delayed laparotomy (3.5 hours or longer after injury). Those authors concluded that serial physical examination, not CT scanning, is the gold standard for diagnosing GI tract perforations in children. We concur.

## Injuries to the Perineum, Anus, and Genitalia

Children present with injuries to the perineum, anus, and external genitalia primarily from two mechanisms: accidental falls and sexual abuse. Accidental injuries are sustained by falling onto blunt or sharp objects in a straddled fashion. These injuries are characterized by bruising, contusion, laceration, or penetration, depending on the object struck and the height of the fall. Accidental injuries frequently involve the external genitalia, urethra, perineal body, and anus but rarely involve the rectum. Conversely, injuries sustained by sexual abuse are commonly rectal or vaginal penetrations from violent, nonconsensual acts or the purposeful insertion of objects into these orifices. Therefore, when examining a child with injuries to the perineum, isolated rectal or vaginal trauma should always be considered child abuse until proved otherwise; conversely, polytrauma to the perineum with genital, perineal, and anal involvement is typically accidental.[149]

Diagnosis of the extent of perineal injury frequently requires examination under anesthesia by means of proctoscopy, sigmoidoscopy, and retrograde urethrogram. After assessing the degree of injury, surgical strategies include repair of urethral injuries (directly or by stenting), urinary diversion with a suprapubic cystostomy, repair of rectal tears, rectal irrigation, placement of drains when required, and, in more complex injuries, fecal diversion by colostomy. After recovery, detailed radiologic confirmation of complete healing (e.g., by intravenous pyelogram, cystogram, urethrogram, contrast enemas) must be performed before reconstruction of fecal continuity or removal of urinary stents or urinary undiversion.

Colorectal and vaginal injuries in personal watercraft passengers highlight another mechanism which should create suspicion and concern.[150] Although rare, pediatric fatalities can occur with rectal impalement from abuse. However, more commonly, rectal insertion of thermometers, Hegar dilators, or enema tubes can cause significant rectal injuries in newborns, requiring surgical repair. We recently treated a 3-day-old infant with perforation of the rectosigmoid junction from frequent enemas required for the treatment of obstipation from cystic fibrosis; laparotomy and colostomy were required. Therefore, in newborns, apparently innocuous rectal manipulation can cause severe injuries requiring surgical evaluation and intervention.

## Diaphragmatic Injuries

Traumatic injury to the diaphragm is infrequently observed, even at the largest pediatric trauma centers. At Children’s Hospital of Illinois, only two traumatic diaphragmatic injuries were treated from 1998 to 2002 out of more than 800 admissions requiring level I pediatric trauma evaluation. At the Hospital for Sick Children in Toronto, only 15 children with this injury were seen from 1977 to 1998.[151,152] In a similar report, covering 1992 to 2002 at Denver Children’s Hospital,

1397 children were admitted and observed for blunt abdominal trauma, 387 had intra-abdominal injuries, but there were only 6 diaphragmatic ruptures (0.5%).[153] The injury is caused by massive compressive forces to the abdominal cavity, creating acceleration of abdominal contents cephalad, rupturing the diaphragmatic muscle. Occasionally, penetrating trauma causes this injury; however, in these cases, the injury is often found incidentally at exploration for other injuries. In the series reported from Toronto, 13 of 15 patients had diaphragmatic rupture from blunt trauma; the mean age was 7.5 years, with the right and left diaphragm equally involved.[152] The diagnosis was made with only a chest radiograph in more than half the patients. Three injuries were missed at the initial evaluation. Because of the force required to cause this injury, multiple associated injuries should be expected. In this report, 81% of patients had multiple injuries, including liver laceration (47%), pelvic fracture (47%), major vascular injury (40%), bowel perfusion (33%), long bone fracture (20%), renal laceration (20%), splenic laceration (13%), and closed head injury (13%). As expected, there were many complications, five deaths, and a mean hospital stay of 20 days. Emergent surgery in children with this constellation of associated injuries should include palpation of both diaphragms as a routine part of the abdominal exploration. Direct suture repair is usually possible after debridement of any devitalized tissue. Pledgeted sutures can be used to buttress the repair and prevent tearing of the muscle, making the closure more secure. If sufficient diaphragm tissue is destroyed, a tension-free closure is optimal using intercostal muscle or a prosthetic patch can be used, similar to the repair of congenital diaphragmatic hernias in newborns.[153] Reports of laparoscopic or thoracoscopic repair of this injury include delayed repairs on stable patients without associated injuries.[154,155] Delayed diagnosis of this injury in infants has been reported, as has renal avulsion into the chest through a traumatically ruptured diaphragm.[156] Because of the infrequent presentation of this injury, one must have a high index of suspicion when the mechanism of injury and the degree and location of other injuries support the possibility of diaphragmatic injury.

Recent advances in the treatment of trauma and the provision of critical care in children have resulted in improved outcomes following major injuries. Much has changed in our understanding of transfusion strategies and coagulation since the previous edition of this textbook.[65,157,158] It is imperative that pediatric surgeons familiarize themselves with current treatment algorithms for life-threatening abdominal trauma. Important contributions have been made in the diagnosis and treatment of children with abdominal injury by radiologists and endoscopists. Clinical experience and published reports addressing specific concerns about the nonoperative treatment of children with solid organ injuries and recent radiologic and endoscopic contributions have made pediatric trauma care increasingly nonoperative. Although the trend is in this direction, the pediatric surgeon should remain the physician of record in the multidisciplinary care of critically injured children. Lucas and Ledgerwood recently posed the provocative question of how we can meet the inherent challenge of teaching the psychomotor skills required for operative hemostasis in an era of nonoperative therapy for most solid organ injuries.[159] As we struggle to meet this challenge, the fact remains that the decision not to operate is always a surgical decision.

CHAPTER 21

# Genitourinary Tract Trauma

Rebeccah L. Brown, Richard A. Falcone, Jr., and Victor F. Garcia

## Epidemiology

Injury is the leading cause of death in children and young adults in the United States, with injury to the kidney from either blunt or penetrating trauma being the most common genitourinary tract injury.[1] Almost 50% of genitourinary tract injuries involve the kidney.[2] Blunt abdominal trauma is responsible for 90% of pediatric genitourinary tract injuries,[3] with the kidney being injured in 10% to 20% of all blunt trauma cases.[2,4] Renal injury occurs in about 3% to 6% of patients with penetrating trauma.[5,6] Serious renal injuries are most often associated with injuries to other organs, with multiple organ involvement occurring in 80% to 95% of patients with blunt or penetrating renal trauma.[6,7] The majority of associated injuries are closed-head injuries and extremity fractures.[8] Associated abdominal injuries occur in 42% to 74% of patients and primarily involve the spleen and liver in blunt trauma and the bowel in penetrating trauma.[4,9–12] The majority of isolated renal injuries can be classified as relatively minor injuries. Mortality is rare from isolated renal trauma and is more often attributed to the combined effects of major multisystem trauma.

## Mechanisms of Injury

Most blunt renal injuries are due to sudden deceleration forces. Confined within the Gerota fascia, the kidney may be crushed against the ribs or the vertebral column, resulting in laceration or contusion. Direct injury to the renal parenchyma and collecting system may also occur from penetration of sharp, bony fragments of adjacent fractured ribs. Rapid deceleration may cause arterial or venous stretching of the fixed renovascular pedicle.[13] Because the intima of the renal artery is less elastic than that of the media, it is predisposed to laceration, which may lead to subintimal dissection and arterial thrombosis.[14] Mechanisms of blunt renal injury include pedestrian/motor vehicle crashes (60%), falls (22.5%), sports injuries (10%), assault (3.5%), and other causes (4%).[15] Most children who sustain renal injury in motor vehicle accidents are unrestrained;[4] however, violent deceleration with severe flexion-extension as seen with lap belts is a well-recognized mechanism of renal injury associated with a higher risk of renal pedicle avulsion and ureteropelvic junction (UPJ) injury. It is of interest that bicycle crashes are the most common sports-related cause of renal injury in children and are associated with a significant risk of high-grade renal injury.[16] Although there is a perception among pediatric surgeons and urologists that contact sports such as football, hockey, and martial arts incur the greatest risk for renal injury in children,[15] a review by McAleer and colleagues[17] demonstrated that bicycle crashes accounted for 24% of injuries compared with only 5% for contact sports. This may have some impact on the type of counseling that should be provided regarding activity for children after severe renal injury and for those with solitary kidneys. Penetrating genitourinary tract injuries are becoming more common in children and should be suspected with any penetrating injuries to the chest, abdomen, flank, and lumbar regions. Penetrating renal injuries, most commonly due to gunshot wounds (86%) and stab wounds (14%),[6] are more frequently associated with multiorgan injury, higher grades of injury, and higher rates of surgical exploration.[1] For example, in patients with penetrating renal injury, nearly 70% will have grade III or higher injury, whereas with blunt trauma, only about 4% will sustain grade III or higher injury.[1]

## Anatomic Considerations

Children are considered to be at increased risk for genitourinary tract trauma owing to unique anatomic differences between children and adults.[3,13,18] In children, the kidneys are larger relative to the size of the child's body and are positioned lower in the abdomen, making them more exposed and vulnerable to injury. They are also less protected because of decreased perirenal fat, weaker abdominal wall musculature, and a poorly ossified thoracic rib cage. Because many pediatric kidneys retain their fetal lobulations, the risk for renal parenchymal disruption and lower pole amputation is increased. Furthermore, the renal capsule and Gerota fascia are less developed than in adults, creating a greater potential for laceration, nonconfined bleeding, and urinary extravasation. Because of the relative mobility of a child's kidney, rapid deceleration is more likely to result in renal pedicle injury and UPJ

disruption. In a comparative series of children and adults who sustained blunt renal trauma, Brown and colleagues[3] concluded that although the likelihood of major renal injury was significantly higher in the pediatric population, the severity of trauma was significantly lower.

For similar reasons, preexisting renal disease or congenital renal anomalies may predispose children to an increased risk of genitourinary tract injury from blunt trauma. The reported incidence of preexisting renal disease or congenital genitourinary anomalies in children sustaining renal trauma varies from 1% to 23%.[19–24] Underlying congenital anomalies associated with hydronephrosis (UPJ obstruction), abnormal kidney position (horseshoe kidneys, crossed fused renal ectopia), abnormal kidney consistency (polycystic kidney disease, urinary reflux), and renal tumors such as Wilms' tumor may predispose the kidney to significant injury despite relatively minor forces.[20] Gross hematuria associated with an ostensibly minor trauma should alert the physician to the possibility of an underlying pathologic lesion of the urinary tract and should prompt further radiologic imaging. Although underlying congenital genitourinary anomalies may produce an increased risk of injury in children, they do not appear to be associated with any increased morbidity or long-term disability.[17]

# Clinical Features

The evaluation of possible injury to the genitourinary tract is part of the systematic and expeditious assessment required in all seriously injured patients. The mechanism of injury is important to know in order to assess the risk of injury. Direct blows to the abdomen or flank and significant deceleration forces as may occur in motor vehicle crashes and falls should alert the physician to the possibility of renal injury. Penetrating injuries to the abdomen, flank, back, chest, and pelvis should also raise suspicion for injury to the genitourinary tract. Although the presence of abdominal or flank tenderness and flank ecchymosis or mass suggests renal injury, up to 25% of patients with severe renal injury have unremarkable abdominal examinations. Indeed, only 55% of children with significant renal injuries present with tenderness over the injured kidney. Conversely, only about half of children with renal tenderness on examination have a condition more serious than minor renal trauma.[25]

Perineal/scrotal ecchymosis, swelling, laceration, and bleeding are highly suggestive of genitourinary trauma. The presence of blood at the urinary meatus or a boggy mass or upward displacement of the prostate on digital rectal examination in boys requires formal urethrography to evaluate possible injury to the urethra before any attempts at urethral catheterization. However, it should be recognized that the sensitivity of the digital rectal examination for identifying urethral disruption may be quite low (2%),[26] especially in children in whom the prostate may not be fully developed.

Gross hematuria is indicative of genitourinary trauma and mandates further radiologic imaging. Conversely, the absence of hematuria, either gross or microscopic, does not exclude the possibility of significant genitourinary trauma. In fact complete avulsion of the renovascular pedicle and disruption of the UPJ have both been described in the absence of hematuria.[1,8,11,21,27–29]

Fractures of the lower ribs and lumbar spine may be associated with renal trauma, whereas fractures of the pelvis may be associated with bladder and urethral injuries. In a large study using data from the National Trauma Data Bank, Bjurlin and associates[30] reported that about 5% of more than 31,000 patients with pelvic fractures had an associated lower urinary tract injury involving the bladder or urethra, or a combination of both. Aihara and associates[31] found that certain types of pelvic fractures were associated with increased risk for rectal, bladder, or urethral injuries. Rectal injury was associated with widening of the symphysis pubis. Bladder injuries were most commonly associated with widening of the sacroiliac joint, symphysis pubis, and fractures of the sacrum, with widening of the symphysis pubis being the strongest predictor of bladder injury. Urethral injuries were most commonly associated with widening of the symphysis pubis and fractures of the inferior pubic ramus. Fractures involving these locations should heighten suspicion of associated rectal and lower urinary tract injuries and prompt directed diagnostic studies. Gross hematuria in the presence of a pelvic fracture strongly suggests a bladder perforation. Any degree of hematuria in the presence of a pelvic fracture is an indication for cystography.

# Diagnostic Evaluation

Although findings on urinalysis (either gross hematuria or microhematuria) may be suggestive of genitourinary tract trauma, the decision to proceed with imaging to assess for injury is usually made before performing urinalysis and is based instead on the clinical scenario and hemodynamic status of the patient. Thus findings on urinalysis are more often than not corroborative rather than diagnostic because imaging usually precedes urinalysis. If, however, urinalysis is obtained early in the course of trauma evaluation, there is great debate regarding the need for further imaging based on this parameter alone. Although most would agree that gross hematuria is an indication for formal diagnostic evaluation, much controversy exists as to whether microscopic hematuria as an isolated finding on urinalysis warrants further radiologic imaging.[9,12,32–41]

It remains unclear what degree of microscopic hematuria, if any, warrants radiographic evaluation in children. Several studies have attempted to answer the question as to whether the adult criteria for imaging of renal trauma, including findings of gross hematuria, microscopic hematuria (>5 red blood cells [RBCs] per high-power field [HPF]) with shock, major associated injuries, significant deceleration injury, and penetrating injury can be applied to children. Although degrees of microhematuria ranging from any degree[36,37] to 20 RBCs per HPF[42] to 50 RBCs per HPF[39] have been reported as significant in the literature, a careful analysis of published reports on 382 children with renal injuries reveals that the application of adult criteria for imaging would have identified 98% to 100% of all renal injuries.[41] One of the pitfalls in applying adult criteria for the imaging of renal trauma in children with regard to the presence or absence of shock is that children are unique in their ability to maintain normal blood pressure in the face of significant hypovolemia and blood loss. In fact only 5% of children with major renal injury have clinical signs of shock.[25] Therefore hypotension itself is not a reliable indicator of the severity of renal injury in the pediatric population. Tachycardia typically precedes

hypotension as an early indicator of shock in children and may be a worrisome sign. Accordingly the decision on imaging in children, as in adults, should be based not on isolated findings but rather on the whole clinical picture, including mechanism of injury (direct blow, major deceleration, flexion-extension injury, penetrating trauma), vital signs (tachycardia or hypotension), physical examination findings (abdominal/ flank tenderness, contusion, penetrating injury in vicinity of genitourinary tract), urinalysis (microhematuria or gross hematuria), and associated injuries. In most cases, microhematuria is not an isolated finding. Most children with microhematuria have some other factor, such as mechanism of injury, physical findings, or other associated injuries, that would warrant further imaging, therefore decreasing the likelihood of missed injury.

Abdominal computed tomography (CT) is the standard for radiographic evaluation of abdominal trauma in children and is the most accurate imaging and staging modality for evaluation of renal injury.[43,44] CT with intravenous contrast is highly sensitive and specific for detection of parenchymal contusions/lacerations, perinephric/retroperitoneal hematoma, urinary extravasation, and segmental or major arterial injuries; delineation of nonviable, nonperfused tissue or segmental infarction; and demonstration of other associated intra-abdominal injuries. Since images with multidetector helical CT are obtained before the contrast medium is excreted in the urine, injury of the collecting system may be missed. In patients with significant renal injury detected on the initial images, delayed images 5 to 20 minutes after the contrast injection may identify urine extravasation associated with injury to the collecting system. A plain radiograph may also be suggestive. Delayed images may be omitted to minimize radiation dose if the kidneys are normal or with injury unlikely to be associated with injury to the collecting system and in the absence of retroperitoneal or pelvic fluid.[43,45,46]

CT has replaced the intravenous pyelogram (IVP) in the hemodynamically stable patient. However, a one-shot IVP still remains useful in the hemodynamically unstable patient before emergent surgical exploration to determine the presence of two functional kidneys, the presence and extent of urinary extravasation, and the presence of renal pedicle injury. In children, 2 to 3 mL/kg of nonionic contrast is injected intravenously, followed by an abdominal radiograph immediately and 10 minutes later.[38] It should be recognized that the IVP provides only very basic information and is not useful in staging of renal injuries. In fact, some studies have shown that as many as 20% of patients with significant renal injuries have a normal IVP. Likewise, nonvisualization of the kidney on the IVP does not necessarily correlate with arterial occlusion or injury. Other factors, including renal contusion with vascular spasm, overhydration, and hypotension or hypoperfusion, may produce similar findings in up to half of patients.[47]

Arteriography has been largely supplanted by CT and CT angiography for the diagnosis and staging of renal injury. More invasive than CT, arteriography requires the expertise of an experienced interventional radiologist and may be associated with a formidable risk for arterial injury in small children whose vessels may be prohibitively small, fragile, and difficult to access or cannulate. The current role of arteriography is in the diagnosis of delayed or ongoing renal hemorrhage, renovascular injury, or delayed arteriovenous fistula or pseudoaneurysm formation in which interventional techniques such as selective embolization[48–53] or endovascular stenting[54,55] may be therapeutic.

Ultrasonography, although used extensively in Europe for the assessment of acute renal trauma, has not found widespread acceptance in the United States. Ultrasonography in the trauma patient in the United States is mostly limited to the focused assessment with sonography for trauma (FAST) examination, which is performed primarily to detect the presence of free intraperitoneal fluid. The focused assessment with sonography for trauma examination has not been particularly useful in children except perhaps in the hemodynamically unstable patient with an associated closed-head injury to rapidly exclude the presence of intra-abdominal hemorrhage. In the hemodynamically stable child, CT provides more useful information. Ultrasonography is not particularly sensitive for detecting parenchymal injuries, except in the most experienced hands, and only with close color and pulsed Doppler interrogation can a vascular injury be diagnosed. Therefore, its utility in the acute setting at present remains limited. Ultrasonography may, however, have utility in follow-up of acute renal injuries staged initially by CT to exclude complications of injury, including urinomas, expanding hematomas, abscesses, or pseudoaneurysms, thus reducing radiation exposure.[56]

CT cystography has been found to be equivalent to conventional cystography in terms of sensitivity (95%-100%), specificity (99%-100%), negative predictive value (100%), and positive predictive value (100%) for the detection of the presence or absence of bladder injury and has largely replaced conventional cystography in most major trauma centers.[57–59] An absolute indication for CT cystography is gross hematuria with a pelvic fracture. Other relative indications include gross hematuria alone, microscopic hematuria with pelvic fracture, or microscopic hematuria alone in the context of other clinical indicators of bladder rupture such as suprapubic pain, inability to void, or significant perineal trauma.[60] It is critical that the bladder be fully distended in order to accurately detect bladder injury. Simply clamping a Foley catheter after intravenous contrast agent administration for CT is not adequate and will result in an unacceptably high rate of missed injuries.[59,61] For CT cystography, the bladder is filled in a retrograde fashion by gravity drainage before or after routine abdominal/pelvic CT. The bladder of adolescents should be filled with 300 to 400 mL of contrast medium. The bladder of smaller children should be filled by gravity infusion until the patient becomes uncomfortable or the bladder capacity is reached. In children younger than 2 years of age, the bladder capacity is 7 mL/kg. In children 2 to 11 years of age, the bladder capacity is age in years plus 2 times 30 mL.[62,63] Multiplanar reformatted images are essential to assess the bladder fully for potential injury. If CT cystography is equivocal in any way for either the presence of extravasation of contrast or in differentiating intraperitoneal versus extraperitoneal extravasation, it should be followed by conventional cystography to confirm or exclude injury.[56]

Retrograde pyelography may play a role in the assessment of ureteral and renal pelvic integrity when UPJ injury is suspected. Failure of opacification of the distal ureter on CT should raise suspicion for a ureteral injury[64]; and if insufficient detail is provided by CT, retrograde pyelography is indicated.

Retrograde urethrography is indicated when urethral injury is suspected.[43] A Foley catheter with a minimally inflated

balloon is inserted into the fossa navicularis of the distal urethra, and approximately 30 mL of contrast medium is instilled under fluoroscopic vision. A normal retrograde urethrogram should demonstrate complete filling of the intact urethra with passage of contrast medium into the bladder. The presence of filling defects or extravasation of the contrast agent indicates urethral disruption. In the presence of hematuria, a cystogram should follow the retrograde urethrogram, even if the retrograde urethrogram is normal, because 10% to 15% of patients with urethral disruption from a pelvic fracture will have a concomitant bladder injury.[47]

# Injury Grading and Scoring Systems for Genitourinary Injuries

In 1989, the American Association for the Surgery of Trauma (AAST) Organ Injury Scaling Committee devised and published a classification or grading system for genitourinary tract injuries (Table 21-1) to standardize injury descriptions for research and data collection purposes.[65] Figure 21-1 illustrates this grading system. Injuries are graded on a scale from I to V ranging from the most minor injury (grade I) to the most complex (grade V). For the kidney, this grading system has proved highly applicable, and its usefulness as a measure of the seriousness of renal injury and as a predictor of clinical outcomes and nephrectomy has been validated in several subsequent studies.[66–70] For example, patients with a grade I injury require observation only, whereas those with a grade V injury are more likely to require nephrectomy. Those with intermediate injuries (grades II to IV) require individualized therapy, with a trend toward more invasive therapy as injury grade increases. It should be noted, however, these validation studies were composed primarily of adult patients. Thus extrapolation of results may not be entirely applicable to children. Furthermore, the AAST system has been criticized for grouping complex parenchymal injury with major renovascular injury in the grade IV and V categories, because management may be quite different for the same grades of injury. Modifications addressing this issue have been proposed for future iterations of the scaling system. The AAST scaling systems for ureteral, bladder, and urethral injuries (see Table 21-1) have not gained as widespread acceptance and have been used less consistently.

**TABLE 21-1**
**Urologic Injury Scale of the American Association for the Surgery of Trauma**

| *Grade** | *Injury Description†* |
|---|---|
| **Renal Injury Scale** | |
| I: Contusion | Microscopic or gross hematuria; urologic studies normal |
| Hematoma | Subcapsular, nonexpanding without parenchymal laceration |
| II: Hematoma | Nonexpanding perirenal hematoma confined to the renal retroperitoneum |
| Laceration | <1 cm parenchymal depth of renal cortex without urinary extravasation |
| III: Laceration | >1 cm parenchymal depth of renal cortex without collection system rupture or urinary extravasation |
| IV: Laceration | Parenchymal laceration extending through the renal cortex, medulla, and collecting system |
| Vascular | Main renal artery or vein injury with contained hemorrhage |
| V: Laceration | Completely shattered kidney |
| Vascular | Avulsion of renal hilum that devascularizes kidney |
| **Ureter Injury Scale** | |
| I: Hematoma | Contusion of hematoma without devascularization |
| II: Laceration | ≤50% transection |
| III: Laceration | >50% transection |
| IV: Laceration | Complete transection with 2 cm devascularization |
| V: Laceration | Avulsion of renal hilum that devascularizes kidney |
| **Bladder Injury Scale** | |
| I: Hematoma | Contusion, intramural hematoma |
| Laceration | Partial thickness |
| II: Laceration | Extraperitoneal bladder wall laceration ≤2 cm |
| III: Laceration | Extraperitoneal (>2 cm) or intraperitoneal (≤2 cm) bladder wall lacerations |
| IV: Laceration | Intraperitoneal bladder wall laceration >2 cm |
| V: Laceration | Intra- or extraperitoneal bladder wall laceration extending into the bladder neck or ureteral orifice (trigone) |
| **Urethra Injury Scale** | |
| I: Contusion | Blood at urethral meatus; urethrography normal |
| II: Stretch injury | Elongation of urethra without extravasation on urethrography |
| III: Partial disruption | Extravasation of urethrographic contrast medium at injury site, with contrast visualized in the bladder |
| IV: Complete disruption | Extravasation of urethrographic contrast medium at injury site without visualization in the bladder; <2 cm of urethral separation |
| V: Complete disruption | Complete transection with >2 cm urethral separation, or extension into the prostate or vagina |

# Management of Specific Injuries

## KIDNEY

### Blunt Injuries

As with traumatic injuries to the spleen and liver, the vast majority of blunt renal trauma in children can be safely managed nonoperatively.[8,11,35,71–82] Nonoperative management of hemodynamically stable children with blunt renal injury has become the standard of care in most centers, with success rates up to 98%.[77] About 85% of pediatric blunt renal injuries are considered low grade (grades I-III). Since the collecting system remains intact in these lower grade renal injuries, they will invariably heal without further sequelae. Because of disruption of the collecting system and/or vascular pedicle, high-grade injuries (grades IV and V) are associated with increased morbidity and mortality. Grade IV injuries account for about 15% of pediatric renal injuries, whereas grade V injuries with major disruption of the renal pedicle occur in the remaining 5% of children.[*]

Children with minor renal injury (grades I and II) may require brief hospitalization for observation or may be discharged home with clear follow-up instructions. Children with higher grade renal injury (grades III-V) or gross hematuria, or both, are hospitalized and placed on bed rest with close monitoring of vital signs and serial physical examinations and blood cell counts. Traditionally, ambulation is begun once the patient is fully resuscitated and hemodynamically stable, blood cell counts have stabilized, and gross hematuria has resolved. It is not unusual for the bladder outlet or Foley catheter to become occluded with clot in patients with gross hematuria. Decreased urine output, bladder distention, or bladder spasms should alert the clinician to this possibility. Placement of a Foley catheter or irrigation or replacement of an existing Foley catheter should remediate the problem. Although it is generally suggested that patients maintain a decreased level of activity until the microscopic or gross hematuria resolves, there are no evidence-based guidelines in the literature addressing appropriate length or type of activity restrictions for renal trauma. The time at which healing is adequate to allow return to full activity without risk has not yet been defined. A multi-institutional prospective study is currently under way to address this issue, allowing for immediate ambulation and discharge based on standard criteria rather than on the resolution of hematuria.[83]

Most pediatric and adult series report successful nonoperative management of even the most complex grade IV and grade V injuries, including shattered but perfused kidneys and complex lacerations with extensive perinephric hematoma and urinary extravasation. Although the AAST grading scale appears to have some predictive value on the need for surgery, indications for surgery are based more on hemodynamic stability of the patient and associated injuries, rather than on grade of renal injury based on imaging criteria. The only absolute indication for surgery is hemodynamic instability with ongoing bleeding and transfusion requirements. Radiographic signs of ongoing renal bleeding include an expanding or uncontained retroperitoneal hematoma or complete avulsion of the main renal artery or vein with extravasation as demonstrated by CT or arteriography. Although not an absolute indication for surgical intervention, active extravasation and pooling of contrast-enhanced blood in the arterial phase of the computed tomographic scan should be considered a relative indication for surgical intervention depending on the clinical status of the patient, and the clinician should maintain a low threshold for prompt exploration in patients with this computed tomographic finding. Recent studies would suggest that about 90% of grade IV injuries with urinary extravasation can be successfully managed nonoperatively in the hemodynamically stable patient.[73,78,80,81,84–87]

Although complications are more common with high-grade renal injuries, most complications associated with urinary extravasation are easily treated by percutaneous drainage or endoscopic stent placement, thereby achieving higher rates of renal salvage.[73,84,86,88] Selective nonoperative management of blunt grade V renal injury in both adults[89] and children[80,82] has also been shown to be feasible for hemodynamically stable patients. Henderson and colleagues[80] reported a 73% kidney salvage rate with nonoperative management of 15 patients with grade V injury, whereas Eassa and colleagues[82] reported a 78% kidney salvage rate with nonoperative management of 18 patients with grade V injury. Superselective embolization was used as adjunctive therapy for nonoperative management in a minority of patients with ongoing bleeding and transfusion requirements, thus permitting salvage of traumatized kidneys with a minimally invasive procedure and avoiding a major surgical procedure. An algorithm for the management of blunt renal injuries in children is presented in Figure 21-2.

### Penetrating Injuries

Penetrating renal injuries are rare in children. Although there is a role for selective nonoperative management, most gunshot wounds to the abdomen require abdominal exploration because of associated injuries from the blast effect. Retroperitoneal dissection and exploration is indicated only if preoperative or intraoperative assessment suggests a major renal injury

*References 47,73,76,77,79,83.

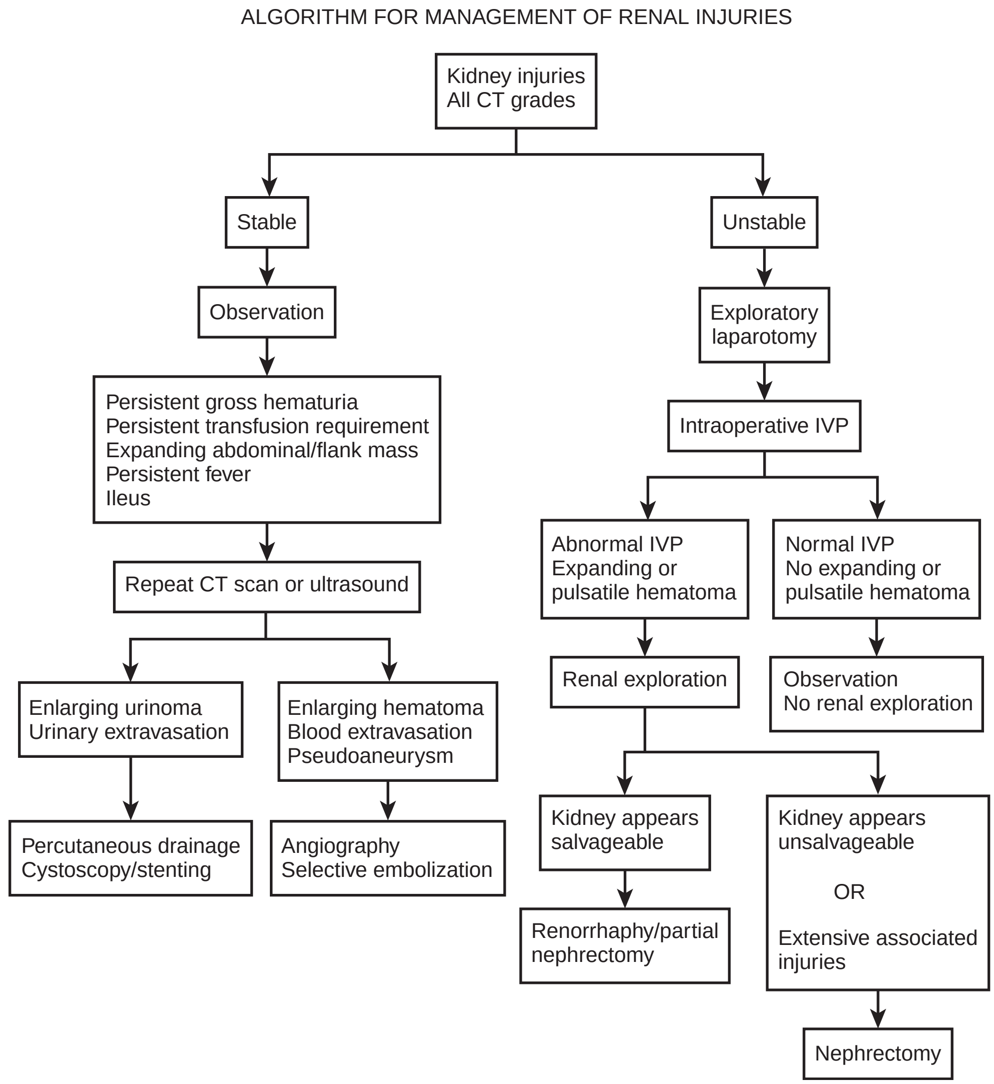

**FIGURE 21-2** Algorithm for the management of renal injuries in children. CT, computed tomography; IVP, intravenous pyelogram.

(grade IV or grade V), there is suspicion of significant nonurologic retroperitoneal injury (great vessels, duodenum, pancreas, colon), inspection reveals an expanding or pulsatile retroperitoneal hematoma, or a combination of these conditions exists.[90] McAninch and co-workers[91] classified gunshot wounds involving the kidney into five categories: (1) contusions (18.4%), (2) minor lacerations (13.8%), (3) major lacerations (50.5%), (4) vascular injuries (6.9%), and (5) lacerations combined with vascular injury (10.3%). In a large study of gunshot wounds seen in 206 renal units in 201 patients over a 30-year period, Voelzke and McAninch[92] reported an overall renal salvage rate of 85.4% using a combination of selective observation/bedrest (25%) and various operative techniques including exploration only, mesh repair, omental flap repair, peritoneal patch, renorrhaphy, vascular repair, and partial nephrectomy. The nephrectomy rate was 14.6%. Nonoperative management of renal injury due to gunshot wounds is evolving. In a 4-year prospective study by Navsaria and Nicol,[93] 34% of 95 patients with gunshot injuries to the kidney were managed nonoperatively without laparotomy with a 91% success rate. Selection criteria for nonoperative management included hemodynamic stability, CT for grading of kidney injury and excluding other associated injuries requiring exploration, and a clinically evaluable patient.

For renal-proximity stab wounds, nonoperative treatment is appropriate in hemodynamically stable patients without associated injuries who have been staged appropriately by triple-contrast CT.[5,94] However, a high index of suspicion for missed ureteral and other associated injuries must be maintained if a nonoperative pathway is chosen.

In a retrospective review by McAninch and co-workers,[95] 55% of renal stab wounds and 24% of renal gunshot wounds were successfully managed nonoperatively with an acceptable complication rate. In the hemodynamically unstable patient with penetrating trauma or in the patient with a retroperitoneal hematoma at laparotomy, a one-shot IVP may be useful to identify renal injury and confirm the presence and function of two renal units to further guide management.

## Renovascular Injuries

Major renovascular injuries are rare in children. Carroll and colleagues[96] and Turner and associates[97] reported penetrating trauma as a cause of renovascular injuries in 64% and 68% of

their patients, respectively. Conversely, Cass and co-workers[98] identified blunt external trauma as the cause of renovascular injury in 76% of patients. Regardless of the mechanism, these patients tend to have high injury severity scores, large transfusion requirements, and associated life-threatening multisystem injury,[96,98] the management of which supersedes that of renal injury. Knudson and colleagues[99] reported that factors associated with a poor outcome after renovascular injuries include blunt trauma, grade V injury, and attempted arterial repair. Elliott and colleagues[100] similarly demonstrated dismal outcomes for vascular repair of main or segmental renal artery injuries, with functional outcomes similar to nephrectomy. Grade V injuries are associated with severe major parenchymal injuries which contribute to poor function of the revascularized kidney. Patients with grade V main renal artery injuries with severe parenchymal disruption may be better served by immediate nephrectomy provided that a functional contralateral kidney is present. Bruce and associates[101] compared 12 patients with blunt renal artery injuries who underwent operative intervention (9 nephrectomies; 3 revascularizations) with 16 patients who were managed nonoperatively, 1 of whom underwent endovascular stent placement. They concluded that nonoperative management of unilateral blunt renal artery injuries is safe and often successful, with a 6% risk of the development of post-traumatic renovascular hypertension.

The pathogenesis of renovascular injuries due to blunt trauma is thought to be caused by rapid deceleration, which results in stretching of the renal vasculature, disruption of the arterial intima, and arterial thrombosis.[96] Blunt arterial injury occurs more commonly on the left side than on the right side because the right renal artery is longer than the left and may be better able to withstand the stretching caused by deceleration.[96]

Although hematuria may be absent or microscopic in 13% to 56% of patients with renovascular injuries,[1,8,11,96,98] most patients have other symptoms or signs that raise suspicion of a major renal injury and prompt further diagnostic imaging.[11,96] Renovascular injury is suggested on CT by (1) lack of renal enhancement or excretion, often in the presence of normal renal contour; (2) vein enhancement; (3) central hematoma; (4) abrupt cutoff of an enhanced renal artery; and (5) nonopacification of the pelvicaliceal system.[11,96]

The approach to this type of injury depends on the time to diagnosis, the type and extent of the vascular injury, and the extent of the associated injuries.[11,96] Repair of the right renal vein may be difficult owing to its short length and proximity to the inferior vena cava. Nonetheless, injuries to the main renal vein can be repaired in most cases.[96] Laceration of the left renal vein at its origin can be managed by ligation because collateral circulation supplied by gonadal and adrenal veins usually allows for adequate venous drainage.[96,102]

Segmental arteries are difficult to repair and may be managed by ligation with accompanying partial nephrectomy if the area of infarction encompasses more than 15% of the kidney. However, nonoperative management should be considered in any patient with segmental artery occlusion that is not associated with uncontrolled retroperitoneal hemorrhage, extensive urinary extravasation, or other intra-abdominal indications for surgery. This management strategy has been associated with an acceptably low incidence of complications.[96,100,103]

Arterial repair is most appropriate and most successful for renovascular injuries caused by penetrating trauma. Notwithstanding occasional reports of successful revascularization in patients 19 hours after injury,[102] the success of the procedure greatly diminishes after 8 hours of renal ischemia.[96,104,105] Ivatury and co-workers[106] reviewed 40 penetrating renovascular injuries and concluded that salvage of a kidney with a renovascular injury is determined primarily by the nature and extent of associated injuries. Furthermore, they reported that although attempts at renal artery repair are often futile, renal vein injuries are more amenable to repair and have a better prognosis. Nephrectomy, however, remains the procedure of choice in the hemodynamically unstable patient with multiple trauma.

Blunt injuries to the main renal artery are associated with the lowest success rate for complete renal preservation.[11,96,97] Renal artery thrombosis due to blunt trauma is often diagnosed by nonvisualization of the affected kidney on CT. Options for treatment include observation with delayed nephrectomy for complications or attempted vascular repair depending on the timing of the injury.[87] Haas and associates[107] reviewed the management of 12 patients with complete renal artery occlusion secondary to blunt trauma. Renal artery revascularization was attempted in 5 patients with a median warm ischemia time of 5 hours (range: 4.5 to 36 hours). Although 4 of 5 revascularizations were deemed technically successful at the time of operation, 3 patients demonstrated no function and 1 showed minimal function on postoperative renal function scans. Two patients required delayed nephrectomy because of complications, and of the 7 patients who received nonoperative management, significant hypertension developed in 3 patients requiring nephrectomy for blood pressure control. Based on these results, the authors were unable to advocate emergency revascularization for unilateral renal artery occlusion in the presence of a normal functional contralateral kidney unless the patient is hemodynamically stable and warm ischemia time is less than 5 hours. Patients with unilateral injury, complete arterial thrombosis, extensive associated injuries, and a prohibitively long period of renal ischemia may be managed either by primary nephrectomy or expectant nonoperative management depending on the hemodynamic stability of the patient. There are reports of successful endovascular stenting for traumatic renal artery dissection and thrombosis in both children[54] and adults.[55] An attempt should be made to revascularize all patients with bilateral renal artery injury or solitary kidneys.[96,108,109] An algorithm for the management of renovascular injuries is presented in Figure 21-3.

## Complications

Although most renal injuries in children can be managed nonoperatively, this type of management is not without complications. If a nonoperative course is chosen, the patient must be carefully monitored. Falling blood counts, ongoing transfusion requirements, and persistent gross hematuria may be indicative of ongoing bleeding. A repeated computed tomographic scan or arteriogram is warranted. An arteriogram may be especially useful because some injuries with ongoing bleeding may be amenable to selective embolization to control the bleeding. Indeed, the success of nonoperative management may be enhanced by angiographic embolization in select

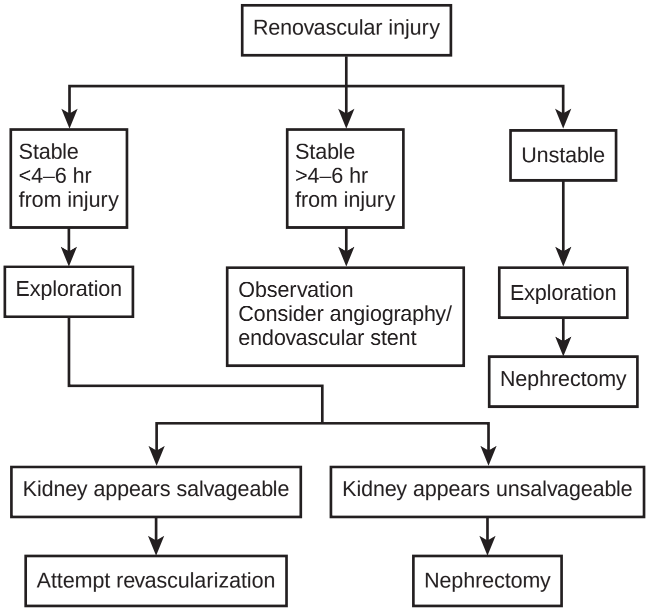

FIGURE 21-3 Algorithm for the management of renovascular trauma in children.

patients.[53,110–112] However, profuse bleeding not amenable to embolization requires emergent operative exploration.

Prolonged ileus, fevers, and an expanding abdominal/ flank mass or discomfort may be indicative of persistent urinary extravasation or urinoma, which is the most common complication after renal trauma. Ultrasonography may be used for diagnosis in patients with suggestive symptoms to reduce radiation exposure associated with CT.[56] Most urinomas are asymptomatic and will resolve spontaneously over time in 67% to 90% of patients.[73,81,84,86,87] Accordingly, small, noninfected, stable collections require no treatment other than observation, whereas larger, expanding collections may be managed by percutaneous drainage[73] or endoscopic placement of ureteral stents.[73,81,84,86,87] Traditionally broad-spectrum antibiotics are administered intravenously on an empirical basis, although this practice is not necessarily evidence based.

Delayed renal bleeding is unusual and most commonly occurs within 2 weeks of injury. However, Teigen and coworkers[113] reported two children in whom massive life-threatening hemorrhage developed several weeks after the initial injury diagnosed by arteriography and successfully treated by percutaneous transcatheter embolization.

Perinephric abscesses may be associated with ileus, high fevers, and sepsis. Ultrasonography or CT are diagnostic. Most of these abscesses are successfully treated with intravenous broad-spectrum antibiotics and percutaneous drainage. Multiloculated abscesses not amenable to percutaneous drainage may require operative drainage.

Late complications may include hydronephrosis, arteriovenous fistula, pseudoaneurysm, pyelonephritis, calculus formation, and delayed renal hypertension. Post-traumatic arteriovenous fistula and pseudoaneurysm may be successfully managed by percutaneous endovascular embolization.[48–50,110,111]

The incidence of renal hypertension after trauma is low, occurring in fewer than 5% of patients.[99,114,115] The incidence is thought to be even lower in children. Although hypertension usually occurs anytime from 2 weeks to several months after injury,[107,115] long-term follow-up is essential because onset may be delayed up to 10 to 15 years after injury.[109]

## Follow-Up and Outcomes

Evidence-based guidelines for follow-up of children after renal injury are conspicuously lacking in the literature. El-Sherbiny and colleagues[116] studied 13 children with grades III (6 children), IV (4 children), and V (3 children) renal injuries managed nonoperatively with a mean follow-up of 3 years with clinical measures (serial blood pressure measurements, urinalysis, and creatinine determinations), renal scintigraphy and/or CT angiography. Although there were residual morphologic changes noted on imaging in 92% of patients, no patient was hypertensive; all had normal urinalysis results and creatinine levels; and there was no significant functional loss, with all kidneys having a split function of 41% to 50% at final follow-up.

A study by Keller and co-workers[117] similarly evaluated the functional outcome of nonoperatively managed renal injuries in 16 children (grades I-III—4 children; grade IV—9 children; grade V—3 children) as measured by blood urea nitrogen (BUN) and creatinine levels, blood pressure, and technetium-99m-dimercaptosuccinic acid (DMSA) renal scans at 3-month and 1-year follow-up. All injuries were noted to be healed radiographically by ultrasonography or CT at 3 months. Normal to mild impairment (>40% split function) was noted in 56% of injured kidneys, with moderate impairment (30% to 40% split function) noted in 31% of injured kidneys. Severe impairment (< 30% split function) was noted in only 3 children—2 of 9 with grade IV injuries, and 1 of 3 with grade V injury. Furthermore, functional outcome did not change significantly from the 3-month to 1-year follow-up period, and all children, regardless of functional outcome on DMSA scan, remained asymptomatic and normotensive and had normal BUN and creatinine levels.

More recently, Eassa and colleagues[82] performed follow-up CT at a mean time of 8 months in 13 of 14 adult patients with grade V injuries managed nonoperatively and noted reapproximation of shattered parenchymal fragments with separation of individual fragments by thin hypoperfused scars. DMSA scans were obtained in 9 of the 14 patients at a mean time of 3 years—4 patients (44%) showed preserved renal function (>40% split function), with the remaining 5 patients showing variable degrees of renal dysfunction, including 2 with severe dysfunction (split function <30%). No patient was noted to be hypertensive or have elevated creatinine levels or abnormal urinalysis results.

Larger prospective clinical and radiologic outcome studies are warranted to further assess time to healing, incidence of complications, residual function, and long-term outcomes after renal trauma to provide the physician with a more evidence-based approach to appropriate follow-up and counseling for the injured child. At present it is generally recommended that children with severe renal injuries (grades III, IV, and V) be followed with ultrasonography and DMSA renal scans at 3 to 6 months after injury as well as biannual to annual blood pressure monitoring and laboratory tests (urinalysis, BUN, and creatinine determinations) for the first several years after injury. Further imaging is also indicated to look for the onset of any urologic symptoms or development of hypertension.

## Operative Management of Renal Trauma

Although most cases of renal trauma in children may be successfully managed nonoperatively, the surgeon should be familiar with techniques of operative management as well. As discussed previously, operative management of renal trauma is generally reserved for hemodynamically unstable patients or patients with severe associated injuries. The patient is usually explored through a generous midline abdominal incision. Although traditionally it has been taught that the surgeon should first gain proximal control of the renal artery and vein before entering the Gerota fascia or the hematoma in order to reduce blood loss and decrease the nephrectomy rate,[118] this approach has recently been challenged. In both retrospective studies[119,120] and a prospective, randomized clinical trial[121] it was concluded that vascular control of the renal hilum before opening the Gerota fascia has no effect on the nephrectomy rate, transfusion requirements, or blood loss but does significantly prolong operative times by up to an hour or more. The nephrectomy rate appears to depend more on the degree of injury rather than on the type of renovascular control.[119]

No matter what the approach, the kidney is exposed and vascular control is obtained at the hilum. With exsanguinating hemorrhage, rapid mobilization of the kidney with digital control of the hilum may be necessary. The left renal vein can be ligated because collateral drainage is provided by the left adrenal and gonadal veins. However, trauma to the right renal vein requires repair. Segmental arteries may be ligated and partial nephrectomy performed if the area of infarction encompasses more than 15% of the kidney. If the patient is hemodynamically stable, the kidney itself is salvageable, and the period of warm ischemia after injury is acceptable (<4–6 hours), renal artery repair and revascularization may be attempted. Otherwise, a nephrectomy should be performed.

If it appears salvageable, the damaged kidney is debrided to viable tissue and intrarenal hematomas are evacuated. Hemostasis should be obtained with absorbable sutures placed in a figure-of-eight pattern. The open collecting system should be closed with fine, absorbable, monofilament sutures because woven sutures may cut through renal tissue. Internal stents may be required if the ureter or renal pelvis has been injured.

The renal capsule should be closed to approximate the renal margins. If the capsule is destroyed, the lacerated margins should be covered with omental pedicle grafts, retroperitoneal fat, or polyglycolic acid mesh. Approximation and covering of renal tissue aids in hemostasis and wound healing and prevents delayed bleeding and extravasation of urine.[92]

## Ureter

Ureteral injury is uncommon, accounting for less than 1% of all genitourinary trauma.[122] The rarity of ureteral injury may be attributed to its narrow diameter, mobility, and position in the retroperitoneum where it is well protected by the overlying peritoneal contents, psoas muscles, bony pelvis, and vertebrae. Not surprisingly, associated injuries, most commonly involving kidney, small bowel, colon, liver, and iliac vessels, occur in greater than 95% of patients with ureteral trauma.[123–125]

Anatomically, the ureter is divided into three portions—the proximal ureter extends from the ureteropelvic junction (UPJ) to the point where it crosses the sacroiliac joint; the middle ureter courses across the bony pelvis and iliac vessels; and the distal ureter extends from the iliac vessels to the bladder. The distribution of injuries is fairly equally divided—proximal ureter (37%); middle ureter (31%); distal ureter (32%).[123,124] Ureteral trauma is classified according to the AAST organ injury scaling system by the anatomic location of the injury and by the extent of mural damage (see Table 21-1).[65] The complexity of repair and number of associated injuries have been found to correlate with increasing AAST grade of ureteral injury.[123]

The overwhelming majority of ureteral injuries are due to penetrating trauma from gunshot wounds (94%) or stab wounds (2.5%), with blunt trauma accounting for only 3.5% of all ureteral injuries.[124] Blunt injury may occur by either direct or indirect mechanisms. Direct injuries may result from crush injuries or severe hyperextension or flexion injuries. Direct compression against a transverse process or vertebral body has been described,[126] and an association with traumatic paraplegia has been noted.[127] Patients with congenital ureteral obstruction are also predisposed to injury of the collecting system.[128] Surgical repair is unlikely to be successful if the underlying obstruction is not recognized and treated.

Indirect mechanisms of ureteral injury in children include falls or rapid deceleration. As noted by Boone and colleagues,[129] the UPJ is particularly prone to disruption secondary to these mechanisms. Howerton[130] reviewed 54 cases of ureteral avulsion within 4 cm of the UPJ and found that this type of injury was three times more common in children than in adults.

The clinical diagnosis of ureteral injury can be difficult because of the paucity of early signs and symptoms. For penetrating trauma, any missile tract in the vicinity of the ureter should raise suspicion for ureteral injury, and appropriate diagnostic testing or exploration should be undertaken depending on the clinical status of the patient. For blunt trauma, flank ecchymosis with significant deceleration or a hyperextension-flexion mechanism should alert the clinician to the possibility of ureteral injury. Overall, hematuria is noted in fewer than half of patients with ureteral injury and is thus not a very sensitive indicator of injury.[123–125] Furthermore, absence of hematuria does not exclude injury.

Imaging modalities for diagnosis of ureteral trauma include CT, retrograde pyelography, and IVP. In the setting of blunt trauma or in the hemodynamically stable patient with penetrating trauma, CT is the gold standard for evaluation. With the faster helical CT scanners currently in use, if an injury to the ureter is suspected, it is critical to obtain delayed images during the excretory phase (5 to 20 minutes) so that ureteral extravasation is not missed. Failure of opacification of the distal ureter on CT should raise suspicion for a ureteral injury,[64] and if insufficient detail is provided by CT, retrograde pyelography is indicated.

IVP is used more commonly for penetrating trauma, since emergent exploration may be required because of associated injuries; however, up to 75% of ureteral injuries are missed by IVP.[122,131] Single-shot IVP is often unreliable and nondiagnostic, whereas complete IVP is more accurate but more difficult to obtain in the emergent setting.[125] Abnormal

findings on IVP suggestive of ureteral injury include ureteric dilatation or deviation, incomplete visualization of the complete ureter, delayed or incomplete visualization of the kidney, and extravasation of contrast medium.[125]

Delayed diagnosis of ureteral injury occurs in approximately half of patients owing to the subtle nature of the clinical findings, frequent absence of hematuria, lack of sensitivity of radiologic imaging techniques, and high incidence of multisystem injury with concomitant patient instability.[122] Although intraoperative inspection of the retroperitoneum when a missile path is in the vicinity of the ureter may be the most sensitive indicator of injury, a comprehensive review of the literature reveals that 11.1% of ureteral injuries are missed at laparotomy despite preoperative or intraoperative imaging, or both, and intraoperative inspection.[132] Meta-analysis reveals a statistically increased rate of nephrectomy as well as prolonged hospital course when ureteral injury is missed at exploration.[128] Delayed signs of a missed ureteral injury that should prompt further investigation include prolonged ileus, continued high output from surgically or percutaneously placed drains, fever or sepsis, persistent flank or abdominal pain, urinary obstruction, elevated creatinine or BUN levels, and flank mass.[125] Delayed diagnosis results in significantly increased morbidity, including fistula, urinoma, abscess, sepsis, renal failure, and renal loss.[125]

A high index of suspicion for the presence of ureteral injury must be maintained by the clinician in order to avoid missing these highly morbid injuries.

Factors influencing optimal treatment of ureteral injuries include time to diagnosis, associated injuries, degree of injury, and hemodynamic stability of the patient. Many blunt and low-grade ureteral injuries (grades I and II) may be managed nonoperatively with observation and ureteral stenting. The treatment of more complex ureteral injuries is primarily surgical and dictated primarily by the location and mechanism of injury, amount of tissue loss, condition of the local tissues, and stability of the patient. The primary goal is renal preservation with maintenance of urinary drainage from the kidney.

A complex armamentarium of percutaneous and surgical techniques is available to the surgeon to address these injuries.[123–125,133] The most common surgical reconstructive techniques include primary ureteroureterostomy, transureteroureterostomy, and ureteral reimplantation by ureteroneocystotomy.[123] Basic surgical principles of ureteral repair include thorough assessment and staging of injury, adequate mobilization of the ureter taking care to preserve the adventitia, wide debridement to viable tissue, a spatulated tension-free watertight repair over a stent, and adequate drainage of the retroperitoneum.[124] Complex ureteral injury associated with a severely damaged or shattered kidney may be best managed by nephrectomy. In the absence of or with limited renal injury, attempts at primary ureteral repair should be attempted. Proximal ureteral injuries are often short and therefore amenable to debridement and ureteroureterostomy. With disruption of the UPJ, ureteropyelostomy or dismembered pyeloplasty are options for repair. If damage to the renal pelvis is extensive, it should be surgically debrided and closed with ureteral continuity restored by ureterocalicostomy. Middle ureteral injuries can usually be managed by primary ureteroureterostomy, transureteroureterostomy, or a Boari flap and reimplantation. Injuries to the distal ureter are often amenable to a simple ureteral reimplantation (ureteroneocystostomy) or psoas hitch.[123–125,133]

Unstable patients with multiple injuries are best managed by exteriorization of the transected ureter as an intubated ureterostomy or by simple ureteral ligation with intraoperative or postoperative percutaneous nephrostomy.[125] Definitive reconstruction of a long ureteral defect is performed on an elective basis once the patient is stable, and options for reconstruction may include ileal interposition and autotransplantation.[133]

Ureteral injuries in which the diagnosis is delayed or in which secondary leaks occur after primary repair are best managed by percutaneous nephrostomy and antegrade ureteral stenting with later elective surgical correction of stenosis or fistula if encountered. Infected urinomas or abscesses can usually be managed effectively with percutaneous drainage.[125]

# Bladder

## ANATOMY

Although the bladder in children is located in the extraperitoneal space of Retzius, it is considered an intra-abdominal organ until about the age of 6 years when, as the bony pelvis grows, the bladder assumes a pelvic position and is increasingly protected from injury. The anatomic attachments of the bladder influence the pattern of injury seen after some forms of trauma. The bladder is bound laterally by the internal obturator muscles and the umbilical ligaments. At its base the bladder is attached to the urogenital diaphragm. Denonvilliers fascia or the rectovesical fascia binds it posteriorly. Unlike the rest of the bladder, the dome is mobile and distensible.

## CAUSES

Injuries to the bladder are distinctly uncommon in children, accounting for about only 0.05% to 0.2% of all injuries.[134,135] Blunt trauma accounts for the vast majority of injuries to the bladder and usually results from a direct blow to the lower abdomen when the bladder is distended with urine or from a pelvic fracture in which there is shearing of the bladder from its fascial attachments or laceration from a bony spicule. The susceptibility of the bladder to injury is somewhat dependent on the amount of urine contained at the time of injury. Motor vehicle accidents are the most common cause of blunt trauma to the bladder, accounting for about 90% of cases, followed by falls and direct blows to the lower abdomen.[134] There have also been several case reports of bladder injury in children due to nonaccidental trauma.[135] Because of its relatively protected position within the pelvis, considerable blunt force is required to cause bladder injury. Not surprisingly, serious injuries to other intra-abdominal organs are seen in almost half of patients with bladder injuries.[134] Although 60% to 90% of bladder injuries are associated with pelvic fractures, only 2% to 11% of patients with pelvic fractures have concomitant bladder injuries.[134]

## CLASSIFICATION AND DEFINITIONS

Bladder injuries due to blunt trauma may be further classified as contusions and extraperitoneal and intraperitoneal ruptures. Extraperitoneal bladder ruptures occur in about 55% to 60% of cases, intraperitoneal ruptures occur in about

25% to 40% of cases, and a combination of the two occurs in about 10% of cases.[136,137] The AAST organ injury grading scale for bladder injuries is shown in Table 21-1.

Contusions are disruptions in the bladder muscular layer without loss of continuity of the bladder wall, whereas ruptures are complete disruptions of the bladder wall with extravasation of urine. Contusions typically resolve without intervention.

Extraperitoneal bladder ruptures are almost invariably associated with pelvic fractures.[134,137]

Nineteen percent of patients (mostly boys) with extraperitoneal bladder ruptures have a concomitant urethral injury, and 8% have an associated intraperitoneal injury.[138] In contrast to extraperitoneal ruptures, intraperitoneal ruptures are infrequently associated with pelvic fractures (Fig. 21-4). These injuries are often caused by compression (burst-type injury) from a suprapubic blow to a distended bladder or sudden, forceful deceleration. Intraperitoneal ruptures most commonly occur at the dome of the bladder, whereas extraperitoneal ruptures are usually caused by bony perforation or shearing forces.[139]

## DIAGNOSIS

The hallmark of bladder injury is gross hematuria, which is noted in 95% of cases.[134] Gross hematuria in association with suprapubic pain, inability to void, and pelvic fracture should prompt further investigation to exclude the presence of a bladder injury. Conventional CT and CT cystogram with multiplanar reformatted images are equally accurate for diagnosing bladder rupture.[57,58] Urinary ascites, intra-abdominal sepsis, ileus, abdominal distention, and unexplained abnormal serum electrolyte, BUN, and creatinine levels should alert the clinician to the possibility of a missed intraperitoneal bladder rupture.[134,140]

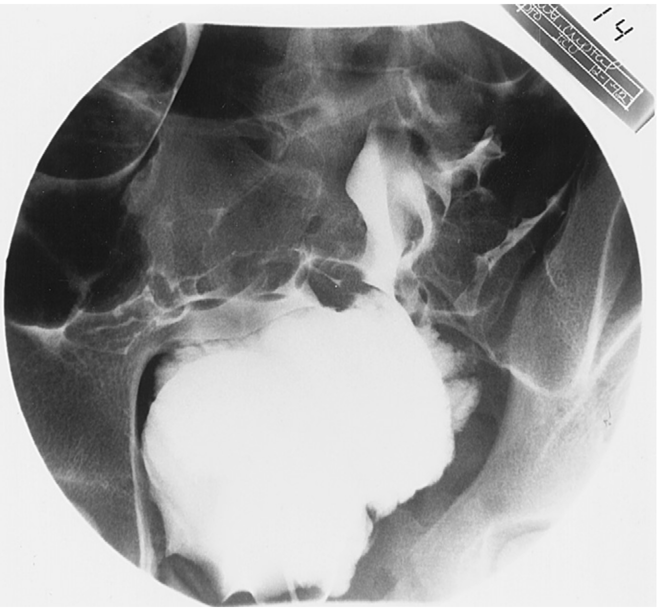

FIGURE 21-4 Voiding cystourethrogram demonstrating intraperitoneal rupture of the bladder. The patient also had bilateral fractures of the superior ischial and inferior pubic rami.

## MANAGEMENT

### Bladder Contusions

Most bladder contusions heal spontaneously without intervention. If the sacral innervation of the bladder is intact, patients with bladder contusions have excellent outcomes. Patients with a large pelvic hematoma that causes considerable bladder distortion may have difficulty voiding and may benefit from Foley catheter drainage.[134]

### Intraperitoneal Rupture

Intraperitoneal ruptures are frequently associated with other significant injuries, necessitating a thorough and deliberate evaluation of the patient. The weakest and most mobile part of the bladder, the dome, is the most common site of intraperitoneal rupture. This type of injury occurs more commonly in younger children. Intraperitoneal rupture is generally associated with a large rent in the dome of the bladder with leakage of urine into the peritoneal cavity.[134]

Intraperitoneal bladder ruptures are best managed by early operative repair through either an open or laparoscopic approach (in select patients).[141,142] For the open procedure the bladder should be approached through a lower midline abdominal incision to avoid lateral contained hematoma. If necessary the rent in the dome of the bladder can be widened to facilitate a thorough examination of the inner aspect of the bladder. Associated extraperitoneal tears can be closed from within by a single running layer of absorbable suture; however, the surgeon must ensure that the patency of the ureteral orifices is preserved. An intravenous injection of indigo carmine or methylene blue may help verify the location and integrity of the ureteral orifices. The dye should be seen exiting the ureteral orifices within 10 minutes. Lacerations extending into the bladder neck should be carefully repaired to reconstruct the sphincteric components and reduce the likelihood of later urinary incontinence. Intraperitoneal bladder injuries are repaired with absorbable suture in two layers.

After the bladder is repaired, a closed-suction drain is placed and brought out through a separate stab incision. Although in the past most surgeons would insert a large-bore suprapubic cystostomy tube instead of or in addition to a transurethral catheter for urinary drainage after repair of an intraperitoneal bladder rupture, more recent literature suggests that transurethral catheter drainage is not only adequate but also preferable. For any degree of bladder injury, transurethral catheters are equally effective, are associated with fewer complications, and may be removed sooner than suprapubic catheters.[143,144]

Urinary drainage is generally maintained for 7 to 10 days. Most surgeons will obtain a cystogram before removal of the urinary drainage catheter to evaluate the integrity of the repair. If no extravasation is documented, the urinary catheter and closed-suction drain can be removed.

### Extraperitoneal Rupture

The preferred management of extraperitoneal rupture is transurethral catheter drainage alone. This approach is safe and effective and obviates the need for bladder exploration, manipulation of the extraperitoneal hematoma, and converting a closed pelvic fracture into an open one. At times, the degree of extravasation of contrast medium may be alarming. However, because it is

dependent not only on the size of the tear but also on the amount of contrast medium instilled, the degree of extravasation alone may not indicate the severity or extent of the tear in the bladder.[138] In most instances, the tear heals completely and transurethral catheter drainage is successful even with extensive urinary extravasation.[138,139] Almost 90% of extraperitoneal bladder ruptures heal within 10 days and the remainder within 3 weeks.[138] Operative intervention is rarely required. Indications for operative management include failure of the transurethral catheter to provide adequate drainage due to persistent extravasation or clot formation, concomitant vaginal or rectal injury, bladder neck/avulsion injury, or internal fixation of a pelvic fracture to prevent infection of the orthopedic hardware.[134]

### Penetrating Injuries

Because of the high likelihood of associated injuries, which often take priority in management, patients with penetrating injuries to the bladder generally require exploratory laparotomy. The peritoneal cavity is opened in the midline, and injuries to the intra-abdominal viscera and major vasculature are addressed first. Attention is then directed to the bladder and the extent of injury is determined. All devitalized bladder tissue and debris from clothing or bony spicules are removed. The integrity of the ureters can be confirmed with intravenous injection of indigo carmine or methylene blue.[134] A diligent search should be made for extravasation, and if necessary the ureters should be intubated.

Bladder mobilization and extensive debridement is unnecessary and invites precipitous bleeding.[134] Large, nonexpanding hematomas should be left undisturbed. The bladder should be entered through the dome. Extraperitoneal defects should be closed intravesically with a single layer of running absorbable suture. A watertight closure is ideal but not essential. With adequate bladder drainage, even a tenuous closure can heal satisfactorily. Intraperitoneal defects should be closed in two layers with absorbable suture to achieve a watertight seal. With rectal or vaginal involvement, once repair is complete, viable tissue should be interposed to avoid overlapping suture lines and subsequent fistula formation.[134] Closed-suction drains are placed as previously described and transurethral catheter drainage is maintained for 7 to 10 days.

## Urethra

Although urethral trauma is a secondary consideration in children with potential life-threatening trauma, such injuries account for a disproportionate degree of long-term morbidity. Blunt trauma with disruption of the bony pelvis accounts for most posterior urethral injuries in children. About 5% to 10% of boys with a fractured pelvis will also have an injury to the posterior urethra, usually at the proximal bulbar urethra.[145] Of these cases, 10% to 20% will have an associated bladder rupture[146] and about 27 % will have associated intra-abdominal injuries.[147] Motor vehicle accidents account for 90% of posterior urethral injuries, and the remaining 10% result from falls, crush injuries, or sporting injuries. A lateral pelvic force without pelvic fracture rarely results in urethral disruption. Penetrating injuries involving the posterior urethra are exceedingly rare. Anterior urethral injuries are often encountered after straddle injuries—such as a fall astride a fence, kicks, or bicycle injuries. Penetrating trauma to the anterior urethra is rare but may be seen with gunshot or stab wounds.[147]

The diagnosis of urethral trauma is relatively straightforward. Symptoms of urethral injury may include the inability to void or the sensation of voiding without passing urine. Blood at the urinary meatus or gross hematuria after trauma strongly suggests urethral injury. Physical examination of the penis, scrotum, and perineum may reveal swelling and ecchymosis. The integrity of and boundaries of the Buck, Colles, and Scarpa fascias indicate the region injured. Digital rectal examination may reveal upward displacement of the prostate or a boggy mass. This, however, may be difficult to assess in young children, so urethral imaging is required to confirm the diagnosis.

If there is suspicion of a urethral injury, blind passage of a transurethral urinary catheter should not be attempted because there is a risk of creating a false passage with the catheter and converting a partial disruption into a complete one. Retrograde urethrography is the imaging modality of choice for diagnosis of urethral trauma. Findings of elongation, filling defect, or extravasation indicate urethral injury. If urethral integrity is demonstrated by retrograde urethrography, the catheter is then advanced and a cystogram is obtained to exclude concomitant bladder injury.

Table 21-1 outlines the classification of urethral injuries, which includes contusions, stretch injuries, partial disruptions, and complete disruptions. A filling defect caused by contusion and hematoma or an elongated urethra without extravasation on retrograde urethrography indicates grade I or grade II injury. Urethral extravasation with bladder continuity indicates partial disruption (grade III). Urethral extravasation with no admission of contrast agent into the proximal urethra or bladder suggests complete disruption (grade IV). Spasm of the periurethral musculature can mimic complete disruption. Figure 21-5 provides an example of injury to the bulbous urethra.

The long-term sequelae of urethral trauma can be devastating and may include impotence, retrograde ejaculation, incontinence, and urethral strictures. Some of these complications may be a direct consequence of the trauma itself or may be related to surgical attempts at repair.

**FIGURE 21-5** Extravasation of contrast from the bulbous urethra due to penoscrotal urethral disruption. The posterior membranous and prostatic urethra is intact.

A diagnosis of anterior urethral injury is suggested if the retrograde urethrogram reveals only minimal extravasation with good urethral continuity and if the patient is able to void. Grade I or grade II injury to the anterior urethra usually heals spontaneously without insertion of any indwelling urinary catheters, as long as the patient is able to void. Intermediate-grade anterior urethral injuries may be managed by an indwelling transurethral Foley catheter, whereas more complex injuries are best managed in the initial stages by placement of a suprapubic catheter. Delayed urethral strictures occur commonly and most are amenable to urethroplasty.

Penetrating injuries to the anterior urethra may be managed by exploration and primary repair or suprapubic urinary diversion. Husmann and colleagues[148] reviewed the management of 17 patients with partial transection of the anterior urethra due to low-velocity gunshot wounds and concluded that patients were best managed by aggressive wound debridement, corporeal repair, primary suture repair of the urethra, and placement of a suprapubic catheter. Strictures developed much less frequently with this approach (1 of 8 patients) compared with suprapubic diversion and transurethral catheter stenting (7 of 9 patients). If there is extensive hematoma at the site of injury, it may be more prudent to place a suprapubic catheter, allow the injury to heal, assess for stricture formation by contrast studies or urethroscopy, or both, after more than 3 months, followed by formal urethral reconstruction if indicated.[147]

In children, the majority of posterior urethral injuries may be managed nonoperatively. Grade I or grade II injuries, which may allow spontaneous voiding, are managed without surgery and without an indwelling urinary catheter. Patients who are unable to void are managed by insertion of a small, transurethral Foley catheter. Grade III injuries with minimal extravasation may also be managed by passing a small transurethral Foley catheter under fluoroscopic guidance immediately after the retrograde urethrogram is obtained. If the catheter does not pass easily, however, a suprapubic tube should be placed.

Options for repair of more complex posterior urethral injuries include primary surgical repair with anastomosis of the disrupted urethral ends, delayed primary repair, primary surgical catheter realignment, primary endoscopic realignment with imaging, or suprapubic cystostomy with delayed urethroplasty.

Primary surgical repair involves evacuation of the pelvic hematoma, mobilization of the prostate and urethra, and direct end-to-end anastomosis between the prostatic and membranous urethra. Problems with this approach include increased risk of uncontrolled bleeding from exploration of the injury site with release of the tamponade effect of the hematoma, increased rate of stricture formation, increased risk of impotence due to dissection of the periprostatic and periurethral tissues, and increased risk of incontinence due to damage to the intrinsic urethral sphincter mechanism by dissection, mobilization, and debridement of torn urethral ends.[147]

Primary surgical catheter realignment, despite not requiring direct suturing of the disrupted urethral ends, still requires an open procedure with entry into and evacuation of pelvic hematoma with all of the attendant risks of primary surgical repair. More recently innovative combined transurethral and transvesical endoscopic and interventional radiologic techniques have been introduced to achieve primary alignment without the risk of exploring the disrupted urethra.[147,149] Furthermore, because there is no manipulation of periprostatic tissues and no additional trauma to the cavernous nerves, there should be no additional risk of erectile dysfunction other than that caused by the injury itself.

Concerns about the impact of primary open surgical repair or catheter realignment on potency and urinary continence led to the introduction of an alternative treatment approach, namely suprapubic cystostomy with delayed urethroplasty. No attempt is made to explore the urethra; rather the urinary stream is simply diverted through a suprapubic cystostomy tube. A stricture is considered inevitable and is repaired several months later. Advantages of this approach include avoiding entry into a fresh pelvic hematoma with risk of blood loss and infection, speed and simplicity of suprapubic tube insertion, and decreased incidence of impotence and incontinence resulting from the avoidance of dissection of the prostate and urethra. Disadvantages include prolonged need for a suprapubic tube with risk of infection and stone formation as well as the nearly 100% risk for urethral strictures, which may be complex and difficult to repair even in the delayed setting. Tunc and colleagues[150] reviewed 77 cases of delayed repair of traumatic posterior urethral injuries and demonstrated adequate urethral continuity in 95%, postoperative incontinence in 9%, and postoperative erectile dysfunction in 16%. They concluded that delayed posterior urethroplasty is a successful treatment option with acceptable morbidity. Although suprapubic drainage with delayed urethroplasty is associated inevitably with stricture formation that may be difficult to repair even in the delayed setting, decreased rates of incontinence and impotence are a definite advantage.

Koraitim[151] reviewed and compared various techniques for repair of complex posterior urethral injuries, including primary repair (37 patients), which was associated with 49% stricture rate, 21% incontinence rate, and 56% impotence rate; immediate and early realignment (326 patients) which was associated with a 53% stricture rate, 5% incontinence rate, and 36% impotence rate; and suprapubic drainage with delayed repair (508 patients), which was associated with a 97% stricture rate, 4% incontinence rate, and 19% impotence rate. After extensive literature review regarding different approaches to management of complex posterior urethral injuries, Holevar and associates[136] in 2004 concluded that these injuries may be treated with either primary endoscopic realignment or suprapubic cystostomy with delayed urethroplasty with similar results. More recent studies in both children and adults, comparing early primary alignment with suprapubic cystostomy and delayed urethroplasty, favor early primary alignment because it may decrease the requirement for subsequent stricture therapy by as much as 50%, resulting not only in fewer strictures but also in strictures that are easier to treat.[152–154] Furthermore, it does not appear to increase the rate of incontinence and impotence.

Urethral trauma in girls is rare, since the urethra is very short and mobile with no significant attachments to the pubic bone.[147,155,156] The usual mechanism of injury involves pelvic fracture incurred during a motor vehicle accident. Straddle injury occasionally results in damage to the urethra. Female urethral injuries may be distal avulsion from the perineal attachment or proximal disruptions and lacerations. The latter type of injury is characteristically associated with other pelvic injuries, including vaginal and bladder neck lacerations.

Perry and Husmann[157] reviewed the evaluation of urethral injuries in girls with pelvic fractures. Blood at the vaginal introitus mandates a meticulous vaginal examination. The urinary meatus must also be carefully examined and its patency confirmed by passage of a catheter. However it is important to note that catheters can often be passed into the bladder even in the presence of a significant urethral injury. Development of vulval edema after removal of the catheter warrants prompt investigation. Because urethrography in young girls is difficult and unreliable, urethroscopy is the preferred diagnostic modality. Delays in diagnosis of urethral injury in girls occur frequently and have devastating consequences.[147,157] Such injury is misdiagnosed in about 50% of cases and can result in life-threatening sepsis and necrotizing fasciitis. Therefore one should have a low threshold for performing urethroscopy when urethral injury is suspected in a young girl.

Treatment is dictated by the extent and location of injury. Urethral injuries that extend into the bladder neck require meticulous repair with reapproximation of the bladder outlet and urethra. Such injuries are encountered about two thirds of the time. Associated vaginal injuries are repaired primarily. Urethral crush injuries that do not involve the bladder neck are managed by extended transurethral Foley catheterization (6 to 8 weeks) or, if necessary, suprapubic catheter drainage. Significant long-term complications associated with pediatric female urethral trauma are common and include urethral stenosis, urethrovaginal fistula, incontinence, and vaginal stenosis.[158] Clearly every effort must be made to promptly detect and aggressively manage this uncommon injury.

# External Genitalia

## GIRLS

Blunt genital trauma in girls is fairly common. The presenting symptoms are usually the presence of blood in the underpants or on the perineum shortly after injury.[159] Blunt genital trauma most commonly results from straddle injury. The most common types of injury in decreasing order of frequency are lacerations or contusions of the perineal body, vagina, labia, urethra, and rectum. Because of the extreme difficulty of performing a thorough genitourinary examination in an awake, uncomfortable, anxious, and embarrassed child, the majority of patients are best evaluated in the operating room under general anesthesia. Indeed, as many as 76% of patients will have more extensive injuries than can be appreciated in the emergency department.[159]

Management of female genital trauma is dictated by the type and extent of injury.[160] Vulvar hematomas may cause urinary retention and may benefit from placement of a urinary catheter and evacuation of large hematomas. Necrotic contused tissue should be debrided. Lacerations are primarily repaired after hemostasis is achieved. Absorbable sutures are used to preclude the need for removal. Vaginoscopy, urethroscopy, and proctoscopy may be necessary to evaluate the injury more thoroughly.

## BOYS

Penile injury resulting from blunt or penetrating trauma is rare in children. All penile injuries, other than very superficial injuries, should be evaluated with retrograde urethrography to exclude concomitant urethral injury. Urethral lacerations should be managed as described in the previous section. The findings of an expanding hematoma, palpable corporal defect, and excessive bleeding suggest cavernosal injuries. When possible these injuries should be repaired primarily. Urinary diversion with a suprapubic tube is occasionally necessary. The preferred method of management of gunshot wounds with a limited extent of injury is debridement of superficial wounds, repair of the cavernosal defects, and primary repair of the urethral injury.[47]

Injury resulting from zipper entrapment of the penis can be addressed in many cases in the emergency department but may require a general anesthetic for release of the penis.[161] Penile strangulation injuries due to constricting bands are managed by division of the constricting band in as atraumatic manner as possible. In children, hair tourniquets are common sources of constriction and may be difficult to remove. Severe strangulation injuries may result in necrosis of the distal penile skin, glans, cavernosum, or urethra. Conservative debridement and urinary diversion may be required.[47] Penile amputation injuries are rare and devastating injuries in children (Fig. 21-6), but reimplantation and reconstructive techniques have been described with variable functional and cosmetic outcomes.[162]

Scrotal injuries may result from penetrating trauma or blunt trauma, or both. High-resolution ultrasonography is useful in the evaluation of these injuries.[163] Ultrasonography of penetrating injuries can identify testicular rupture and extratesticular soft tissue abnormalities as well as the presence and location of foreign bodies.[164] This technique is also useful in distinguishing less serious injuries, such as scrotal hematomas, hydroceles, and hematoceles, from surgical emergencies, such as testicular rupture and infarction. Patients with

hematoceles should be considered for exploration to evacuate the blood from the tunica vaginalis testis because this approach reduces morbidity and hastens recovery. Testicular disruption is managed by debridement and primary closure even if 50% of the parenchyma is destroyed. This approach results in a testicular salvage rate of 30% to 39%.[165] Orchiectomy is reserved for the completely shattered testicle.

CHAPTER 22

# Musculoskeletal Trauma

Richard S. Davidson and B. David Horn

Musculoskeletal trauma is the most common medical emergency in children. The number of cases continues to increase in association with the popularity of motor vehicles, all-terrain vehicles, and power lawn mowers. In a child with multiple injuries, optimal treatment requires a cooperating team of medical professionals with diverse specialties who understand the priorities of each team member. As in all other pediatric specialties, it is important to remember that children are not "little adults." Priority management need not compromise complete patient management.

This chapter reviews the important differences between the musculoskeletal systems of children and adults, and it highlights the principles of evaluation and management in children with musculoskeletal injuries. The treatment of high-priority musculoskeletal injuries is specifically discussed, including open fractures, compartment syndrome, femoral neck fractures, mangled extremities, spine trauma, and suspected child abuse. For details on the management of specific musculoskeletal fractures and injuries of childhood, readers should refer to textbooks on children's fractures.[1–3]

## Musculoskeletal Systems of Children and Adults

Differences in the musculoskeletal anatomy and biomechanics of children and adults determine the unique patterns of musculoskeletal injury seen in childhood. Injuries to growing bones are a double-edged sword: They can have a remarkable capacity for healing and remodeling, but they are also subject to the problems of overgrowth and growth disturbance, which can have lifelong consequences.

### ANATOMY

The major anatomic distinctions of skeletally immature bones are the physis and the periosteum. Each long bone in a child consists of the epiphysis, physis, metaphysis, and diaphysis (Fig. 22-1). The epiphysis is the end of the bone beyond the physis, or growth plate, and contains the articular cartilage. The secondary center of ossification arises within the epiphysis and progressively enlarges as the cartilage ossifies during skeletal maturation. The physis, or growth plate, provides longitudinal growth of the bone by forming cartilage that is then converted into bone in the metaphysis. The diaphysis, or shaft, is surrounded by periosteum, which generates new bone and provides circumferential bone growth. In younger children, the periosteum also provides structural support to the bone. By adulthood, the growth plate closes, and there is limited potential for remodeling.

### BIOMECHANICS

Skeletally immature bones are more porous, less brittle, and better able to tolerate deformation than mature bones. The increased porosity of immature bones stops the progression of a fracture line but weakens the bone under a compressive force. As a result, a greater variety of fractures is seen in children than in adults. A child's bone may undergo plastic deformation, where it bends without fracture; it can buckle under compression, resulting in a buckle or torus fracture; it can fracture like a "green stick," with an incomplete crack on the tension side and a bend on the compression side; or it can fracture completely (Fig. 22-2).

The thick periosteum that surrounds the diaphysis of the bone can minimize or prevent displacement of diaphyseal fractures. The periosteum tears on the tension side of a fracture but often remains intact on the compression side. The intact periosteum can then function as a hinge or a spring, increasing deformity. Depending on the injury, the periosteum may simplify or complicate reduction of a fracture (Fig. 22-3).

In the complex of bone, ligaments, and cartilage in a child, the physis is the weakest part and therefore is the most likely site of failure. An angular force to a joint in a young child is most likely to cause a fracture along the growth plate, whereas in an adolescent or an adult, a ligamentous injury or dislocation would occur; so, it is not uncommon for growth plate fractures to be misdiagnosed as sprains. Frankel and Nordin[4]

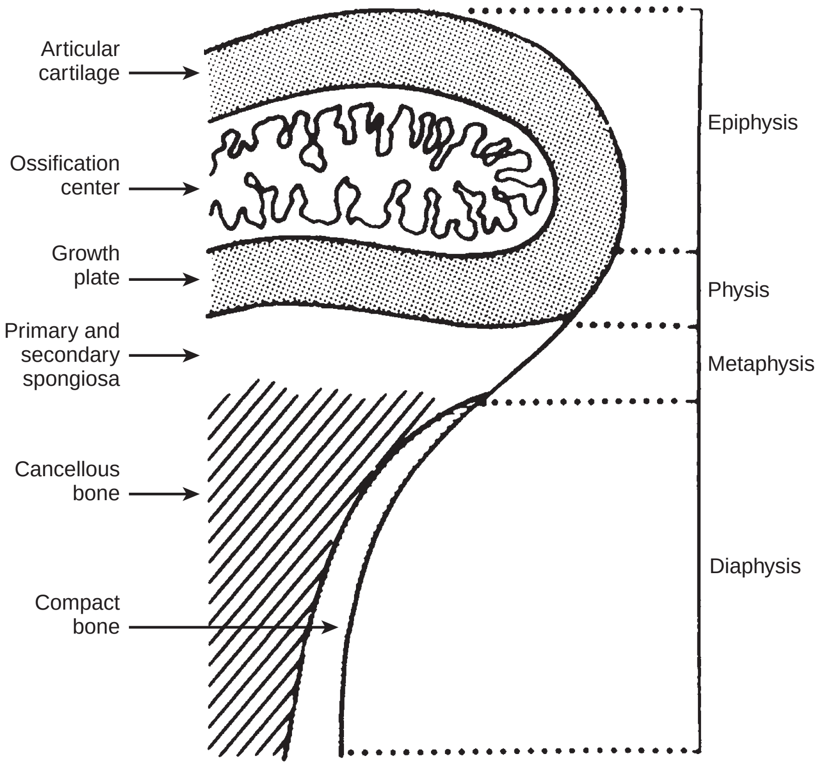

**FIGURE 22-1** Anatomy of a child's bone.

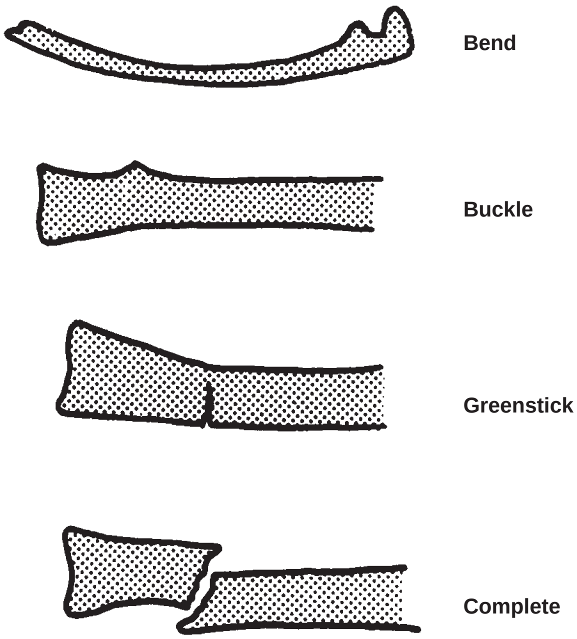

**FIGURE 22-2** Fracture types commonly seen in children. (From Rang M [ed]: Children's Fractures. Philadelphia, JB Lippincott, 1974.)

provide extensive information on the biomechanics of bone. In a fall on an outstretched hand, a young child is unlikely to sprain a wrist; more commonly, a child sustains a fracture through the growth plate of the distal radius. Similarly, instead of spraining an ankle, a child is more likely to sustain a physeal fracture of the distal fibula. Under low-energy forces, these injuries are unlikely to lead to growth disturbance.

The Salter-Harris classification system of fractures involving the physis can guide proper management (Fig. 22-4).[5] Type 1 fractures extend along the entire physis. Type 2 fractures involve part of the growth plate and part of the metaphysis; these fractures are seldom associated with growth arrest except when they occur in the distal femur and proximal tibia. Type 3 fractures involve part of the physis and pass across the epiphysis into the joint. Because of the possibility of incongruity of the joint, type 3 fractures often require open reduction and fixation. Type 4 fractures occur longitudinally, crossing the physis from the metaphysis into the epiphysis. This type of fracture is commonly associated with subsequent formation of a bony bar across the physis, which causes partial growth arrest with subsequent angulation. Open reduction and internal fixation are usually required for type 4 fractures, because joint incongruity and fusion across the physis are common. Type 5 fractures are diagnosed retrospectively, when all or part of the physis fails to grow. It is hypothesized that injury to the physis results from direct compression or local vascular insult. Growth disturbance may result in loss of longitudinal growth or angular deformities. Damage to the physis in high-energy injuries can lead to asymmetric growth in any of the fracture types.

## PHYSIOLOGY

Important physiologic differences between the musculoskeletal systems of children and adults are found in healing and remodeling. Growing bones are also at risk for the unique problems of overgrowth and growth disturbance.

Healing in children is rapid and age-dependent. A newborn may achieve clinically stable union of a fracture in 1 week, whereas a similar fracture in an adolescent may take

6 weeks to heal. In children, the rapid healing process partially results from the thick periosteum, which may form its own bone bridge. Except for displaced intra-articular fractures or fractures with gross soft tissue interposition, nonunion of fractures is rare in children.

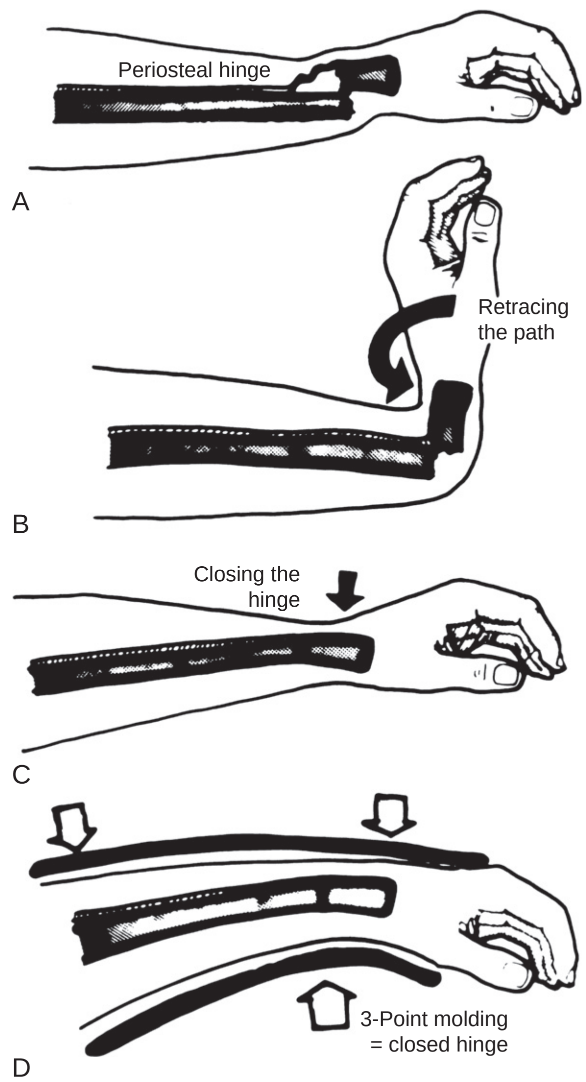

**FIGURE 22-3** **A,** In children, the intact periosteum of a fracture prevents reduction by traction. **B,** By retracing the path of injury, the fracture can be reduced. **C,** Closing the hinge. **D,** A cast with three-point molding holds the hinge closed and keeps the fracture reduced. (From Rang M [ed]: Children's Fractures. Philadelphia, JB Lippincott, 1974.)

The bones of children have great potential for remodeling, but limitations must be understood. Remodeling potential is better in younger patients, in deformities closer to the physes, and where angulation is in the plane of motion of the nearest joint. Remodeling does not effectively correct angulation perpendicular to joint motion or rotation. These deformities should be reduced before healing begins (Fig. 22-5).

Growth stimulation may follow fractures of long bones. This can be especially apparent in the lower extremity in children between 2 and 10 years of age. In this group, an average overgrowth of 1 cm can be expected in femur fractures.[6–8] Although discrepancies in leg length are unpredictable, it is often possible to reduce the ultimate inequality by allowing the fracture to heal with a 1-cm overlap in an otherwise anatomic alignment. Most of the growth stimulation occurs within the first year after injury; so, follow-up visits for 1 year are recommended, even after uneventful healing.

Damage to the physis can produce severe shortening, angular deformity, or both. Although this may be caused by the initial trauma, it can also result from failure to obtain anatomic reduction of a physeal fracture or from repeated or overzealous attempts at reduction (Fig. 22-6). Treatment depends on the amount of remaining skeletal growth and the projected difference in limb lengths and may involve timed ablation of the growth plate on the normal limb, shortening osteotomy of the normal limb, or lengthening of the short limb. Angular deformities can also be addressed, taking into consideration the patient's skeletal age and the severity of the deformity.

# Evaluation of Musculoskeletal Injuries

## CLINICAL ASSESSMENT

The initial assessment of children with multiple injuries may be difficult. Details of the incident may be missing, and the patient's history may be incomplete. The Advanced Trauma Life Support (ATLS) system of assessment involves a primary evaluation to identify and immediately address life-threatening injuries, followed by a secondary evaluation to find and treat other significant injuries. The injuries identified in the secondary evaluation must also be treated in a timely manner to prevent devastating lifelong consequences. Postponing the management of serious musculoskeletal injury for an extended period can be associated with a poor prognosis for return to normal function.

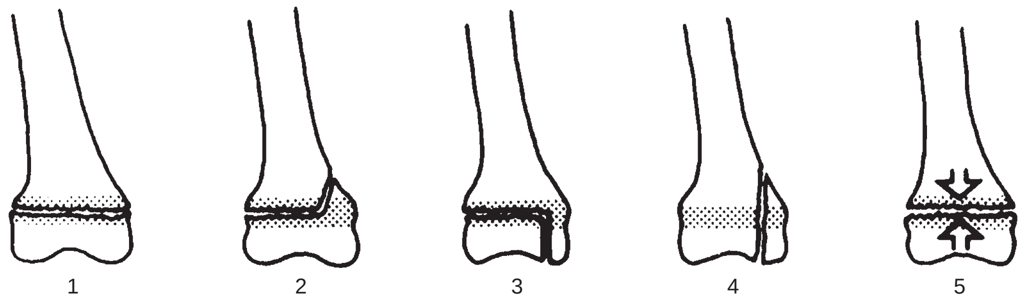

**FIGURE 22-4** Salter-Harris classification of epiphyseal fractures. Type 1 involves the entire physis. Type 2 involves part of the growth plate and part of the metaphysis. Type 3 involves part of the physis and passes across the epiphysis into the joint. Type 4 is longitudinal, crossing the physis from the metaphysis into the epiphysis. Type 5 is diagnosed retrospectively when the physis fails to grow. See text for clinical implications of each fracture type.

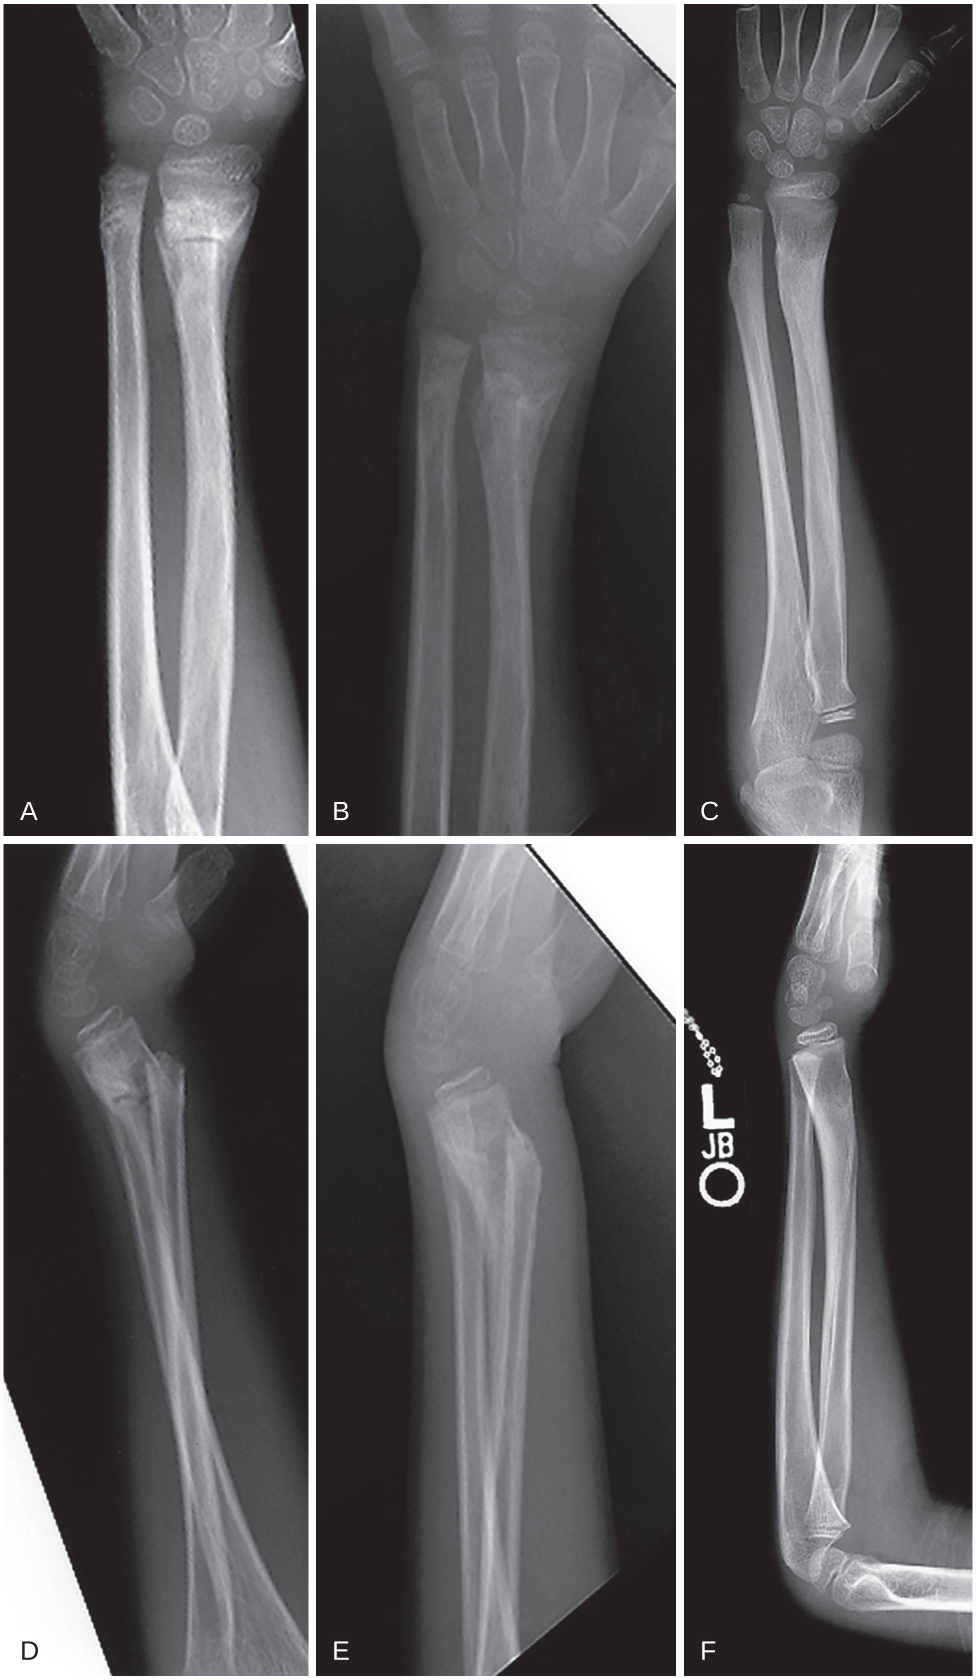

**FIGURE 22-5** Forearm radiographs of a 7-year-old boy demonstrating remodeling of a forearm fracture over a 9-month period. **A** to **C,** Anteroposterior plane. **D** to **F,** Lateral plane.

**FIGURE 22-6** Anteroposterior radiograph of the knees in a 13-year-old boy shows growth disturbance of the left distal femoral growth plate after a fracture (on right in photo).

The musculoskeletal examination begins with observation of the patient for sites of deformity, swelling, contusions, abnormal color, and open fractures. If a fracture is suspected, confirmatory diagnostic studies may be integrated into the complete physical examination. If such studies cannot be done, it must be assumed that a fracture exists, and the suspected site must be splinted until the fracture is confirmed or ruled out. Splinting may also reduce discomfort and limit further damage to soft tissue. A complete neurovascular examination is essential in any case of suspected limb or spine injury. When an uncooperative patient will not allow an adequate physical examination or, in the case of comatose patients or preverbal children, cannot provide a history, judicial use of special diagnostic studies can be critical.

## RADIOGRAPHIC ASSESSMENT

Plain radiography is the first and most widely used test to identify skeletal injury in children, but it can also be a major source of misdiagnosis in this age group. Cartilage, which makes up a large percentage of the child's skeleton, is radiolucent but can fracture. Ossification centers appear at different ages in different locations. The timing of their appearance and their location vary greatly and can suggest fractures. Confusion most frequently occurs in the elbow, knee, and cervical spine. Comparison of the injured and uninjured limbs can be useful. Plain radiographic soft tissue signs, such as the posterior fat pad sign in elbow injuries, are associated with a high likelihood of underlying fracture (Fig. 22-7).[9] A number of imaging studies are available for the assessment of pediatric musculoskeletal injuries and are injury and age specific. Radiographs may confirm fractures. Ultrasonography is a readily available, noninvasive imaging test that can be used to evaluate the unossified epiphysis, especially in injuries about the elbow.[10] Magnetic resonance imaging (MRI) may also be helpful, especially in evaluating the injured spine, but it may require general anesthesia in a young or uncooperative patient. Computed tomography (CT) scanning is useful in periarticular fractures in children approaching skeletal maturity. For example, ankle physeal fractures with articular extension in children with partially closed physes are best delineated with CT scan.[11] Arteriography may be required to assess vascular injury associated with a fracture. Rarely, proximal tibial physeal fractures and distal humerus fractures through the supracondylar region can be associated with disruption of the blood supply to the distal limb. These injuries require emergent treatment, and an intraoperative arteriogram may be of value in diagnosis and treatment (although in

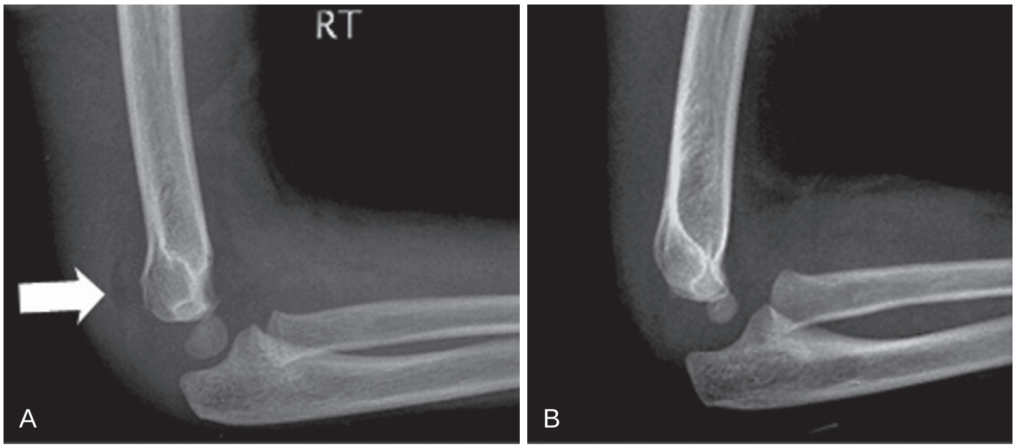

**FIGURE 22-7** Lateral elbow radiographs of a 2-year-old boy with a mildly displaced supracondylar humerus fracture and arrow showing a posterior fat pad sign (**A**) and a normal age-matched elbow (**B**).

most situations surgical treatment should not be delayed in order to obtain an arteriogram in the radiology suite).[12] Joint aspiration can identify blood and fat, which indicate an intra-articular fracture that would not be identified on radiographs. Finally, arthrography and arthroscopy may define intra-articular injury to the cartilage and ligaments.

# Management of Musculoskeletal Injuries

## IMMEDIATE TREATMENT

Priority treatment cannot interfere with complete treatment of an injured child. Proper timing and coordination of management with other disciplines are imperative. Traction or splinting often adequately stabilizes the musculoskeletal injury until other tests and treatments have been completed. Immobilization may also reduce the need for pain medications, which can mask the symptoms of other disorders, such as intra-abdominal injuries, and inhibit diagnosis.

Although there are many types of splints, ranging from plaster to traction bows, the basic principles of fracture management remain the same. The injured part should be splinted as it is found, and the joints above and below the injury should be immobilized without compromising the circulation of the soft tissues. Portable traction splints or custom-molded, well-padded plaster or fiberglass splints can be used in the initial management of fractures. Failure to immobilize the fracture can cause further soft tissue damage from sharp bone ends or the crushing of entrapped neurovascular elements.

## DEFINITIVE FRACTURE MANAGEMENT

Adequate stabilization of fracture fragments prevents further soft tissue injury, frequently decreases pain, and facilitates wound care and patient mobilization. Techniques of definitive stabilization in children include splinting, casting, skeletal traction, external fixation, pinning, flexible intramedullary nailing, and plating. The choice of fixation method depends on the child's age, the location of the fracture, the presence and extent of soft tissue injury, and the presence of multitrauma.

Metaphyseal undisplaced or impacted fractures are likely to heal faster than diaphyseal or displaced fractures. Fractures with devitalized bone or soft tissues take longer to heal. Radiographic evaluation in conjunction with clinical judgment and experience is needed when determining the healing time of fractures in children.

Fragments of bone must be held together until they are sufficiently strong to withstand the forces specific to the bone. A satisfactory position must be obtained, without harming adjacent tissue, before the fracture becomes fixed. Fractures in newborns and infants begin to heal within a few days, but fractures in adolescents can be moved freely for 10 to 14 days. Excessive cast padding, resolution of swelling, or a poorly applied cast may permit progressive malposition within the cast. Fractures should be followed with frequent radiographs until union is secure, to avoid displacement. Unstable fractures should be imaged before consolidation to evaluate for loss of alignment. This allows for easier repeat reduction.

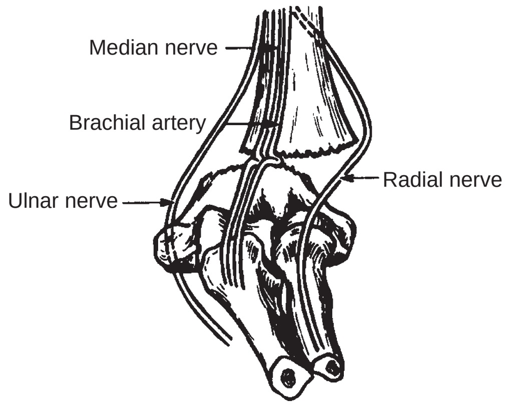

FIGURE 22-8 Supracondylar humerus fracture. Soft tissue and neurovascular structures may become entrapped between bone fragments in these types of fractures.

In children, the thick periosteum tears on the tension side of a fracture but often remains intact on the compression side. The intact periosteum can then function as a hinge, increasing the success of closed reduction of displaced fractures by three-point molding (see Fig. 22-3). Reduction must be performed gently. Forceful and repeated manipulation of physeal fractures can produce iatrogenic damage and growth disturbances. Entrapment of soft tissue occasionally prevents reduction of an otherwise stable fracture (Fig. 22-8) and requires open reduction and stabilization with internal or external fixation or immobilization in a cast.

In some cases, internal fixation with crossed pins, plates and screws, intramedullary nails, or external fixation with pins in metal outriggers or rods may be useful (Fig. 22-9). The benefits of each of these devices must be weighed against their risks, such as need for future operative removal and the possible disturbance to the growth plate, and should be individualized for each particular clinical scenario. Specific indications for internal and external fixation may include fractures with significant soft tissue injury, fractures in children with closed head injury, those associated with neurovascular injury, and fractures that fail nonoperative treatment. Comminuted and oblique fractures and those with complete tears of the periosteum may also prove to be too unstable for cast immobilization. In cases of intra-articular fractures, such as Salter-Harris types 3 and 4, open reduction and stable internal fixation are frequently necessary to avoid incongruity of the joint or growth disturbance. Fractures associated with neurovascular injury requiring repair should be stabilized first.

# High-Priority Musculoskeletal Injuries

Although many musculoskeletal injuries in children can be treated on an urgent rather than an emergent basis, the discussion of some high-priority musculoskeletal injuries in children is warranted. Even in nonurgent cases, it is important to remember that injuries to growing bones can have lifelong consequences.

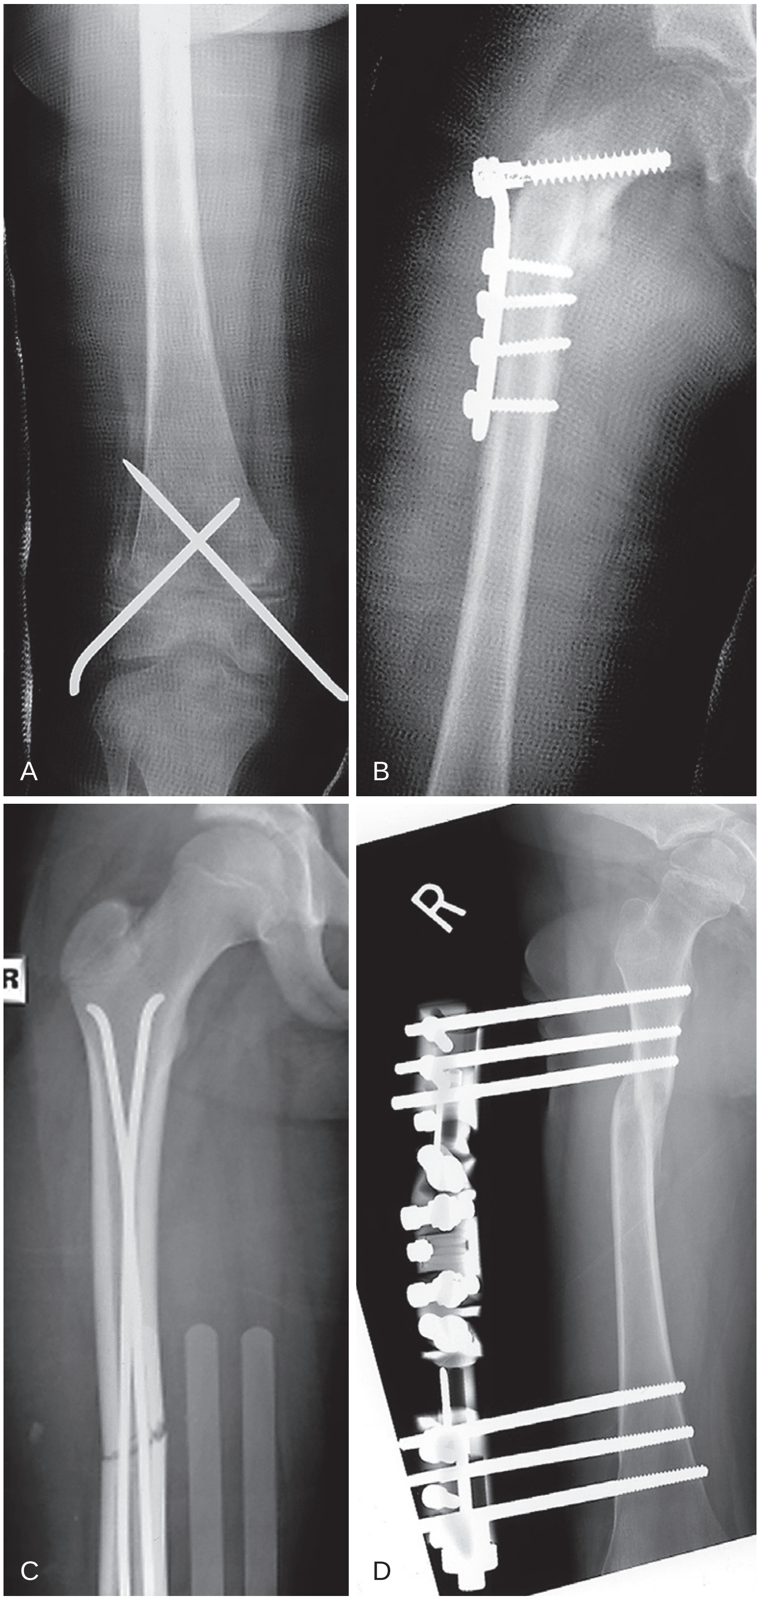

FIGURE 22-9 Anteroposterior radiographs of right femur fractures fixed with a variety of fixation methods. **A,** Salter-Harris type 2 fracture with crossed pins in a 9-year-old girl. **B,** Intertrochanteric fracture with screws and side plate in a 7-year-old boy. **C,** Transverse shaft fracture with elastic intramedullary nails in a 13-year-old boy. **D,** Subtrochanteric fracture with external fixator in an 8-year-old boy.

## OPEN FRACTURES AND TRAUMATIC ARTHROTOMIES

Open fractures frequently result from high-energy trauma and communicate with the outside environment, and so are at increased risk for infection.[13–14] The cornerstones of management include recognition, administration of appropriate antibiotics, stabilization of the fracture, and adequate irrigation and debridement of wounds. Open fractures may require multiple surgical procedures to achieve adequate soft tissue coverage and fracture healing.

When a laceration or abrasion is noted in proximity to a fracture, an open fracture must be suspected. Radiographic evidence of air shadows around the fracture may confirm the diagnosis. A sharp fragment of bone can tear through the skin, and the elastic properties of a child's bone can readily straighten the fracture fragments after the force is discontinued. The protruding point of bone can then draw back under the skin, taking debris and bacteria with it into the deep tissues. Minimal signs of injury do not necessarily mean a minimal chance of infection. Wounds should not be probed in the emergency department, where the risk of iatrogenic contamination is high and the likelihood of adequate debridement is low; if necessary, such procedures should be done in the operating room.

The Gustilo system classifies open fractures according to the size and extent of soft tissue damage.[13–15] Type I is an open fracture with a clean wound smaller than 1 cm. Type II is an open fracture with a laceration longer than 1 cm without extensive soft tissue damage, flaps, or avulsions. Type III is an open fracture with extensive soft tissue injury and is further divided into three subtypes: Type IIIA has adequate soft tissue coverage of a fractured bone despite extensive laceration of soft tissue, type IIIB involves extensive soft tissue injury with periosteal stripping that requires grafting or a flap for coverage, and type IIIC is an open fracture associated with arterial injury that requires repair. The risk of infection is related to the severity of the injury: 2% in type I open fractures, 2% to 10% in type II open fractures, and up to 50% in type III open fractures.[15] Wounds should initially be dressed with sterile gauze soaked with antiseptic. Hemorrhage should be controlled by direct pressure. Patients should receive tetanus prophylaxis and antibiotics at recognition of the injury. First-generation cephalosporins cover the gram-positive organisms found in type I and type II injuries. An aminoglycoside is added for type III injuries, and ampicillin or penicillin is added for farm injuries or other massively contaminated wounds to fight potential anaerobic infection.

Each wound must be adequately debrided and copiously irrigated with the patient under general anesthesia. Current evidence suggests that this should be accomplished as soon as the patient is stable, and within 24 hours after injury if possible.[16] Wounds may need to be re-evaluated after 2 or more days for additional debridement. Primary closure or delayed primary closure may be appropriate for some open fractures, whereas grafting or flap coverage is needed for larger soft tissue defects. The goal of debridement is removal of devitalized tissue to avoid the catastrophic consequences of an infection, which may include limb loss or chronic osteomyelitis. Adequate immobilization is necessary for soft tissue healing. For small lacerations, immobilization in a cast that has been windowed for wound inspection may suffice. For larger lacerations, external or internal fixation is often necessary to provide stable fixation with access to the wound.

Joint penetration by a foreign body can cause a diagnostic dilemma. Radiographs can be helpful if they reveal an "air arthrogram." Injection of sterile normal saline into the joint, or saline load test, can also be diagnostic.[17] If the saline load test results in the liquid exiting the wound or laceration, joint penetration has occurred and requires irrigation and debridement in the operating room.

## COMPARTMENT SYNDROME

Compartment syndrome occurs when pressure is elevated within a confined fascial space. This causes circulatory compromise and can progress to tissue necrosis. Closed fractures and crush injuries with associated edema may cause compartment syndrome. Forearm and leg compartments are most often involved. Ischemic injury starts when tissue pressure is 30 mm Hg less than mean arterial pressure.[18–19] The pressure within the compartments surrounding a fracture should be measured if compartment syndrome is suspected. Commercially available tissue pressure monitors or other measuring devices, including electronic arterial pressure monitoring devices, can be used.

The diagnosis of compartment syndrome in children can be difficult. Adults with compartment syndrome verbalize extreme pain and demonstrate pain with passive stretch of the muscles within the affected compartments, whereas children often have difficulty communicating their discomfort. The classical signs of compartment syndrome are the five Ps: pain, pallor, paresthesia, paralysis, and pulselessness. These signs are rather unreliable in children and may manifest late in the process. An increasing analgesia requirement is an important sign of compartment syndrome in children.[20]

With early recognition and timely management, full recovery can be achieved. All external compression is removed from the limb, compartment pressures are measured, and, if elevated, the compartments are surgically decompressed. In the forearm, volar and dorsal fasciotomies are required.[19] In the leg, all four compartments (anterior, lateral, deep posterior, and superficial posterior) must be released. This can be accomplished with either a one- or two-incision technique.[18] Without prompt intervention, the result is irreversible damage to soft tissues with loss of function, subsequent contractures, and deformity.[18–19]

## FEMORAL NECK FRACTURE

Although rare in children, fractures of the femoral neck and intertrochanteric region require attention (Fig. 22-10). These fractures frequently result from high-energy impact, including traffic accidents and falls from a height, and are associated with a high complication rate from avascular necrosis, coxa vara, nonunion, delayed union, and premature physeal closure.[21] The upper end of the femur lies within the joint capsule. After roughly 4 years of age, blood is supplied primarily by retinacular vessels that course from distal in the neck to proximal in the head. Delay in treatment of a fracture at the

**FIGURE 22-10** Anteroposterior pelvis radiograph of a 14-year-old boy shows a displaced left femoral neck fracture that required internal fixation.

neck is associated with increased risk of avascular necrosis of the head and destruction of the joint and can cause lifelong disability. Early decompression of the hip joint, reduction of the fracture, and internal fixation may minimize the complications.[21]

## MANGLED EXTREMITIES

Severely traumatized or mangled extremities in children must be assessed and treated through a multidisciplinary approach on a case-by-case basis. They may involve extensive injury to or segmental loss of skin, muscle, bone, and neurovascular structures. Some limbs may be unsalvageable owing to extensive damage, some can be reconstructed with a resulting dysfunctional limb, and others can be salvaged with a good outcome. The Mangled Extremity Severity Score rates injuries based on objective criteria at initial presentation, including skeletal and soft tissue injury, limb ischemia, shock, and patient age. Although originally developed in a primarily adult population,[22] it can be a useful adjunct to managing lower extremity trauma in children.[23]

Segmental bone loss is rare in children and does not necessitate amputation. If periosteum can be preserved, the potential to reform bone is extensive. Proper techniques of debridement and stabilization, along with adequate time for healing, may produce good results in children. External fixation techniques can allow for bone transport and osteogenesis to replace lost bone and axial deformity.

Power lawn mower injuries are uncommon, preventable injuries that cause significant morbidity in children.[24–26] Direct contact with the blade leads to laceration of tissue, amputation, or devitalizing shredding of the extremity. Such injury can result in damage to the vasculature and growth plate, joint stiffness, infection, or amputation. If salvage is undertaken, treatment follows that of open fractures.

In the case of amputation, preservation of bony length and retention of all viable soft tissue are important for the ultimate functional outcome. Amputation through the diaphysis of a child's bone frequently results in overgrowth of the bony stump through

**FIGURE 22-11** A pediatric backboard should have a torso mattress or an occiput recess to accommodate the child's relatively large head and avoid potentially dangerous cervical spine flexion.

the skin. This is especially true of the fibula, tibia, and humerus and can necessitate cutting back the bone every few years.

## SPINE TRAUMA

Injuries of the spine in children can be divided into those affecting the cervical spine and those in the thoracic and lumbar spine. Just as in other parts of the body, patterns of injury to the spine in children differ from those in adults. Radiographic imaging can be challenging. Principles of immobilization are different for children as well.

Cervical spine injuries in children differ from those in adults.[27–28] Children have greater ligamentous laxity and weaker neck musculature. In addition, they have large heads relative to body size; this effect is more pronounced in younger children. Cervical spine injuries in children tend to occur higher in the neck and can be primarily ligamentous or apophyseal without bony fracture.[29] When immobilizing a child on a backboard, the relatively large head should be considered; a child's backboard splint should have a recess for the occiput or a mattress for the torso to maintain the alignment of the cervical spine, avoiding flexion of the neck (Fig. 22-11).[30]

Radiographic evaluation of the pediatric cervical spine can be challenging. Pseudosubluxation, or the apparent forward displacement of C2 on C3 and, less commonly, C3 on C4, is a well-described plain radiographic finding in normal children younger than 8 years.[27,31] Other sources of difficulty in interpreting radiographs include incomplete ossification, epiphyseal variation, and elasticity of the disks and vertebral bodies relative to the neural structures, which allows extensive injury to the soft tissues without evidence of abnormality on plain radiographs or SCIWORA (spinal cord injury without radiographic abnormality). MRI is helpful in evaluating soft tissues in cases of possible cervical spine ligamentous injury in children.[27,32]

Injuries to the thoracic and lumbar spine are rare in children. The growth of vertebral bodies occurs through the apophyses or growth centers on the cranial and caudal ends of the bodies. With compression injury, adolescents are at risk for traumatic displacement of the vertebral apophysis and the attached disk into the spinal canal, especially in the lumbar region.[33] Symptoms are similar to those seen in central disk herniation, including muscle weakness and absent reflexes. This injury requires recognition and emergent surgical decompression.

Lap-belt injuries are flexion-distraction injuries that typically occur in the thoracolumbar region when children violently flex over the seat belt.[28,34] A fracture propagates from the posterior portions of the vertebra to the disks or vertebral body in the front (Fig. 22-12). In addition to the vertebral injury, children can sustain serious abdominal and aortic injuries, and these should be suspected when an abdominal contusion, or the telltale seat-belt sign, is evident in a trauma patient. Lap-belt injuries frequently require immobilization and possible internal fixation.[28]

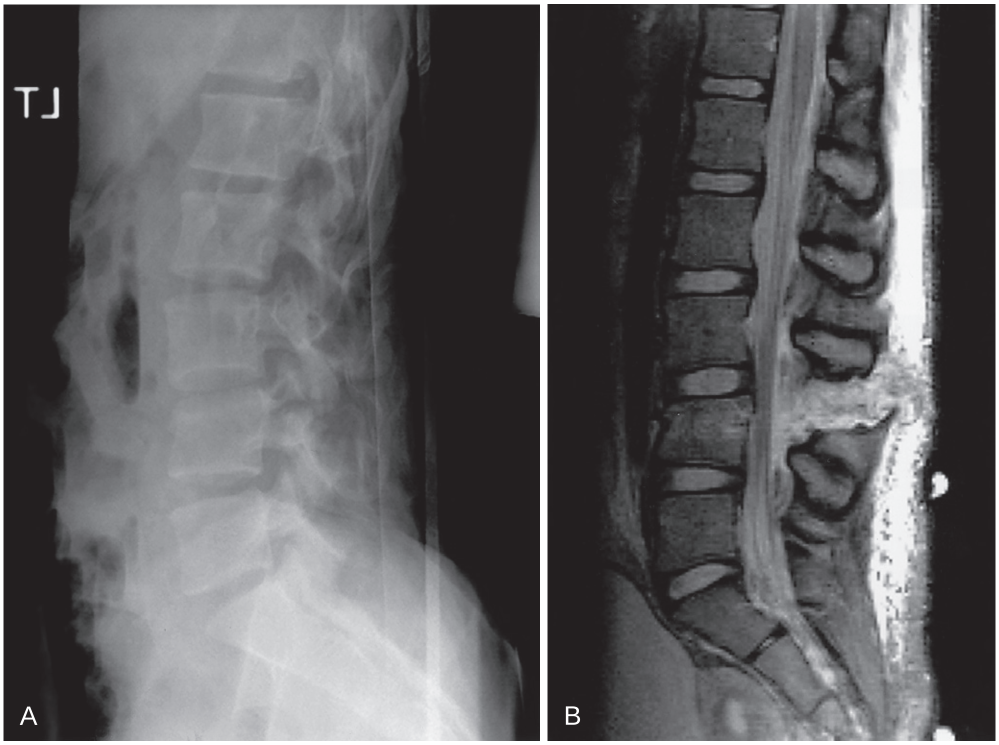

FIGURE 22-12 Lap-belt injury of L4 in a 15-year-old girl without neurologic injury. **A,** Lateral lumbar spine radiograph shows fracture of both the L4 body and the posterior spine. **B,** Sagittal magnetic resonance image of the lumbar spine shows the extensive bony and soft tissue injury.

## CHILD ABUSE

The maltreatment of children is a complex medical and social problem, and its recognition is key to management. Fractures before walking age in the absence of metabolic disease or child abuse are rare. Fractures are the second most common manifestation of child abuse after skin lesions.[35] Suspicion of abuse must be raised when there is a discrepancy between history and injury, when multiple fractures are present in different stages of healing, or when bruising, metaphyseal fractures, or long bone fractures appear in children younger than 1 year.[35]

CHAPTER 23

# Hand, Soft Tissue, and Envenomation Injuries

Daniel B. Schmid and Michael L. Bentz

Evaluation of pediatric hand and soft tissue injuries requires a systematic approach that includes all relevant organ systems at the site of trauma.[1,2] A high index of suspicion is necessary to make an accurate diagnosis and exclude subtle problems, particularly in toddlers and infants who are unable to cooperate with a detailed examination. Injuries undergo triage according to their threat to life. After triage has taken place, the more peripheral and often more dramatic and distracting injuries can be better defined.[2] The history is important to define baseline function, previous injuries, right- or left-hand dominance, and the mechanism and timing of injury. The initial physical examination must define vascularity and perfusion because an ischemic or poorly perfused extremity necessitates emergent surgical intervention. Other findings can be handled in a less urgent fashion after an orderly assessment is complete. The patient should be examined in a well-lighted area with the parents present to exert a calming influence over a frightened child and thus increase the reliability of findings. This chapter focuses on the acute evaluation and management of hand, soft tissue, and envenomation injuries to provide a foundation for the accurate triage of injured children.[3,4]

## Hand and Soft Tissue Injuries

### EVALUATION

#### Vascularity

The goal of the initial examination is to determine the presence or extent of vascular injury, hypoperfusion, or ischemia. Symptoms of ischemia include pallor, paresthesia, paralysis, pain, and lack of pulse. The digits should be pink and warm if the patient has not had hypothermic exposure or proximal tourniquet application. Normal capillary refill time is 3 seconds and is most accurately tested by compressing the lateral aspect of the distal phalanx adjacent to the nail plate. A delayed refill time indicates impaired arterial inflow, whereas a rapid refill time suggests venous hypertension or insufficiency. The pulse should be palpated bilaterally at the radial, ulnar, and brachial arteries. Percutaneous Doppler ultrasonography can be used to qualitatively and quantitatively define inflow if the pulse cannot be detected or if it is asymmetric. An Allen test is important to define the relative contributions of the radial and ulnar arteries to the palmar arches of the hand. The ulnar artery is the dominant source of inflow to the hand and continues into a patent palmar arch in 85% of uninjured hands.[5,6] Significant bleeding noted during the initial evaluation is managed by firm manual compression or, if the time until definitive intervention is expected to be prolonged, by proximal tourniquet application. A hemostat or clamp should not be placed blindly into the wound because lack of blood flow may injure adjacent neural structures. Impaled or retained foreign objects should be left in situ until definitive management is possible because they may staunch the flow of blood from a vascular injury.

#### Peripheral Nerves

Peripheral nerves should be evaluated after vascular inflow has been assessed. Isolated nerve injuries cause predictable neurologic deficits that manifest as abnormalities in sensation or motor function depending on the location of injury.[7,8] Vascular injuries can also cause neurologic deficits, particularly in subacute wounds; therefore the evaluation of nerve and vascular injuries should generally occur in tandem. A clear concept of cross-sectional anatomy is helpful in visualizing potential at-risk structures.[8] Sensory examination requires a child to cooperate, but even in a young child anhidrosis (loss of sweating function) can be seen and indicates underlying nerve damage.[9,10] In the cooperative patient, evaluating the nerve function at the distal aspect of the hand can be used to screen for a more proximal nerve injury.

The median nerve is responsible for sensation to the three and one-half volar radial digits. The function of this nerve can be tested by a pinprick or, more objectively, by two-point tactile discrimination. Median nerve motor function can be tested by palpating the contraction of the abductor pollicis brevis and opponens pollicis muscles as the patient forms an "O" with the index finger and thumb (Fig. 23-1). The ulnar nerve supplies sensation to the one and one-half ulnar digits. Motor function of this nerve is most accurately tested by palpating the contraction against the force of the first dorsal interosseous muscle while the fingers are spread (Fig. 23-2). There is no radial nerve motor innervation of the intrinsic hand muscles,

FIGURE 23-1 The ability to form an "O" with the index finger and thumb, with palpable contraction of the thenar muscles, indicates an intact median nerve.

FIGURE 23-2 Digit spread with palpable contraction of the first dorsal interosseous muscle is consistent with an intact ulnar nerve.

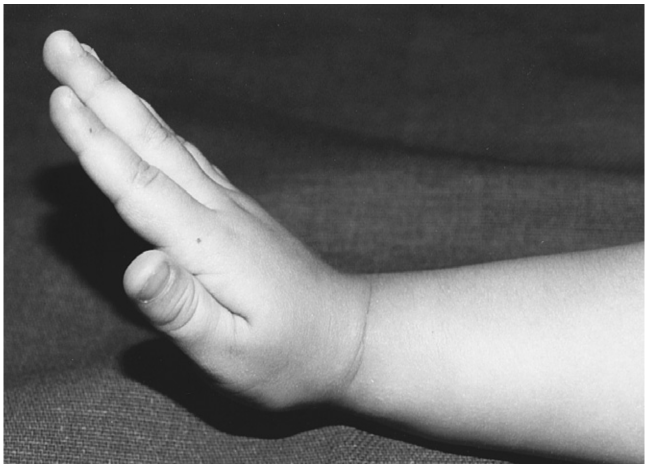

FIGURE 23-3 Digit and wrist extension demonstrates radial nerve integrity because no muscles in the hand are innervated by radial nerves.

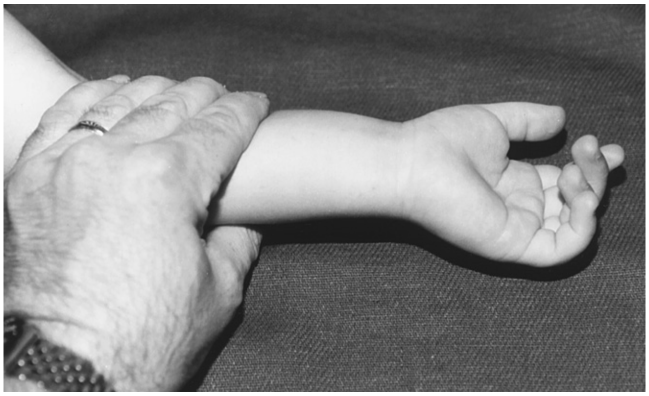

FIGURE 23-4 Forearm compression has failed to cause flexion of the index finger in this patient; this suggests flexor mechanism discontinuity to the index finger.

so the motor function of the radial nerve is best screened by wrist and digit extension (Fig. 23-3). The radial nerves provide sensation to the three and one-half dorsal radial digits of the hand to the level of the distal phalanges, although overlap is common. Serial examination can be helpful, and cooperation and a focused effort are essential for a reliable evaluation. Further, neurologic findings associated with compartment syndrome evolve over time and may not be obvious during the initial examination.[11,12]

## Skeleton, Tendons, and Ligaments

Although some skeletal injuries are obvious on routine examination, most require radiographic evaluation. Physical examination findings of fracture include deformity, crepitus, ecchymosis, pain, instability, and swelling. Anteroposterior, lateral, and oblique radiographs should be obtained for all but the most minor injuries to evaluate for fractures, dislocations, and foreign objects. Familiarity with the Salter-Harris classification of pediatric fractures is important because the specific fracture patterns offer prognostic information relevant to subsequent growth (see Chapter 22).[13,14] The presentation of fractures has been well documented.[15–19] Examination and radiographic appearance are combined to describe the fracture accurately. Open fractures have an associated full-thickness soft tissue injury, whereas closed fractures do not. Simple fractures result in two bone fragments, whereas comminuted fractures involve several fragments. Greenstick fractures involve one cortex and are particularly relevant in children because of their malleable bones. The description of a fracture should also include information regarding length (shortened, elongated, normal), angulation (volar, dorsal, radial, ulnar), rotation (present or absent), and displacement as a percentage of normal alignment.

Tendon injuries can be difficult to diagnose, particularly in young or uncooperative children. In such cases, surgical exploration is necessary to definitely confirm certain injuries. The posture of the hand at rest gives information regarding tendon integrity. In a relaxed position, the hand should form a gentle cascade; this position results from passive tension of the tendons. With compression of the distal forearm, all digits should adopt flexion posturing as a result of the tenodesis effect. A digit that remains extended out of the cascade suggests disruption of the flexor mechanism (Fig. 23-4). The flexor digitorum superficialis tendon to each of the four fingers is tested by holding the adjacent digits in a fixed position and

**FIGURE 23-5** Function of the flexor digitorum superficialis tendon is tested by demonstrating isolated metacarpophalangeal and proximal interphalangeal joint flexion. Flexor digitorum profundus tendon function is tested by holding the middle phalanx fixed and observing distal interphalangeal joint flexion.

allowing metacarpophalangeal joint flexion (Fig. 23-5). The flexor digitorum profundus and flexor pollicis longus tendons are evaluated by holding the middle phalanx and observing distal interphalangeal joint flexion.

Ligament injuries can be difficult to diagnose, particularly in the presence of associated soft tissue or skeletal injuries.[20] Abnormal joint stability is an indicator of disruption of the ligaments.[15] If the opposite side is uninjured, joint stability should be compared with that side as an indicator of preinjury status. Plain and stress radiographs of an avulsion fracture at the site of ligament insertion can confirm clinical findings.

### Soft Tissue

A thorough determination of soft tissue injuries is important for a knowledgeable evaluation of wound healing, but even more so for the evaluation of long-term function and outcome of primary or secondary reconstructive surgery.[21] The amount of soft tissue present in the area of a wound determines the feasibility of primary repair of vascular, neural, and osteoligamentous injuries, and an adequate amount is required for proper healing. The size (measured objectively), shape, location, and general configuration of each wound is recorded, and the mechanism of injury and preinjury status of the patient is established. Obvious foreign objects are removed, although projectiles impaled through an extremity are left in situ until they can be managed definitively. Exposed vital structures as well as associated fractures and tendon injuries are noted.

## EARLY TREATMENT

### Vascular Structures

Ischemia is one of the few surgical emergencies associated with upper limb trauma. Revascularization is a top priority after the correction of life-threatening injuries. Because irreversible changes start to occur after 4 hours of ischemia, expeditious surgical intervention is mandatory, especially if the ischemic tissue involves muscle. Primary vascular repair is the most effective procedure and is ideally accomplished by debridement, mobilization, and primary anastomosis of injured segments. Reversed vein grafts, which are frequently performed with foot, forearm, saphenous, or cephalic veins, should be used liberally if tension or lack of tissue prevents easy approximation of adjacent segments. In general, all arteries and veins proximal to the elbow should be repaired. Repair of arterial injuries below the elbow should also be considered to prevent cold intolerance; however, only about half of these repairs remain patent.[22,23] If necessary, the radial artery can be ligated primarily. Once repairs are complete, fasciotomy should be considered if ischemia has been prolonged, soft tissue damage is significant, or adequate postoperative monitoring is not available.[11] Serial examination should then be pursued in an effort to make an early diagnosis of recurrent ischemia or postsurgical thrombosis or bleeding. The role of anticoagulation therapy in this setting is controversial and is based on the surgeon's preference and experience.

### Peripheral Nerves

Injury to the peripheral nerves is not an emergency and can frequently be addressed when an adjacent vascular injury is being repaired. When a wound is clean, uninfected, and well vascularized, primary nerves should be repaired in an end-to-end fashion. Such repair can be facilitated through the mobilization of proximal and distal injured segments, which can reduce tension and augment blood flow. If mobilization of the injured segments cannot adequately repair the defect, interpositional nerve grafts, nerve conduits, or vein grafts can be used for definitive reconstruction.[8,24] In such cases, early secondary repair in the first 10 days after injury is optimal. To ensure that the injured area remains intact, the involved limb should be splinted to minimize further proximal migration of the transected nerve before surgery and to relieve anastomotic tension.

### Skeleton, Tendons, and Ligaments

When injuries to the skeleton, tendons, or ligaments are diagnosed, restoration of normal or acceptable anatomy followed by appropriate immobilization is indicated. In children, an injury that is suspected but not objectively defined is particularly common. Hand fractures may not be evident on radiographs for several weeks. In this situation, presumptive treatment should be carried out, which usually involves immobilization of the potentially injured area despite equivocal physical examination or radiographic findings. Immobilization is rarely contraindicated in children because it allows protection from further injury, improves pain control, and maintains local anatomy. Use of a splint (instead of a cast) is ideal because it allows swelling into a nonfixed space and limits the possibility of vascular compromise during the acute injury and postreduction periods.

Anatomic reduction of fractures and dislocations can be done at the time of injury or in the following week with good functional results.[25] In the acute setting, excellent anesthesia can be obtained by performing a hematoma block. This is accomplished by injecting 2 to 3 mL of lidocaine 1% without epinephrine into the fracture site. Reduction in the subacute setting most commonly requires a traditional digital block. It must be kept in mind, particularly in smaller children, that the limiting dose of plain lidocaine is 4 mg/kg of body weight. A description of the reduction maneuvers for specific types of fractures is beyond the scope of this chapter, but in general gentle manual traction or finger-trap distraction with

simultaneous rotation or derotation allows improvement in many types of fractures and dislocations. Postreduction radiographs should be obtained in most if not all patients before or after immobilization. The specific position of immobilization is less critical for children than for adults because children are less prone to stiffening and tightening of the ligaments. The "position of safety" can always be used at least initially for splinting: the wrist is placed in 30 to 45 degrees of extension, the metacarpophalangeal joints are placed in 70 degrees of flexion, and the interphalangeal joints are left straight. Serial physical and radiographic examinations are tailored to the specific injury and clinical course.

### Soft Tissue

After soft tissue and associated vital structure injuries are documented, irrigation of all significant wounds should be performed with normal saline solution, after which foreign objects are removed and tissue that is clearly devitalized is debrided.[26] These procedures may require a local anesthetic, which should be given only after a thorough neurologic examination has been completed. Simple lacerations and small surface area avulsions can be closed primarily using the same layered closure method used for deep or gaping wounds under tension. Suture choice depends on the location, size, and cause of the wound, as well as the patient's age. A smaller child who requires sedation for the primary wound repair will be hypersensitive to suture removal, when sedation is usually not available. In such cases, absorbable sutures reinforced with adhesive strips (Steri-strips) are ideal. Permanent sutures should be used in older or cooperative patients to minimize the inflammatory response and avoid early scarring. The potential for scarring depends on the location of the wound and the mechanism of injury. Scarring can be minimized through judicious wound closure.

Open wounds that cannot be closed primarily require more elaborate intervention. To bridge the gap between injury and wound closure, the wound must be managed and protected. Normal saline wet-to-wet dressings are a simple and effective way to provide limited debridement, allow the initiation of granulation, and prevent desiccation. Povidone-iodine dressings should be reserved for short-term use in infected wounds. Acetic acid solution (0.25%) is appropriate for wounds that have culture documentation of infection with *Pseudomonas* species. Subatmospheric pressure dressings are effective as temporary cover of a contaminated or extensive wound, as a bridge to more extensive soft tissue reconstruction, or for definitive closure of extremity wounds in the pediatric population.[27–29] Quantitative wound biopsies should be reserved for nonthermal burns.

If the skin defect is partial thickness only and no vital structures are exposed, split-thickness skin grafting or skin distraction is appropriate. Split-thickness skin grafts are used for larger wounds, less cosmetically significant wounds, or those in which the wound bed may not be optimal because of infection, inflammation, or ischemia. Full-thickness skin grafts contract less after revascularization and thus are ideal for cosmetically significant areas or where wound contraction is undesirable. Local skin flaps can also be used in such settings, offering a cosmetically favorable replacement of like tissue. These skin flaps can be random if they have no specific blood supply or axial if the blood is supplied by a specific vessel.[30] Regional muscle flaps can be used almost anywhere in the body, especially when highly vascularized tissue of significant bulk is required to cover exposed critical structures and fill dead space. Similar to axial pattern skin flaps, these muscle flaps are used on the basis of a known blood supply, which makes their dissection reliable and safe. Finally, when local tissue is not available or is inadequate to provide wound closure, microvascular free tissue transfer is indicated using specific donor "free flaps" to accomplish specific tasks.[31]

### Amputations

Traumatic amputations in children should be considered for replantation by a qualified microsurgical team, given the excellent results obtained when compared with adult series.[32–34] To optimize the chance of success, the amputated part should be wrapped in saline-moistened gauze, sealed in a plastic bag, and placed in a bag of ice and saline solution; the part must not contact the ice directly.

# Envenomation Injuries

## SNAKEBITES

More than 2700 species of snakes exist; 115 of these species are indigenous to the United States, and only 19 of the 115 species are poisonous.[35] In the United States approximately 8000 bites occur annually from poisonous snakes, half of which occur in children.[36,37] Pit vipers, which are named for the pit located between their eyes and nostrils, account for most bites. Pit vipers include rattlesnakes, copperheads, and cottonmouths (family Viperidae, subfamily Crotalinae).[38] Coral snakes (family Elapidae) represent the other poisonous family. Most bites occur during the summer months in the morning, late afternoon, or evening. Not all bites are associated with envenomation. Signs of envenomation include pain, edema, local tissue necrosis ecchymosis, nausea, vomiting, hypotension, disseminated intravascular coagulopathy, hemolysis, mental status changes, seizures, and death.[39] The severity of signs is proportional to the degree of envenomation. Early intervention includes reassurance and support, immobilization, limb elevation, venous tourniquet application, and rapid transfer to the nearest medical facility. Cryotherapy and wound incision and suction are no longer recommended because of potential damage to vital structures.[40–42] Tetanus immune globulin and toxoid should be given to patients who have had two or fewer immunizations.

The antivenin Fab AV is sheep immunoglobulin immunized with antigen from four snakes—three variety of rattlesnakes and a cottonmouth or water moccasin—that has been shown to be effective after envenomation by all North American rattlesnakes and was found to be safe in children in a small study of 12 subjects.[43–45] Antivenin is administered intravenously only after a skin test has been done to rule out the possibility of an anaphylactic reaction. Four to six vials (4-6 g) of Fab AV is given immediately, with redosing in 1 hour if the patient does not respond.[45] Initial dosing should be followed by aggressive intravenous hydration and close monitoring. A review of 93 patients receiving Fab AV noted immediate allergic reaction in approximately 5% of cases.[46] Because envenomation injuries and the use of antivenom require close monitoring, antivenom administration should not be delayed for skin testing.[47] Fasciotomy should be considered but is seldom required.[48] A review of 227 patients with rattlesnake bites of whom 211 were treated with antivenom showed favorable outcomes in nearly all

patients.[47] After initial treatment and baseline testing, patients should be closely observed for at least 12 hours in cases of crotalid envenomation and 24 hours for coral snake bites because of possible delayed-onset neurotoxicity.[49]

## OTHER BITE INJURIES

Gila monsters, which are found in the southwestern United States, and their relative the Mexican beaded lizard are active in late spring. These lizards inject venom as long as they cling to the victim. Wounds show edema, but tissue loss is less pronounced than that associated with envenomation by pit vipers; however, systemic signs can ultimately be similar. These injuries are managed by removing the animal from its victim, followed by local and systemic supportive care. Antivenin is not available. Radiographs should be obtained to exclude retained teeth.[50–52]

Black widow spiders are venomous New World spiders; the females are black with an hourglass-shaped red mark on the abdomen.[53–55] Local signs of a bite can be limited and are followed by systemic neuromuscular symptoms of diffuse rigidity and spasm that potentially lead to respiratory arrest approximately 1 hour later. Envenomations by black widow spiders are managed by local care, fluid and cardiovascular support, parenteral calcium gluconate, muscle relaxation, and antivenin.[3,51,55–58]

Scorpion stings in children have serious sequelae. Bark scorpions are the only toxic species in the United States; however, others are common in Mexico and equatorial countries. Local signs of envenomation are minimal, whereas systemic neuromuscular findings are present in the sympathetic and parasympathetic systems. Children are particularly susceptible to the severe cardiorespiratory and neuromuscular dysfunction associated with envenomation. Therapy of scorpion stings includes local wound care, topical ice, specific antivenin, and systemic support, including ventilation, control of tachyarrhythmias, and sedation. Treatment is similar to that for spider bites, although scorpion stings are generally less serious.[55,57,59–61]

Finally, human bite wounds can pose some of the most challenging definitive management problems among all bite-induced injuries.[62,63] Based on the quantitative and qualitative characteristics of oral flora, including the principal pathogen *Eikenella corrodens*, aggressive primary intervention is mandatory to achieve a satisfactory outcome in all these injuries. Thorough irrigation of penetrating bite wounds is mandatory as is broad-spectrum antibiotic coverage followed by frequent wound checks.[64]

CHAPTER 24

# Central Nervous System Injuries

Andrew Jea and Thomas G. Luerssen

Injuries to the brain and spinal cord continue to be major contributors to mortality and morbidity from childhood trauma. Despite over 25 years of intensive clinical research, there is still not a specific medical therapy for traumatic neurologic injury. Nevertheless, there has been a steady and substantial advance in our understanding of the natural history of brain and spinal cord injuries, and accompanying changes in management that continue to be refined and have clearly resulted in improved outcomes.

We are now well into the era of evidence-based medicine, whereby recommendations for disease and injury management are supposed to be derived from critical analysis of scientific research. In the last decade, the management strategies for central nervous system (CNS) injuries have been subjected to this type of analysis, resulting in the publication and continuous updating of practice management guidelines.[1–4] The analysis of the clinical evidence and the development of these recommendations represented a substantial amount of work by many leading experts in the field. Unfortunately, these reviews also uncovered a remarkable lack of strong scientific evidence upon which to develop recommendations, especially in the pediatric age group, so that most of the available recommendations regarding the diagnosis and treatment of neurologic injuries can only be supported by the lowest degree of medical certainty. Nevertheless, these published practice parameters are useful summaries of the current understanding of the various treatments for brain and spinal cord injuries.

Even in the face of limited evidence, we are also learning that "quality improvement" strategies are beneficial in the management of injury. These strategies allow multidisciplinary agreement and reproducible diagnostic and treatment processes that have specific outcomes that can be measured and continuously improved. Thus although there may be variation between centers, approaches within a single center can be uniform and workable for that institution.

## Basic Strategy of the Therapy of Central Nervous System Injury

One of the most enduring concepts underlying the management of brain and spinal cord injury is that of primary and secondary injury.[5] The primary neurologic injury involves the immediate disruption of neuronal, axonal, supportive structures, and vascular tissues. The magnitude and location of the primary injury along with the variety of irreversible cellular processes that immediately ensue, which has been referred to as the delayed primary injury, are directly related to the mechanism of the injury. These immediate tissue disruptions are also considered to be self limited and are, by definition, essentially untreatable. Given all of this, one can easily see that the primary brain injury is still the major determinant of injury outcome.

The primary injury triggers a cascade of intracellular and extracellular biochemical changes, both in the region of the injury and systemically, many of which are deleterious and cause acceleration and augmentation of the initial injury. These reactive processes represent the onset of what has been termed the secondary injury. These secondary reactive processes can begin at almost any time after the injury and can persist for some time. The secondary injury results not only in new damage both in the region of the primary injury, but also in areas of previously uninjured brain or spinal cord. It can also cause deleterious effects in other organs and body systems.

Systemic reactions commonly seen after brain or spinal cord injury include alterations in blood pressure and respiration, usually manifested by hypotension and hypoxia. It has been clearly shown that even brief and mild episodes of either hypoxia or hypotension can have profoundly deleterious effects on the outcome of both brain and spinal cord injury.[6–8] Although it is well known that spinal cord–injured patients can be rendered hypotensive by an isolated injury, it is now also clear that isolated brain injury can cause systemic hypotension. Multiple injuries, occult organ injuries, or other causes of exsanguination that result in hypovolemia are not required for this hypotensive response to occur. Of the early systemic complications, it appears that hypotension is much more deleterious to the acutely injured brain than is hypoxia. This is probably also true for the acutely injured spinal cord. Finally, it is clear that these complications can occur very early, frequently, and, in many cases, so briefly that they can go undetected.[9,10]

There are also other common systemic responses, many of which occur shortly after an injury but can also cause further injury even days after the institution of therapy. Hyperthermia, either from fever or as the result of overly aggressive warming, is harmful to the injured brain.[11] Hyperglycemia, which is commonly seen in the stress response and which can be aggravated by fluid administration or attempted nutrition, is also thought to be deleterious to the acutely injured neurons.[12–14]

Tissue disruptions, commonly referred to as cerebral or spinal cord contusions, cause reactive changes in the tissues immediately surrounding the area of injury. A variety of tissue factors, such as those in the kallikrein-kinin system, are released, and these factors can cause disturbances of microcirculation and the blood–brain or blood–spinal cord barrier, which ultimately results in the complex entity that has been generally referred to as post-traumatic edema.[15] There are hypermetabolic responses related to neural-tissue injury that may outstrip the local or regional substrate supply.[16] Excitotoxic amino acids, such as glutamate and aspartate, are released from injured neurons.[17] Post-traumatic seizures, especially prolonged subclinical seizures, may contribute to this response in the injured brain.[18] Along with the reactive biochemical changes, expanding local hemorrhages can cause further compression of adjacent vessels and tissues, resulting in an ischemic penumbra around the acute injury.

Although the systemic and biochemical processes of the secondary injury are complex, it appears that the pathophysiologic end point of all of them is ischemic damage. Ischemic neuronal damage is almost universally seen in the neuropathologic examinations of patients who have suffered traumatic brain and spinal cord injuries.[19,20]

Even though numerous biochemical cascades have been identified and physiologically characterized, and many have been the targets of pharmaceutical intervention, no drug has yet been shown to be specifically effective for CNS injury treatment. Trials of high-dose steroids, calcium channel blockers, free radical scavengers, and glutamate antagonists have been generally negative, although small and specific subgroups of patients were identified in post hoc analyses, which may have benefited from one or another of these therapies. More concerning is that some groups of patients were apparently harmed by the administration of some of these agents.[21] Despite this lack of development of a specific therapy, there has been steady improvement in neurologic outcomes, more so in the arena of brain injury than in spinal cord injury. This trend in improved outcome is almost certainly because of the realization that many of the ischemic processes can be prevented by aggressively applying various systemic manipulations, beginning with the resuscitation phase of the injury and continuing through the acute therapy period.

The essential therapeutic strategies for brain and spinal cord injury are based on preventing ischemic injury by the aggressive support of intravascular volume and blood pressure at all times. The historical idea of restricting fluids to head-injured patients is no longer accepted or acceptable management. The early use of vasopressors for both brain and spinal cord injury is appropriate. Reduction of focal vascular compression by removing mass lesions and aggressively preventing and managing reactive brain or cord swelling to protect perfusion are beneficial. These three relatively simplistic concepts—support of systemic blood pressure, reduction of intracranial pressure to assure cerebral perfusion, and removal of compressive lesions and the prevention of deleterious complications—are still the mainstay of management for brain and spinal cord injuries.

# Immediate Issues: Resuscitation and Transport of Injured Children

Effective, supportive, and preventative therapy should begin as quickly after the injury as possible. Goals of the initial resuscitation are twofold: to prevent as much secondary injury as possible and any new primary injury prior to the undertaking of neurodiagnostic studies. One can accomplish the first goal by assuring oxygenated perfusion of the brain and spinal cord, by restoring and maintaining age-appropriate normal blood pressure, and maintaining normal ventilation. These factors are of primary importance and are more important than the administration of any drug. The exact means of accomplishing this goal—the type of resuscitation fluid or the means of assuring ventilation—is probably less important than accomplishing the goal itself. Most current studies indicate that isotonic or slightly hypertonic saline solutions are appropriate fluids for resuscitating and maintaining blood pressure for neurologically injured patients.[2,22,23]

Tissue oxygenation is important; so, adequate airway support and ventilation are required. Early intubation by experienced personnel and using appropriate analgesia and sedation certainly will accomplish this goal. However, the role of intubation of injured children (and adults) in the field is still controversial. This maneuver is associated with a relatively high complication rate and may not be warranted in many situations.[1,24,25]

For patients with possible spinal injuries, prevention of further injury begins with stabilizing the spine. This maneuver involves much more than applying a collar or securing a child to a rigid board. It is important that the normal anatomic alignment be maintained. Very young children have proportionately larger heads and therefore have a tendency for cervical flexion when lying supine.[26] A cervical collar alone does not completely immobilize a child's injured spine.[27] The spine should be immobilized in anatomic position, with the head in a normal relative position to the body. Young children will require some additional elevation of the body so that the head falls back to a truly neutral position. Once these parameters have been achieved, that is, stabilization of the spine in anatomic position and the establishment of support of systemic blood pressure and respiration, the injured child may be transported for definitive diagnosis and therapy of the injury.

# Traumatic Brain Injury

## EPIDEMIOLOGY

Despite the frequency of head injury in children, epidemiologic data in this area are relatively limited. A study in the United Kingdom indicated that 40% of all patients seen in emergency rooms for the treatment of head injuries were children.[28] It is important, however, to distinguish between

head injury and brain injury when discussing outcomes and therapy, although it is probably equally important to group these entities when discussing mechanisms and prevention. Accordingly, population-based studies indicate an average incidence of clinically important head injury in children at about 185 per 100,000, with the incidence generally dropping with increasing age.[29,30] Boys are injured at a rate approximately twice that of girls.

Overall, 85% of the brain injuries sustained in childhood are mild and non–life threatening.[31,32] On the other hand, well over half of all deaths resulting from blunt trauma in children are caused by a brain injury.[33,34]

The severity and mechanism of brain injury are determinants of outcome. The mechanism of injury also depends on age. The most common mechanism resulting in head injury in children is a fall, but the usual falls of childhood rarely cause severe injury. Inflicted injury is by far the leading cause of severe brain injuries in very young children. In older children, severe brain injury is most commonly seen in relation to motor vehicle accidents.

Many accidental brain injuries that occur in children are preventable. Proper use of occupant restraints in motor vehicles can prevent up to 90% of the serious injuries to young children.[35] The implementation of a mandatory child restraint law in Michigan reduced the number of motor vehicle–related injuries in children by 25%.[36] Wearing helmets for bicycle riding as well as for other recreational activities, such as skateboarding, skating, skiing, and horseback riding, should decrease the risk for brain injury,[37–39] although educational programs regarding helmet use have had only limited success so far.[40] Many falls are preventable. Vigilance regarding open windows and stairways, including the use of gates or bars substantially reduces the occurrence of these injuries.

## SPECTRUM OF TRAUMATIC BRAIN INJURY

There are many ways to undertake an overview of the major types of traumatic brain injuries. The authors have come to prefer one that includes a relationship of injury types, mechanism, and natural history. The simplest way to do this is by categorizing major injury types as either focal or diffuse. Accepting the caveat that many traumatic injuries are mixtures of focal and diffuse injury, one can still undertake individual management strategies based on the initial appearance of the type of brain injury.

### Focal or Diffuse Brain Injury?

Focal injuries include contusions, lacerations, traumatic hematomas, and localized damage resulting from expanding masses, shifts, and distortions of the brain. Diffuse injuries include the spectrum of diffuse axonal injury, which includes what is commonly called cerebral concussion, as well as other diffuse insults, such as global ischemia, systemic hypoxia, diffuse brain swelling, and diffuse vascular injury. Focal injuries are usually immediately apparent on the admitting computed tomography (CT) scans even when they appear to be clinically asymptomatic. In contrast, diffuse injuries may show much less striking changes on early neuroimaging studies, even though the patient may exhibit profound alterations in consciousness and neurologic function. Diffuse injuries may require a series of diagnostic studies to determine the type and magnitude of the injury. They are also more likely to require prolonged monitoring and management of intracranial pressure.

### Focal Brain Injury

Most focal brain injuries are associated with impact-related mechanisms. Because short falls are the most common cause of accidental head injuries in childhood, cranial impacts and resulting focal injuries are also common. Impact mechanisms also result in skull fractures, which are also commonly seen in the pediatric age group. In fact, about 20% of head-injured children who are admitted to the hospital have skull fractures.[41] Despite the frequency of skull fracture in childhood, the majority of children with this injury will not require any treatment. Therefore the clinical importance of most skull fractures is that the fracture serves as an indicator of both the mechanism and the severity of the head injury. Most studies of the importance of skull fractures have determined that finding a skull fracture in a head-injured patient is statistically associated with a higher likelihood of developing an expanding intracranial hematoma or harboring a significant brain injury.[41–45] Furthermore, complex skull fractures, or the occurrence of multiple fractures, are generally associated with higher-energy mechanisms and are therefore associated with more severe injuries to the brain.

As indicated previously, most focal brain injuries are immediately apparent on initial neuroimaging studies and, depending on the size and location, result in focal neurologic dysfunction. The most common focal injury resulting from nonpenetrating mechanisms is a cerebral contusion (Fig. 24-1). These are generally surface lesions related to cranial impacts or brain movement over irregular intracranial surfaces or along the edges of dura. The clinical presentation of cerebral contusions depends mostly upon the extent of the

FIGURE 24-1 A cerebral contusion underlying a linear skull fracture (not demonstrated). This was the result of a cranial impact, as demonstrated by the overlying soft tissue swelling and hemorrhage. The patient had no neurologic deficit.

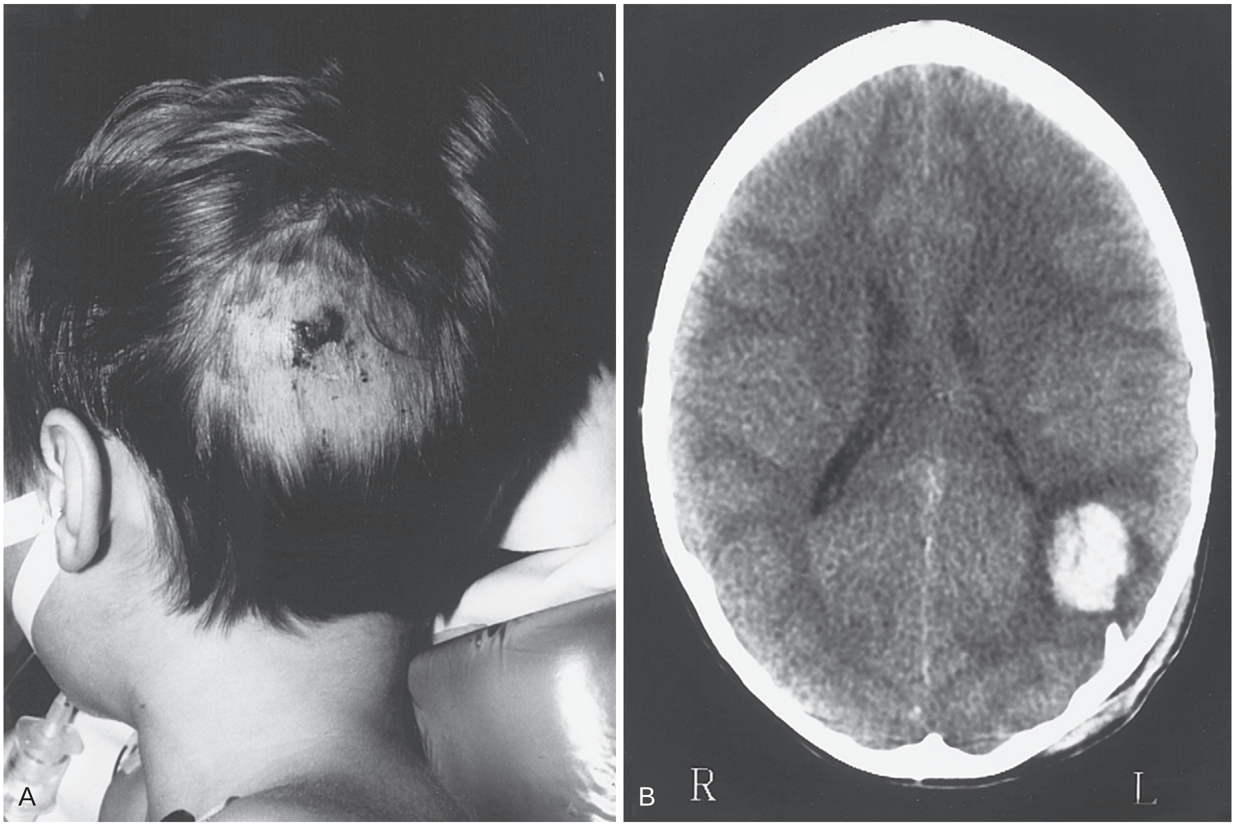

**FIGURE 24-2** The occult injury frequently seen with low-velocity cranial penetration in young children is demonstrated. The patient was struck in the left parietal region by a lawn dart, and loss of consciousness did not occur. The lawn dart fell out immediately. The injury was misinterpreted as a minor scalp laceration and was closed with butterfly bandages. Three days later, fever and headache developed. **A,** Appearance of the entry wound before surgical exploration. **B,** Computed tomography shows a compound fracture and intracerebral hematoma. During surgery, hair, dirt, and bone fragments were removed from the cerebral cortex.

initial injury, the amount of associated hemorrhage resulting in mass effect, and the location of the contusion in the brain. Even though cerebral contusions may develop localized swelling, isolated lesions are not generally life threatening. Many cerebral contusions are neurologically silent and only discovered on the initial CT scan, underlying a skull fracture or along the anterior cranial base. When these injuries are symptomatic, they usually cause focal neurologic deficit or seizures. The latter are thought to occur commonly in adults with acute cerebral contusions.[46] However, the incidence of seizures in children with cerebral contusions appears to be no greater than in children with either normal CT scans or epidural hematomas.[47]

Traumatic intracerebral hematomas are unusual lesions in the pediatric age group. The pathogenesis of these hemorrhages is unclear, but it seems to be related to the disruption of central arterial blood vessels. Accordingly, these lesions are associated with more severe mechanisms of injury and with more profound neurologic dysfunction. In many cases, these lesions are part of a larger picture of diffuse axonal injury that is discussed later. Traumatic intracerebral hematomas are distinguished from hemorrhagic contusions by their lack of contact with the surface of the brain.[48] They can be quite large and, because of the location, can leave a child with a profound neurologic deficit. Surgical evacuation can be considered if intracranial pressures are high, but, in the authors' experience, neurologic outcomes are not improved by the evacuation of these hematomas.

Children are prone to nonmissile penetrating injuries of the skull and brain. These injuries usually occur when a child falls onto or is struck by sharp objects, such as nails, pencils, sharp sticks, or lawn toys (Fig. 24-2). One of the major dangers of these injuries is that, unless the offending object remains embedded, the entry wound may be hidden or seem trivial.[49–51] The anterior penetrations of the skull base can be transorbital (through the orbital roof) or through the nose or mouth.

Penetrating injuries can result in focal contusions, intracerebral hemorrhages, and cerebral lacerations, but these lesions are usually silent because of their locations and small size. The deeper penetrations are more likely to be symptomatic, not only because the tissue injury is more extensive but also because of the potential for injuring major vessels. Many penetrating injuries become symptomatic in delayed fashion because of expansion of intracerebral hemorrhage, the recognition of cerebral spinal fluid (CSF) fistula, or by the appearance of symptoms indicating infection. Therefore a very high index of suspicion is required, and careful radiologic studies are called for whenever there is a possibility of subtle cranial penetration. Wood, glass, and residual bits of debris may be difficult to detect on routine imaging studies, including CT scans.[52]

Cranial penetrating injury is also strongly associated with direct cerebrovascular injury.[53] When there is evidence of deep cranial penetration or if there is substantial subarachnoid hemorrhage or focal intracerebral hemorrhage, one should

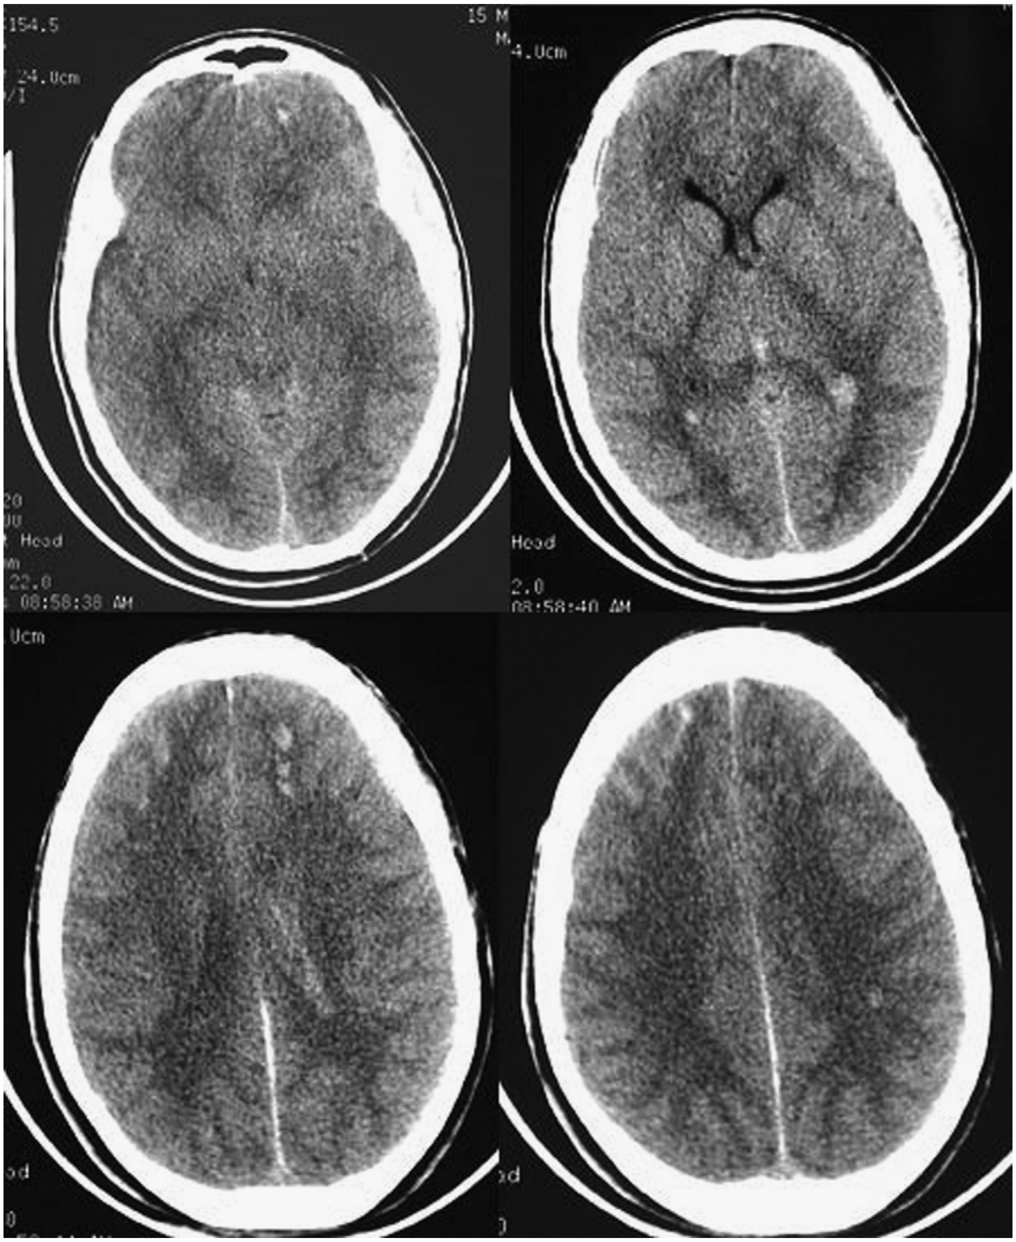

**FIGURE 24-3** The classical appearance of diffuse axonal injury on an admitting computed tomography (CT) scan. This includes subarachnoid and intraventricular hemorrhages, brain swelling, and small petechial hemorrhages throughout the brain.

consider magnetic resonance imaging (MRI) with the addition of magnetic resonance angiography or the increasingly useful modality of CT angiography.

## Diffuse Brain Injuries

The majority of brain injuries occurring in childhood are diffuse injuries that are characterized by general disturbances of neuronal function that begin immediately at the time of injury, while showing general preservation of brain structure on early CT scans. Diffuse injuries are a direct result of energy dissipation within the substance of the brain or as the result of systemic insults. All of these injuries exist on a continuum from extremely mild—and, apparently, completely reversible—to lethal. Frequently, the different types of diffuse brain injury occur together, or in sequence, and can act synergistically to affect the neurologic presentation and the outcome.

Diffuse primary brain injuries are generally the result of angular or translational accelerations (or decelerations), with the amount of tissue disruption being roughly proportional to the amount of energy dissipated in the brain substance.[54] As the amount of neuronal disruption increases, the depth and duration of neurologic dysfunction increases and the neurologic outcome worsens. The appearance of certain hemorrhages on the CT scans (specifically, subarachnoid hemorrhage), small but widespread intracerebral hemorrhages and intraventricular hemorrhage, are a typical finding (Fig. 24-3).[55] Finally, although the occurrence of traumatic surgical masses is not characteristic of the diffuse brain injuries, subdural hematomas occur commonly with

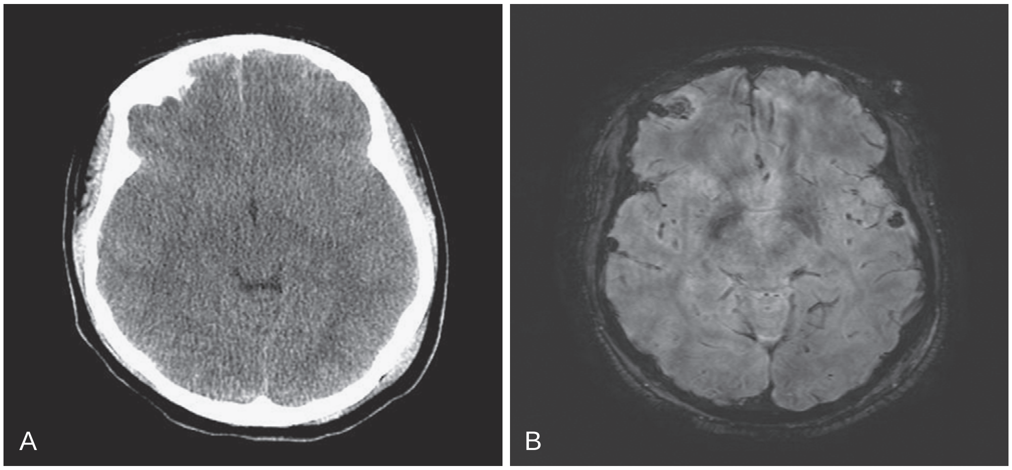

FIGURE 24-4 The importance of imaging in mild traumatic brain injury. Patients with apparently normal consciousness at presentation can suffer widespread cerebral damage when subjected to mechanisms that cause diffuse axonal injury. Cognitive disturbances and neurologic symptoms are common in these patients. **A,** Unenhanced computed tomography scan of conscious patient (GCS 15) showing subarachnoid hemorrhage. **B,** Susceptibility-weighted gradient echo magnetic resonance image (MRI) showing widespread parenchymal hemorrhages characteristic of diffuse axonal injury. (Courtesy Jill Hunter, MD.)

diffuse axonal injury, and some of these hemorrhages need early surgical evacuation. However, subdural hemorrhages are better viewed as another marker of the diffuse brain injury rather than as a mass that should be treated in isolation, such as an epidural hematoma or a hemorrhagic contusion.

Like all brain injuries, diffuse primary brain injuries occur within a spectrum of severity. At one end of the spectrum are the very mild, transient physiologic disturbances of neurologic function (which includes the syndromes commonly referred to as cerebral concussion), while at the other is the progressively more damaging and ultimately lethal entity that is now called diffuse axonal injury (DAI).

The modern view of cerebral concussion is based on the pioneering work of Ommaya and Gennarelli,[56,57] who define concussive brain injuries as a graded set of clinical syndromes with increasing disturbances in the level and content of consciousness. This definition allows specific post-traumatic disturbances commonly seen in children after so-called “mild” head injuries to be included, such as confusion without amnesia, confusion associated with amnesia of varying depths and duration, and the classical loss of consciousness with and without transient sensorimotor paralysis or disturbances of respiration or circulation.

As the amount of energy in the injury mechanism increases, tissue disruption occurs and results in DAI. It is now clear that the most common cause of prolonged coma from mechanical brain injury is DAI. Patients who have suffered DAI are unconscious from the time of injury and remain so for a prolonged period.[58] It is not uncommon to note pupillary changes, skewed gaze, and decerebrate posturing. This constellation of symptoms had historically been called a brainstem contusion in the era prior to MRI. Most comatose patients who appear to show brainstem dysfunction after closed head injury have really suffered DAI.

The appearance of DAI on CT scans depends upon the severity of the injury and the degree of associated hemorrhages. In some cases, the initial CT scan may appear to be normal. Subsequently, the characteristic lesions may be discovered on MRI, varying from some transient signal changes in the deep white structures to widespread hemorrhagic and nonhemorrhagic shears (Fig. 24-4). The characteristic CT scan appearance of DAI is multiple petechial hemorrhages in the deep white matter and central structures. However, the finding of intraventricular hemorrhage or focal subarachnoid hemorrhage specifically located in the prepontine cistern is also strongly suggestive of DAI.

## Gunshot Wounds

Children’s injuries from firearms are a major public health problem. Recent reports indicate that 10% of all childhood-injury deaths are related to firearms, a number exceeded only by deaths from motor vehicle accidents, drowning, and house fires.[59,60] From the standpoint of management and outcomes, there is little to differentiate gunshot injuries in children from those in adults. Poor outcomes are related to depth of coma, bilateral or transventricular injury, elevated intracranial pressure, and large intracerebral hemorrhages.[61] Aggressive treatment of all patients is recommended, except those with clearly nonsurvivable injuries,[62] although substantial neurologic and cognitive deficits can be expected.[63,64]

In childhood, injuries resulting from nonpowder firearms, such as BB and pellet guns, are more common than true gunshot wounds.[60] Adolescent males have the highest risk of this type of injury.[65] These injuries are generally less severe and therefore carry lower mortality rates. Surgical treatment is not usually required for BB gun injuries. Pellet rifle injuries, being higher velocity and larger caliber missile injuries, are more severe and are probably best treated as true gunshot wounds.

## Crush Injuries

Young children are susceptible to the unusual static-loading type crushing injury to the skull, which happens when a heavy object falls on a child or when the child is run over by a vehicle. These injuries are dramatic, both in the clinical presentation and in the radiographic findings (Fig. 24-5), but

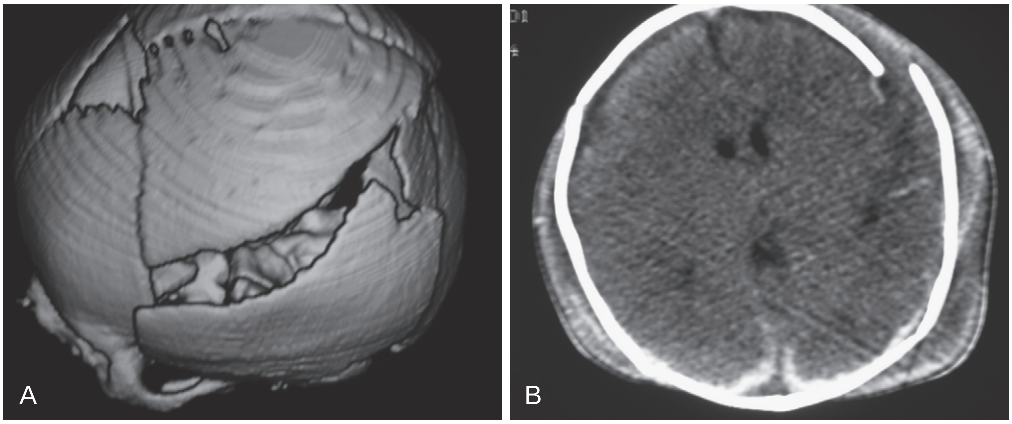

**FIGURE 24-5** A crushing type injury in an infant. **A,** This shows a cranial "burst" injury on CT three-dimensional reconstruction of the skull. **B,** Although there is intracranial hemorrhage and dural laceration, the structure of the brain is preserved and decompressed. The child required dural and cranial reconstruction but recovered with minimal deficits.

the neurologic outcomes can be quite good.[66] Multiple skull fractures, including complex basilar skull fractures and facial fractures, are typical. Cerebrospinal fluid leaks and cranial nerve palsies are commonly seen. However, despite the initial appearances of the injury, major cortical structures are often preserved. Therefore, if the child has survived the initial injury, aggressive multidisciplinary management can yield satisfactory long-term functional outcomes.

### Inflicted Injuries

The most common cause of severe and life-threatening brain injury in infants is inflicted injury. All physicians involved in the care of injured children should be familiar with the clinical presentations and the characteristic radiographic findings of inflicted injuries. This entity has been reviewed in detail.[67,68] Infants presenting with alteration of consciousness (with or without the new onset of seizures), retinal hemorrhages, and acute intracranial hemorrhages on the CT scan are likely to have suffered nonaccidental injuries, especially if the history of the injury is unknown or reported to be minor. The additional finding of new or healing skeletal fractures or other solid organ injuries are pathognomonic for this injury. All infants who are suspected to have been abused need a comprehensive multidisciplinary evaluation by physicians knowledgeable about the mechanisms and clinical spectrum of inflicted injury.

## INITIAL ASSESSMENT OF BRAIN-INJURED CHILDREN

The purpose of the initial assessment of a brain-injured patient is twofold. First, and most important, one establishes a working diagnosis of the type and severity of the injury that directs the selection of initial therapies as well as the planning and coordination of other diagnostic studies and the management of any associated systemic injuries. Second, it establishes a baseline to measure the effects, both positive and deleterious, of the therapies or interventions.

Historically, the main focus of a brain-injured patient's initial assessment was to determine the severity of the injury by scoring the level of consciousness. The most widely used scale for this purpose is the Glasgow Coma Scale Score (GCS),[69] which, as it was designed, correlates well with outcome. However, with improvements in transportation and field resuscitation of severely injured patients, which usually requires the prehospital administration of analgesics and sedation, a neurologic assessment to determine brain injury type and severity becomes less useful.[70] Furthermore, there is a small but important group of brain-injured patients who present with little or no impairment of consciousness and who subsequently deteriorate from mass lesions or brain swelling.[71–73]

It is now clear that neuroimaging is probably a better predictor of outcome from brain injury than is the clinical examination. Regardless of the apparent level of consciousness, the early radiographic identification of injury types and the institution of appropriate management or monitoring have substantially improved the overall outcome from traumatic brain injury. Furthermore, it is now clear that a head-injured patient who has a completely normal CT scan has an exceedingly low risk of either deterioration or poor outcome. In the authors' experience, the CT scan has become the most important element in diagnosing brain injury early, especially for young children.

The important CT scan findings not only involve the detection of potentially surgical mass lesions but also the search and detection of the constellation of findings typically seen with diffuse brain injury. These are subarachnoid, intraventricular, or intraparenchymal hemorrhage and what may be very subtle early signs of brain swelling, including compression of the perimesencephalic cisterns or shift or compression of the ventricular system. These findings should influence the expectations for outcome and the decisions for monitoring and therapy. Diffuse brain injury severity can be graded by the appearance of the admitting CT scan and can direct therapeutic decision making.[74]

Most current practice parameters regarding the evaluation of head-injured patients include recommendations for an early diagnostic CT scan.[1,2,22,75,76] Essentially, all potentially severely injured patients, that is, patients presenting with an alteration of consciousness, should undergo CT scanning as soon as they are physiologically stable and can be safely transported and maintained in the scanner. Older children with apparently trivial injuries can be observed clinically. However, as mentioned previously, the finding of a normal CT scan after

head injury can mitigate further clinical observation and allow return to home sooner. On the other hand, children with the following symptoms should undergo CT scanning as soon as possible: a history of more than a few seconds of unconsciousness; a seizure; clinical signs of cranial impact, skull fracture, cranial penetration, or CSF leak; and headache, persistent vomiting, lethargy, or irritability.[77,78] Finally, children who have been injured in accidents with high-energy mechanisms that result in apparently isolated chest, abdominal, or skeletal injuries should undergo a brain CT scan prior to anesthetic administration or the institution of narcotic analgesia or sedation that would preclude accurate ongoing neurologic examinations.

It should be clear from the previous discussion that plain skull radiography has only a limited and secondary role in the initial evaluation of head injury. CT scanning will detect most clinically important skull fractures. Conversely, skull radiographs provide only limited information about the type and location of any brain injury. MRI is more sensitive than CT scanning for detecting most brain pathology, and it has supplanted CT scanning as the study of choice for many neurologic disorders. Some centers are using “fast” MRI techniques to assess acute brain injury.[79] This may become more common, especially in view of the long-term effects of radiation in children.[80]

Finally, although acknowledging the expanding primary role of neuroimaging in the diagnosis and management of traumatic brain injury, a careful physical and neurologic examination is still extremely important. The entire head should be inspected for indications of impact, scalp injury, cranial deformities, and indications of cranial or orbital penetration. It is necessary to document cranial nerve function, especially pupillary size, shape, and reactivity, which will serve as a comparison for serial examinations. Evidence of anterior basilar skull fractures, manifested by periorbital ecchymoses, nasal hemorrhage, or CSF rhinorrhea, is a contraindication to the placement of nasogastric tubes until the integrity of the anterior cranial skull base can be determined. Retroauricular bruising, hemotympanum, otorrhagia, or CSF otorrhea are indicative of temporal bone fractures. In the circumstance of possible inflicted injury, dilated funduscopic examination by an ophthalmologist is recommended.[81] It is still necessary to document the level of consciousness and any apparent motor or sensory deficits and note the presence of confounders to the examination (such as intubation, medications, swelling, splints, etc.), in the initial evaluation of the head-injured patient.

## EARLY MANAGEMENT OF SEVERE BRAIN INJURY

The primary objective of resuscitating brain-injured patients is to preserve cerebral perfusion during transport and evaluation. The ongoing objective of therapy for severe brain injury is to optimize the perfusion of the injured and uninjured brain and create a milieu that minimizes the chance for secondary injury and maximizes the amount of neuronal recovery. One must do this while avoiding or reversing deleterious processes that would result in further neuronal injury or the expansion of hemorrhagic masses, including systemic complications that directly affect an injured brain, such as sepsis, acute lung injury, hyperglycemia, and coagulopathy.

There are a variety of treatment strategies that have been propounded for the treatment of traumatic brain injury. Most of these therapies involve systemic manipulations to achieve what is believed to be either a therapeutic or a protective response. All of the newer therapies have theoretical attractions, and their proponents report outcomes that appear to be better than historical controls. However, at least so far, when these therapies have been tested directly against what could be termed standard therapies, no benefits have been demonstrated. Given this, the treatment recommendations currently in place are essentially descriptions of how to apply the historically standard therapies of controlled ventilation, fluid management, sedation, and control of blood pressure and intracranial pressure (ICP).

To do this, one must understand intracranial dynamics and optimize cerebral perfusion by removing surgical masses and by managing the intracranial pressures, which can be done by safely manipulating, as much as possible, the cerebral blood volumes (arterial and venous), the cerebrospinal fluid volume, and the brain or skull volume.[82] For severely injured patients, and for some less severely injured patients, intracranial pressure monitoring guides the institution and manipulation of therapies. ICP monitoring provides the basis for making many of the important management decisions for brain-injured patients.[83,84]

The application of individual medical therapies is beyond the scope of this chapter. However, it is important to realize that each of the current therapies for elevated intracranial pressure has both general and specific effects, and each has complications associated with its use. The historically common administration of high-dose steroids to brain-injured patients is no longer considered to be beneficial and may, in fact, be harmful. Accordingly, the current guidelines do not recommend that *any* specific therapy—for instance, hyperventilation, osmotic diuretics, or other medications—be administered prophylactically or universally for brain-injured patients. It is also suggested that specific therapies be applied in a logical sequence, guided by ICP monitoring and by frequent reassessments of the responses to the therapy.

The basic level of therapy for severe traumatic brain injury includes controlled ventilation and maintaining normal oxygenation and $Pa_{CO_2}$ concentrations. Intubated patients should have adequate sedation and analgesia at all times. Intravascular volume should be supported at all times with blood and fluids, maintaining normal hematocrit and electrolyte concentration. Fluid restriction is not recommended. Hypotonic fluids should be avoided in order to avoid any trend toward hyponatremia. The head of the bed may be elevated to reduce intracranial venous pressure as long as normal central venous pressures are maintained by adequate volume replacement. For many severe diffuse brain injuries, this level of therapy may be all that is necessary.

Escalated therapies include the use of CSF drainage, usually by way of a ventricular catheter, osmotic therapy, and mild hyperventilation. Whenever escalation of therapy is considered, one must also escalate the physiologic monitoring for treatment effect and complications. Table 24-1 summarizes the authors' approach to escalating medical therapy for brain injury, based on current treatment guidelines. Others have different strategies, including the use of decompressive craniectomy early in the treatment cascade. As discussed at the outset of this chapter, the available evidence allows many

**TABLE 24-1**
**Medical Therapies for Traumatic Brain Injury**

| *Treatment* | *Monitoring* |
|---|---|
| **Evaluation and Resuscitation** | |
| Restoration of normal blood pressure | Systemic blood pressure and oxygenation |
| Intubation and ventilation | Neurologic examination |
| | End-tidal $CO_2$ |
| **Basic Level Therapy** | |
| Elevating head of bed | Systemic blood pressure and oxygenation |
| Keeping head in neutral position | Intracranial pressure |
| Sedation and muscular paralysis | Arterial $Po_2$, $Pco_2$, and pH |
| Mechanical ventilation to maintain $Paco_2$ at 35-40 mm Hg | Weight, urine output, pulse, and pulse pressure |
| Maintaining normal to slightly increased intravascular volume | Hemogram, serum electrolytes, glucose, and BUN |
| Normal fluid and electrolyte status (no fluid restriction) avoiding anemia, hyperglycemia | Monitoring and aggressively treating fever and sepsis |
| | CT scan |
| Body temperature normal to slightly hypothermic | |
| **Escalated Therapy** | |
| Ventricular CSF drainage | Ventricular catheter |
| Osmotic therapy including hypertonic saline | Central venous pressure |
| Moderate hyperventilation to maintain $Paco_2$ at 30-35 mm Hg | Serum osmolality and electrolytes |
| **Intensive Therapy of Refractory Intracranial Pressure** | |
| High-dose barbiturate therapy | Continuous or compressed spectral EEG |
| Decompressive craniectomy | Barbiturate levels |
| Optimized ventilation | Brain oximetry, monitors of cerebral blood flow |

BUN, blood urea nitrogen; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; $Paco_2$, partial pressure of arterial carbon dioxide; $Pco_2$, partial pressure of carbon dioxide; $Po_2$, partial pressure of oxygen.

different logical strategies for the management of traumatic brain injury, and each center should develop their own protocols and carefully measure the outcomes and complications.

Surgical decision making for severely injured patients is usually straightforward. Obviously, penetrating injuries, including compound skull fractures, require urgent surgical attention. The removal of large, surgically accessible mass lesions may be the first step in the overall therapeutic management of a severe brain injury. Some centers advocate decompressive craniectomy as an initial therapy. In many cases, such as closed depressed fractures, burst fractures, comminuted cranial, and craniofacial fractures, surgical correction can be performed when the patient is stable or improving from the neurologic injury.

Typically, major surgical therapy for brain injury involves the removal of traumatic intracranial hematomas. The overall incidence of surgical hematomas in childhood is substantially lower than in adults, and the distribution of hematoma types is different. Subdural hematomas are most common in infants but rarely reach a size that requires surgical removal. As discussed at the outset of this chapter, acute subdural hematomas in older children are generally more indicative of a severe diffuse injury (Fig. 24-6). Extradural hematomas are the more common surgical mass in children, especially older children who have suffered cranial impacts (Fig. 24-7). Small epidural hematomas over the cerebral convexity are likely to resolve without surgical removal, that is, those that occur in more limited "spaces" (like the temporal fossa) or the posterior fossa are more concerning, and even small epidurals in these locations may need removal. Large hemorrhagic contusions or traumatic intracerebral hematomas are very rare in the pediatric age group.[32] In summary, the decision to remove a traumatic intracranial hematoma is simply one part of an overall treatment strategy for the brain injury.

**FIGURE 24-6** Acute subdural hematoma. The hemorrhage overlying the hemisphere (left side of image) seems small. Note however, the extensive shift of the brain and the hemispheric swelling that are indicative of severe diffuse injury.

## Management of Minor Brain Injuries

The vast majority of children with head injury have trivial, minor, or minimal primary brain injuries. These children will most likely recover without any intervention. However, within this large group, there exists a small fraction of patients who

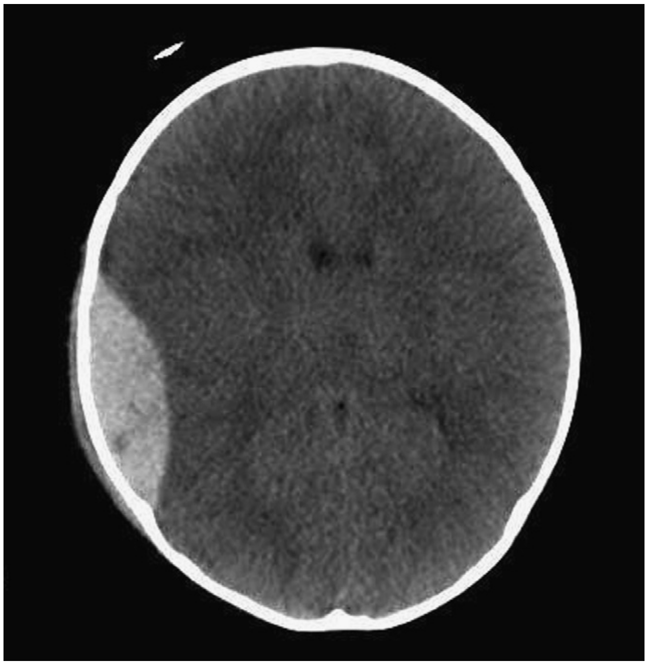

FIGURE 24-7 Acute extradural hematoma. Note the thickness of the hemorrhagic mass but also the lack of shift compared with what is demonstrated with a subdural hematoma shown in Figure 24-6. This lack of swelling and shift is an indication of an uninjured brain responding normally to the expanding mass. As long as this mass is removed prior to onset of coma, mortality and morbidity is essentially nil.

harbor enlarging hematomas or who are in the early stages of brain swelling. These patients face increased risk of delayed but rapid deterioration that will result in death or disability. The focus of evaluating of the apparently minor brain injury is twofold: (1) to identify patients at risk of neurologic deterioration or delayed complications and (2) to prevent either from occurring.[77] In many ways, the diagnosis and management of these patients is more challenging and important than managing severe injuries, because successful intervention results almost universally in good outcomes.[72,73]

There are published recommendations about this issue.[75,85] As with other types of brain injury, early neuroimaging is the lynchpin to accurately diagnose and recognize brain-injured patients at risk for deterioration.[44,86–88] Identification of cisternal compression, hemorrhagic shear, and contusion, or small traumatic hematomas indicates that the patient is at risk for deterioration regardless of their level of consciousness. These patients are candidates for frequent reassessments, including repeat neuroimaging, intracranial pressure monitoring, and even the early application of therapies to control the intracranial dynamics.[89,90] It appears that paying attention to intravenous fluid management is very important, because many children with trivial brain injuries seem to deteriorate in the face of even a mild hyponatremia.[91,92] Therefore maintenance fluids for these patients, as for most patients with brain injury, should be normal saline or its equivalent.[23] One should also pay close attention to maintaining normal intravascular volume and serum electrolyte status.

Identifying patients at risk for deterioration includes the appearance of certain abnormalities on CT scanning, but an even more important finding from the burgeoning literature about CT scanning and head injury is emerging: A completely normal CT scan in a mildly injured patient is associated with essentially no risk of life-threatening deterioration.[93,94] Given this additional information from a normal CT scan, a child with a history of an accidental minor head injury, who has neither a skull fracture nor a history of seizure and who is asymptomatic, may be released to competent caretakers and not be admitted for observation.

For adolescents who suffer cerebral concussion as a result of sporting activities, there are now published guidelines describing how to evaluate and manage these individuals, along with recommendations about when the athlete may return to sporting activities after a concussion.[95–98]

## EARLY COMPLICATIONS OF HEAD INJURY

Acute complications of head injury include those related to skull fractures, infectious processes related to cranial penetrations and CSF fistulas, and acute neurologic complications such as post-traumatic epilepsy. As with most aspects of head injury management, the key to optimizing the outcome is recognizing patients with injuries that put them at risk for these complications, followed by appropriate diagnostic studies, monitoring, and, when possible, intervention.

### Complications of Skull Fractures

Simple nondepressed or minimally depressed skull fractures will heal spontaneously. Widely diastatic or cranial burst fractures[99] in young children are indications of dural injury and are not likely to heal without surgical reconstruction. With modern neuroimaging, the early identification of these injuries allows elective early repair, thereby avoiding the complication usually referred to in the literature as "growing skull fracture."[100,101] The typical syndrome of an enlarging skull defect and progressive neurologic deterioration, both of which are related to a craniocerebral erosion and enlarging leptomeningeal cyst that appears during the course of months to years after the injury, is completely avoidable with early repair of the dura and skull. However, focal brain injury is commonly seen with severely depressed, diastatic, and cranial burst fractures, and these patients will have an increased incidence of seizures and focal neurologic deficits.

### Basilar Skull Fractures

For patients with presumed basilar fractures, the important clinical issue is that these are potentially compound fractures; therefore they place the patient at increased risk for infection. The obvious indication of CSF leaking from the nose or ear is present in only 10% to 20% of cases.[102,103] Therefore one must search for other signs of basilar fracture, which include bilateral orbital ecchymoses or swelling, signs of midface or orbital fracture, hemotympanum, otorrhagia, or the Battle sign, because these are easily missed on routine neuroimaging studies. These patients are at increased risk for developing meningitis, and this risk continues for several weeks after the injury. Given this, and considering that compounding of basilar fractures probably occurs more often than not without any evidence of CSF fistulas, it is necessary for parents and caretakers of children considered to have suffered basilar fractures to be counseled not only about the importance of recognizing CSF rhinorrhea or otorrhea, if it should occur at home,

but also about the urgent importance of seeking immediate medical attention for children who develop signs or symptoms even remotely suggestive of bacterial meningitis up to several weeks following the injury. Despite the increased risk of bacterial meningitis, the administration of prophylactic antibiotics has not been shown to be beneficial.[104–106] Some centers are administering pneumococcal vaccine to patients with presumed basilar skull fractures, although it is not yet clear that this reduces the occurrence of pneumococcal meningitis.

Basilar skull fractures are also associated with cranial neuropathies. The olfactory nerve is the most commonly injured of all cranial nerves, and patients with anterior basilar fractures are especially at risk of injuring them. Fractures that occur more posterior along the skull base, or that include the orbit and midface, place the optic nerves at risk. Visual loss may be acute or delayed, and ophthalmologic evaluation and follow-up are warranted. Basilar fractures involving the petrous bone can result in auditory, vestibular, and/or facial nerve injury. These patients may need otologic evaluation and audiometric studies.[107]

### Direct Cerebrovascular Injuries

Although traumatic intracranial aneurysms are exceedingly rare after closed head injury, greater than 20% of all post-traumatic aneurysms occur in the pediatric age group.[108] Penetrating injuries, especially stab wounds and deep penetrations, are associated with a high incidence of vascular injury. Suspicion of direct cerebrovascular injuries is raised when there is a large amount of subarachnoid hemorrhage or a focal intracerebral hemorrhage on the CT scan. CT angiography and/or magnetic resonance angiography can screen for injury, but in some cases, diagnostic angiography should be performed. If the studies are not conclusive, early repeat imaging is warranted.

### Post-traumatic Seizures

One of the most common complications of brain injury, even mild brain injury, is epilepsy. Most studies indicate that the incidence of post-traumatic seizures is substantially higher in children than in adults.[109,110] Risk factors associated with post-traumatic epilepsy include younger age and increasing injury severity.[47,111] However, it is not clear that the infants with inflicted injuries, who would have a very high incidence of early epilepsy, were excluded from these studies.[112] If one removes this particular group from the analysis, the incidence of post-traumatic epilepsy in children appears to be relatively low.

One must make a distinction between early and late post-traumatic seizures. Early seizures are generally defined as those that occur within the first week after injury. For pediatric patients, this definition would include the so-called impact-related seizure that occurs in up to 10% of mildly head-injured children.[47,113,114] These seizures are usually self limited, and the CT scan is normal. Treatment is not recommended, and the long-term outcome is good.[115,116] This particular syndrome is almost never seen in head-injured adults, in whom early epilepsy is strongly associated with structural brain injury or subdural hematoma.

For severely head-injured children, that is, children in coma or with structural injury on the admitting CT scan, there is limited and conflicting information regarding the clinical significance and the management of early and late post-traumatic epilepsy.[111,117,118] Current recommendations indicate that all severely injured patients who experience recurrent seizures should be treated with anticonvulsant medication. Phenytoin is still the most widely recommended drug for this purpose,[1,119] although newer agents are being introduced and studied.

### Postconcussion Syndromes

A syndrome of neurologic dysfunction that seems to be unique to young children has been called the pediatric concussion syndrome. Shortly after what would seem like a mild cranial impact injury, the child exhibits the acute onset of pallor, diaphoresis, and impaired responsiveness. CT scans are normal, and the syndrome appears to resolve as rapidly as it occurs. The underlying mechanism is unknown, although it has been suggested that it may be a variation of post-traumatic epilepsy.[120]

Other much more rarely occurring transient neurologic disturbances have been reported after mild head injury in childhood. This includes transient cortical blindness, speech arrest, ataxia, receptive dysphasia, and prolonged disorientation.[121,122] CT scans are, again, normal, and the symptoms resolve spontaneously. The etiology is not clear.

## OUTCOMES FROM TRAUMATIC BRAIN INJURY

There is substantial variability in the reporting of outcomes from childhood head injury. With the exception of infants suffering inflicted head injuries, the overall mortality from head injury in childhood is roughly half of that reported for similarly severe head injury in adults.[2] In larger series of patients, mortalities for head injury in childhood are generally less than 5% for all levels of injury severity and less than 20% for those children who are defined as having severe injuries based either on the GCS or other injury severity scoring systems.[32,117,123] Factors related to poor outcomes include high-energy mechanisms, structural injury, swelling and shift on admitting CT scans, persistent or resistant elevations in intracranial pressure, the presence of chest or abdominal injuries, and systemic complications.

Traumatic brain injury is the leading cause of acquired disability in childhood[124]; children who survive have neurologic and cognitive outcomes related to their age, severity of injury, and amount of permanent structural injury to the brain.[123,125–128] Children who have suffered severe brain injuries are likely to show persistent adverse effects on intellectual function, memory, attention, language, and behavior.[129] It is likely that these deficits have ongoing and perhaps compounding effects on learning and socialization. Given that, it is possible that the overall neurobehavioral outcomes for significant childhood head injury are worse for children than for similarly injured adults.

Outcomes from inflicted brain injuries deserve separate discussion. This particular injury is associated with the highest mortality and morbidity of childhood head injuries. Reported mortalities approach 40%.[130,131] Morbidity is also high, especially if the infant shows evidence of cerebral infarction or hypoxic-ischemic injury.

### POSTCONCUSSION SYNDROMES

Mild brain injury—a brain injury with a limited effect on consciousness and with preservation of brain structure—is by far the most common central nervous system injury in the pediatric age group. Greater than three quarters of all childhood head injuries are classified as mild.[32,132] Only recently have pediatric specialists begun paying attention to the long-term outcomes from cerebral concussion in children.[133] Although there is still variability in defining mild head injury and the spectrum of severity within that taxonomy,[134–136] there appears to be two general emerging concepts in the available literature. First, somatic complaints, such as headache, visual disturbances, light and noise intolerance and dizziness, emotional disturbances (such as depression, anxiety, or irritability), and cognitive impairments, including poor school performance, are common in mildly brain-injured children in the days and weeks immediately following the injury.[137] Second, as long as the child did not have any cognitive or behavioral disturbances before the brain injury, all of the early postconcussion symptoms described previously appear to resolve completely during weeks or months.[136]

## Spine and Spinal Cord Injury

Spinal cord injuries in children are rare, but the consequences of such injuries can be devastating. As with traumatic brain injury, modern neuroimaging has contributed considerably to the diagnosis and management of traumatic myelopathy. As discussed at the beginning of this chapter, the major therapeutic efforts for spinal cord injury are the same as for brain injury and aim to prevent new primary injury and ameliorate secondary injury. The first objective is accomplished by maintaining anatomic alignment of the vertebral column during the period of resuscitation and evaluation. The second objective is much more difficult[138] but begins with supporting blood pressure and oxygenation.

In general, the diagnostic and therapeutic algorithms for children with spinal and spinal cord injuries are similar to those used for adult patients. Guidelines for the management of spinal cord injury have been published recently and summarize current knowledge.[4] However, there are important differences in clinical presentations, anatomic and radiographic findings, and management for spinal injuries in children, especially very young children. This section will concentrate on those issues.

### EPIDEMIOLOGY

Less than 10% of spinal cord injuries[139–142] and approximately 1000 new spine[143] or spinal cord injuries[144] each year occur in children. Vertebral column injuries that do not involve the spinal cord are much more common. In a large recent series, only half of children with vertebral injuries had neurologic deficits.[145]

The mechanisms and pattern of injury are related both to age and gender. In very young children, the male to female ratio is roughly equal. In older children, the more "adult" distribution appears with a male to female ratio of about 4:1. Adolescent boys are most affected.[146] The most common causes of pediatric spine injury include falls, athletic activities, child abuse, diving accidents, and motor vehicle trauma.[146–151] Approximately one half of pediatric spinal injuries are the result of motor vehicle accidents.[152] One quarter of injuries are the result of diving accidents. Prevention efforts directed at those two mechanisms alone would dramatically reduce the rate of spinal injury in children. The remaining major mechanisms of injury—falls, child abuse, and sporting activities—each account for about 10% of reported injuries. Younger children are more likely to be injured as the result of a fall, while older children are more likely to be injured in diving accidents or sports.[153,154]

### ANATOMY

Younger children tend to have spinal column injuries in the cervical region, while older children tend to have a distribution of spinal injuries similar to that of adults.[155] Children are more likely to experience spinal cord injury without apparent vertebral fractures or dislocations. These characteristics are generally thought to be related to the anatomic properties of the juvenile spine and are independent of the mechanism of injury. The pediatric spine has several properties that essentially allow significant, self-reducing displacement of the vertebral column. These properties include increased elasticity of the joint capsules and ligaments, shallow- and horizontally-oriented facet joints, anterior wedging of the vertebral bodies, and poorly developed uncinate processes.[156,157] Furthermore, young children have disproportionately larger heads and weaker cervical musculature. All of these elements permit a wider range of flexion and extension and rostrocaudal distraction. The fulcrum of motion is higher in the juvenile spine, which explains the greater incidence of rostral injuries in children. This tendency decreases—and the incidence of more characteristic vertebral fracture and dislocation increases—with increasing age.[158] Finally, it is important to remember that 10% to 15% of spinal injuries in children involve "skip" injuries with vertebral or cord injuries at multiple levels.[145,159] Therefore, and depending on the injury mechanism, when a child is determined to have spinal cord injury or vertebral disruption, the entire spinal axis should be surveyed for other injuries.

Spine fractures in children represent 1% to 2% of all pediatric fractures.[160] Overall, injuries to the thoracic and lumbar spine are uncommon in children. When spine injury does occur, the thoracic region (T2-T10) is most commonly injured, followed by the lumbar region (L2-L5).[161] Trauma to the lower thoracic or lumbar spine in children is rarely associated with spinal cord injury,[160] most often occurring at the cervical spinal cord. Less than 20% of all spinal injuries in children occur below the cervical spine.[162] Pediatric cervical spine injuries are typically soft tissue, ligamentous injuries without associated bony fractures for the aforementioned reasons.

### EVALUATION OF SPINE AND SPINAL CORD INJURY

Because spinal cord injury is rare in children, it may be overlooked, especially in the very young and in the presence of multiple injuries. As discussed later, the presence of apparently normal plain radiographic studies will not completely

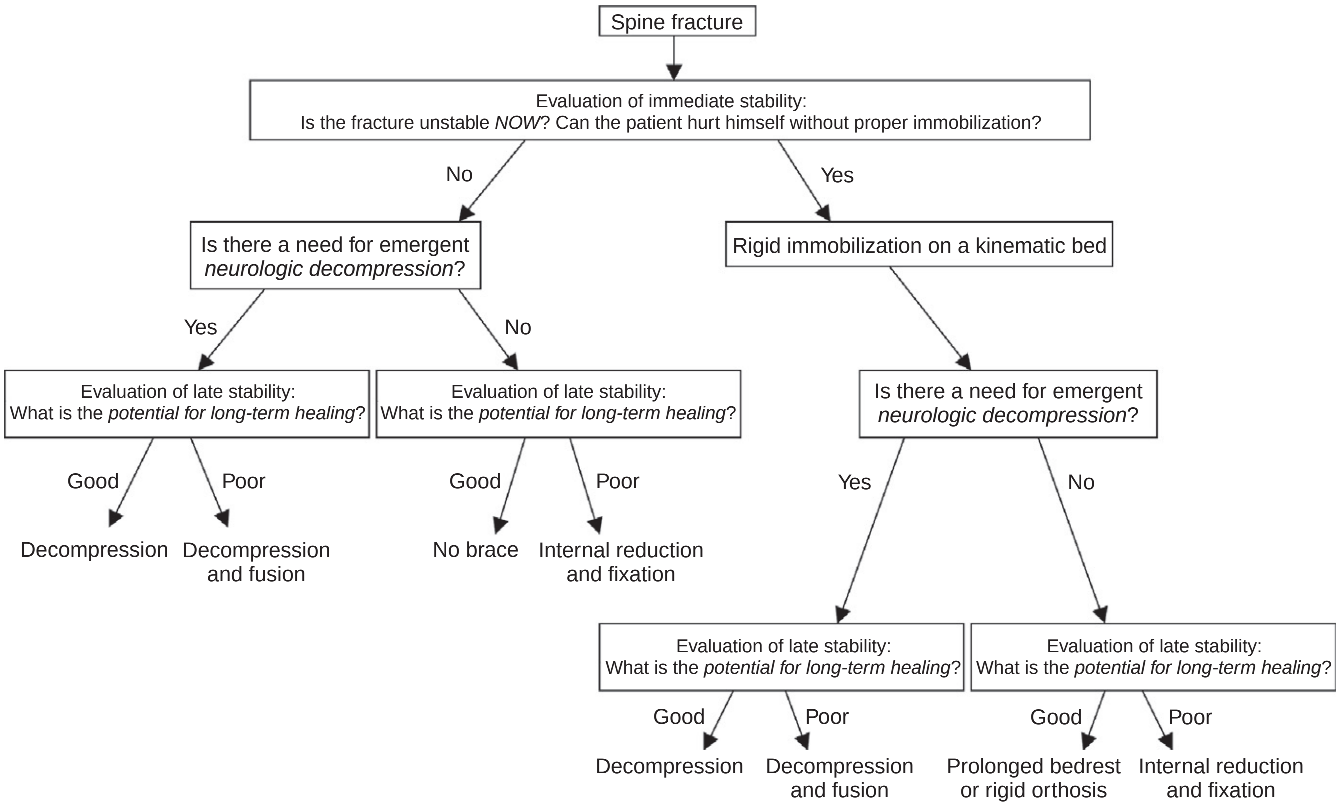

**FIGURE 24-8** A systematic approach to spine injuries. Indications for closed or open reduction and decompression and external or internal fixation borne out by answers to three fundamental questions: (1) Is the injury acutely stable or unstable; (2) is there a need for urgent neurologic decompression; and (3) what is the potential for healing with external orthosis?

rule out either vertebral instability or spinal cord injury. Therefore one must have an increased index of suspicion based on injury mechanism and the neurologic presentation. High-energy mechanisms, such as motor vehicle accidents and falls from heights, are more likely to cause spine or spinal cord injury. Until a complete assessment is possible, one should assume that an unconscious patient of any age has a spinal cord injury (Fig. 24-8).

## HISTORY

Neck or back pain after a major accident or fall from a significant height may increase suspicion for spine injury. A major accident may include significant vehicular damage, head-on high-speed collision, vehicular rollover, or death at the scene. Accidents that may be associated with spine injuries include those involving the lack of seatbelt use, prolonged extrication, airbag deployment, damage to the steering wheel or windshield, passenger ejection from the vehicle, or passenger space intrusion. Vehicular accidents involving motorcycles, bicycles, or pedestrians have a high association with spine injuries. Transient or persistent symptoms may include pain, weakness, numbness, and tingling. Children can present with torticollis as the result of atlantoaxial rotatory subluxation, which can occur from a minor injury or even a coughing spell. The children are usually neurologically normal. The plain radiographs can be deceiving, but the CT scan of the spine in the axial plane is diagnostic (Fig. 24-9).[163]

## PHYSICAL EXAMINATION

Examination should start with a general survey to look for tenderness, swelling, ecchymosis, or a palpable defect posteriorly along the spinous processes. A seatbelt mark across the abdomen or injury of abdominal organs should increase suspicion for any type of thoracic or lumbar fracture.[160] Injuries in the lower thoracic region to upper lumbar region (T11-L1) are notably associated with a significant increase in risk of gastrointestinal injury. Injuries in the lumbar and sacral regions (L2-sacrum) are noted to be associated with risks of orthopedic injuries and gastrointestinal injuries.[146] Any loss of sensation or motor function should be accurately documented. A child with spinal cord injury above the T6 level may present in spinal or neurogenic shock (hypotension and bradycardia), which represents a loss of descending sympathetic tone. This must be recognized early, because pure fluid resuscitation may not be effective and a vasopressor may be needed to restore adequate perfusion.[162]

## CLINICAL SPECTRUM OF SPINE AND SPINAL CORD INJURY

Spine injuries must be assessed in terms of immediate and late stability (Table 24-2). Immediate stability refers to the risk of new or further neurologic injury while bearing physiologic loads without immobilization. Late stability implies the potential to heal with proper immobilization based on a specific injury pattern.[164] Management decisions are based on the degree of stability (see Fig. 24-8).

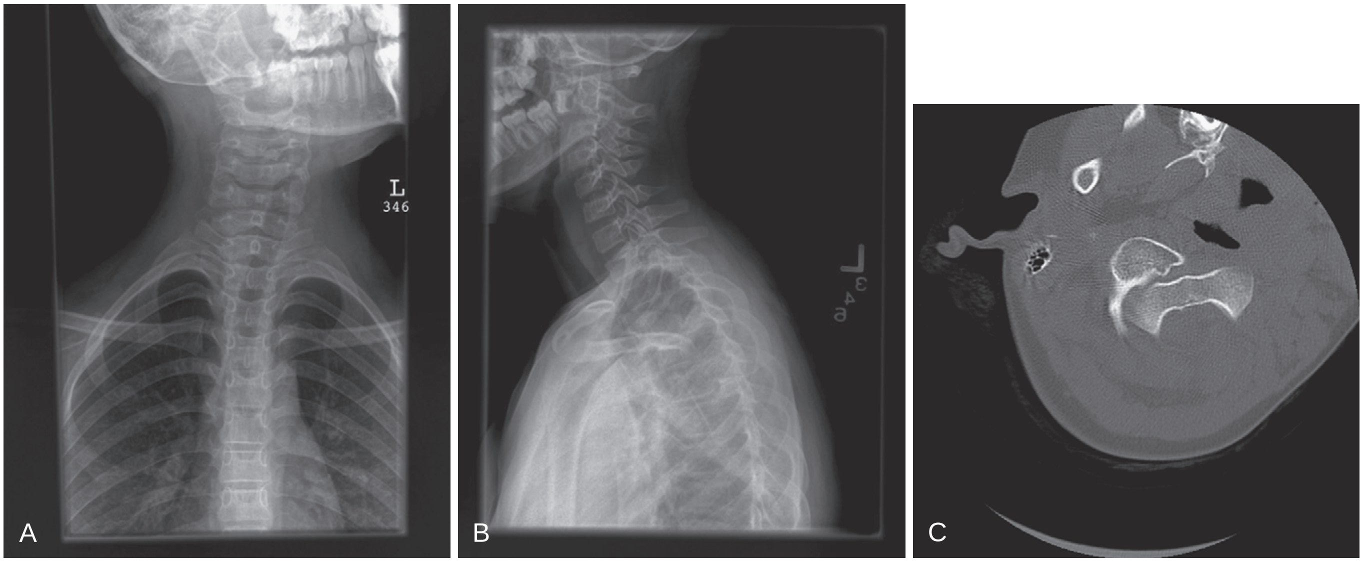

FIGURE 24-9 An example of C1-C2 rotatory subluxation. The patient is a 9-year-old girl with painful torticollis for 3 months after a motor vehicle accident. Anteroposterior (AP) (**A**) and lateral (**B**) cervical spine radiographs confirm torticollis; however, bony details and relationships are obscured at the craniocervical junction. **C,** Axial computed tomography (CT) shows the right C1 lateral mass dislocated and rotated clockwise relative to C2, which is diagnostic of C1-C2 rotatory subluxation.

**TABLE 24-2**
**Common Spine Injuries, Association with Spinal Cord Injury, and Stability**

| | | Stability | |
|---|---|---|---|
| *Fracture Type* | *Associated Spinal Cord Injury* | *Immediate* | *Late* |
| **Upper Cervical Spine** | | | |
| Atlanto-occipital dislocation | Common | Poor | Poor |
| Occipital condyle fracture (Montesano and Anderson type I or II unilateral) | Uncommon | Good | Good |
| Occipital condyle fracture (Montesano and Anderson type III or type I or II bilateral) | Uncommon (may be associated with cranial nerve deficit; XII most common) | Poor | Fair |
| C1-2 rotatory subluxation (Fields and Hawkins type I) | Uncommon | Good | Good |
| C1-2 rotatory subluxation (Fields and Hawkins type II or III) | Possible | Poor | Poor |
| C1 burst (Jefferson fracture) (sum C1/2 lateral mass overhang $<$ 14 mm) | Uncommon | Good | Good |
| C1 burst (sum C1/2 lateral mass overhang $>$ 14 mm) | Uncommon | Poor | Poor |
| Odontoid fracture (d'Alonso and Anderson type I or III) | Uncommon | Good | Good |
| Odontoid fracture (d'Alonso and Anderson type II) | Possible | Fair | Fair |
| C2 pars fracture (Effendi type I or II) | Uncommon | Good | Good |
| C2 pars fracture (Effendi type IIA or III) | Possible | Poor | Poor |
| **Subaxial Cervical Spine** | | | |
| Unilateral jumped facet | Uncommon | Good | Fair |
| Bilateral jumped facets | Common | Poor | Poor |
| Teardrop fracture (flexion-compression) | Common | Poor | Poor |
| **Thoracic and Lumbar Spine** | | | |
| Compression | Uncommon | Good | Good |
| Burst | Possible | Fair | Good |
| Fracture-distraction | Possible | Fair | Good |
| Fracture-rotation | Common | Poor | Poor |

The cardinal sign of a spinal cord injury is neurologic dysfunction below an anatomic spinal motor or sensory level. Complete or severe incomplete cord injuries with motor dysfunction are readily detectable in conscious patients. A spinal cord injury generally presents as symmetrical flaccid paralysis with sensory loss at the same anatomic level. There are strong indirect indicators of spinal cord injury in comatose patients or those with multiple injuries. Cervical spinal cord injuries can cause profound systemic hypotension, a syndrome known as neurogenic shock, which is caused by disruption of sympathetic pathways below the level of injury. Unlike the more common hypovolemic shock, neurogenic shock is suggested

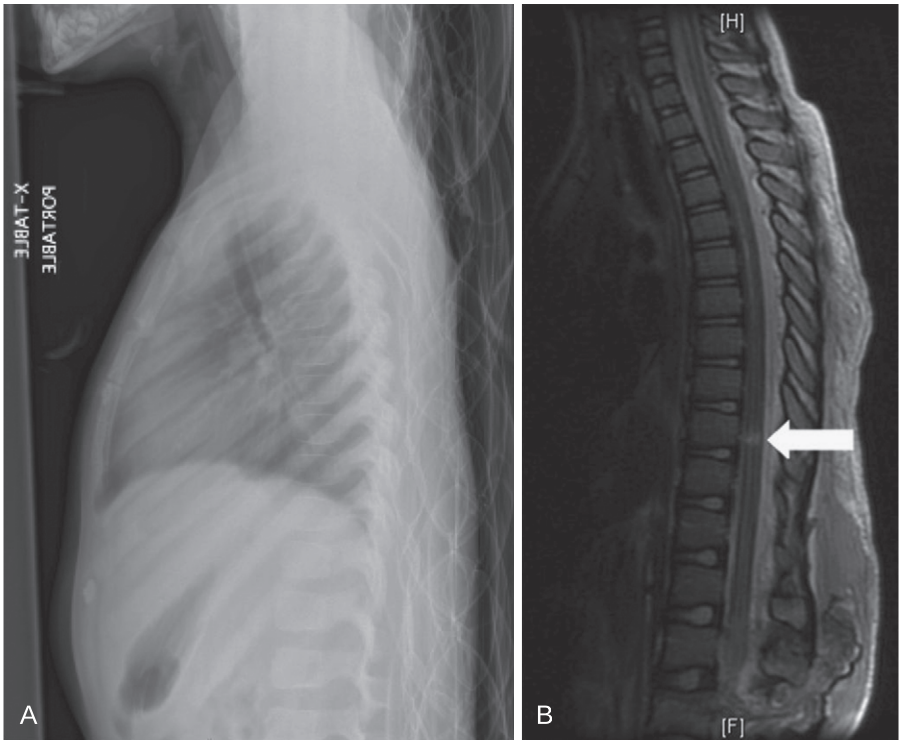

**FIGURE 24-10** An example of spinal cord injury without radiographic abnormality (SCIWORA). The patient is a 6-year-old girl who, on neurologic examination, is a T10 complete paraplegic after a motor vehicle accident. **A,** Normal-appearing plain radiograph of the thoracic spine. **B,** Further workup with magnetic resonance imaging (MRI) shows cord signal change *(white arrow)* at the T10 level on the sagittal T2-weighted sequence, indicating a spinal cord injury without evidence of abnormality on the plain radiograph at the T10 level.

by the finding of bradycardia in the face of hypotension. These patients are also vasodilated despite being hypothermic. Hypovolemic shock results in hypotension, tachycardia, and vasoconstriction. Other systemic findings suggesting spinal cord injury include paradoxic respiration, priapism, Horner syndrome, and inability to sweat.

Less severe injuries may present with transient neurologic dysfunction, dysesthesias, focal weakness or sensory loss, or a dissociation of motor and sensory dysfunction, such as Brown-Séquard or central cord syndromes. Any history of transient neurologic dysfunction involving the limbs or bladder, regardless of duration and apparent complete recovery, must be taken as strong evidence for spinal cord injury.

### Spinal Cord Injury Without Radiographic Abnormality

Pang and Wilberger defined spinal cord injury without radiographic abnormality (SCIWORA) in 1982 to describe patients who exhibit objective findings of traumatic myelopathy with no evidence of fracture or ligamentous instability on routine screening plain radiography or CT scanning.[165] SCIWORA is essentially an injury of children, especially younger children, and is likely directly related to the biomechanical properties of the juvenile spine outlined previously. As with vertebral injury, there is a tendency toward more rostral injury with younger age. Younger children suffering SCIWORA are more likely to have severe or complete spinal cord injuries than older children. Severe spinal cord injury in older children is more often associated with a vertebral injury than with SCIWORA.[145,166,167]

The diagnosis of this syndrome is complicated by the frequent occurrence of delayed neurologic deficits. Many children with this injury will develop neurologic deficits hours to days after the reported injury and in the absence of any further injury. The mechanism of this delayed deterioration is unknown, but Pang has speculated that there is repeated injury to an already mildly injured spinal cord either because of the innate normal flexibility of the spine or because of subtle ligamentous injury with increased segmental movement at the injury site.[168] This argument is supported by the observation that recurrent SCIWORA may occur in about 20% of children who are not immobilized and that immobilization of the cervical spine markedly reduces the incidence of this phenomenon.[169]

Finally, this syndrome was initially described before the widespread use of MRI for spinal disease diagnosis. Although it is still true that these children do not have evidence of bony injury or overt instability on plain spine radiographs or CT scans, most (but not all) patients will have evidence of spinal cord and/or ligamentous or other soft tissue injury on MRI (Fig. 24-10).[170–172] Therefore it is essential that all physicians who provide early evaluations of injured children be aware of this disorder and continue to consider the possibility of spine or spinal cord injury, even when the initial radiographic studies may be reported as normal.

## INITIAL MANAGEMENT OF SPINE AND SPINAL CORD INJURY

### Spine Stabilization

The mainstay of management of spine injury is immobilization of the entire spinal axis in the field. An appropriately sized cervical collar should be used; in the absence of an appropriately sized collar, blocks and tape are effective for immobilizing the head on the backboard.[162] In young children less than the age of 8 years, the disproportionately large head places them in flexion when placed on a neutral board. Proper immobilization requires either a special board with a recess for the occiput, allowing the head to rest in-line with the body, or placement of a thin mattress under the torso relative to the head.[162]

## Imaging

Currently, no national guidelines exist for the clearance of the pediatric spine, particularly the cervical spine, after trauma. In addition, no institution-specific spine clearance protocol has been shown to be superior versus another. A meta-analysis conducted and published in 2002 found insufficient evidence to support a standardized, diagnostic protocol.[173]

Radiologically, the integrity of the pediatric spine (especially the cervical spine), may be difficult and time consuming to assess. However, an accurate and timely evaluation is important in pediatric trauma. Younger children present an additional challenge, because they are developmentally unable to communicate crucial symptoms or are unable to cooperate with a detailed neurologic examination.

Most institutional spine clearance protocols require pediatric trauma victims to undergo lateral and anteroposterior (AP) plain radiography of cervical spine, with the addition of an odontoid image for children older than 3 years.[174] An improper radiographic evaluation has been shown to be the leading cause of missed injury and subsequent neurologic deterioration in large series of trauma patients.[175–178]

Performing CT of the cervical spine has recently led to a more efficient evaluation of the cervical spine in adult trauma victims.[179–181] Little is known about the use of CT for evaluating the cervical spine in pediatric victims of acute trauma. However, the number of repeat radiographs required to ascertain that the pediatric cervical spine is free of injury after suspected head trauma has been shown to be significantly decreased when initial CT of the cervical spine is performed at the time of head CT.[182] Including cervical spine CT in trauma protocols for children undergoing workup for traumatic brain injuries may lead to more effective clearance of the pediatric cervical spine; likewise, reconstructing thoracic and lumbosacral spine CTs from chest and abdomen and pelvis CTs in patients undergoing workup for multisystem blunt trauma may effectively clear the pediatric thoracic and lumbosacral spines (Fig. 24-11).

***Plain Radiographs*** In general, plain radiographs are able to detect most osseous injuries of the cervical, thoracic, and lumbosacral spine in children and give an adequate global view of the spine.[162] Flexion/extension radiographs of the cervical spine are important to rule out subluxation in any patient with reported transient neurologic symptoms. Paraspinous muscles will often "splint" the cervical spine, rendering any subluxation undetectable in the acute setting; follow-up radiographs should be performed in 5 to 7 days after muscle spasm subsides.[165]

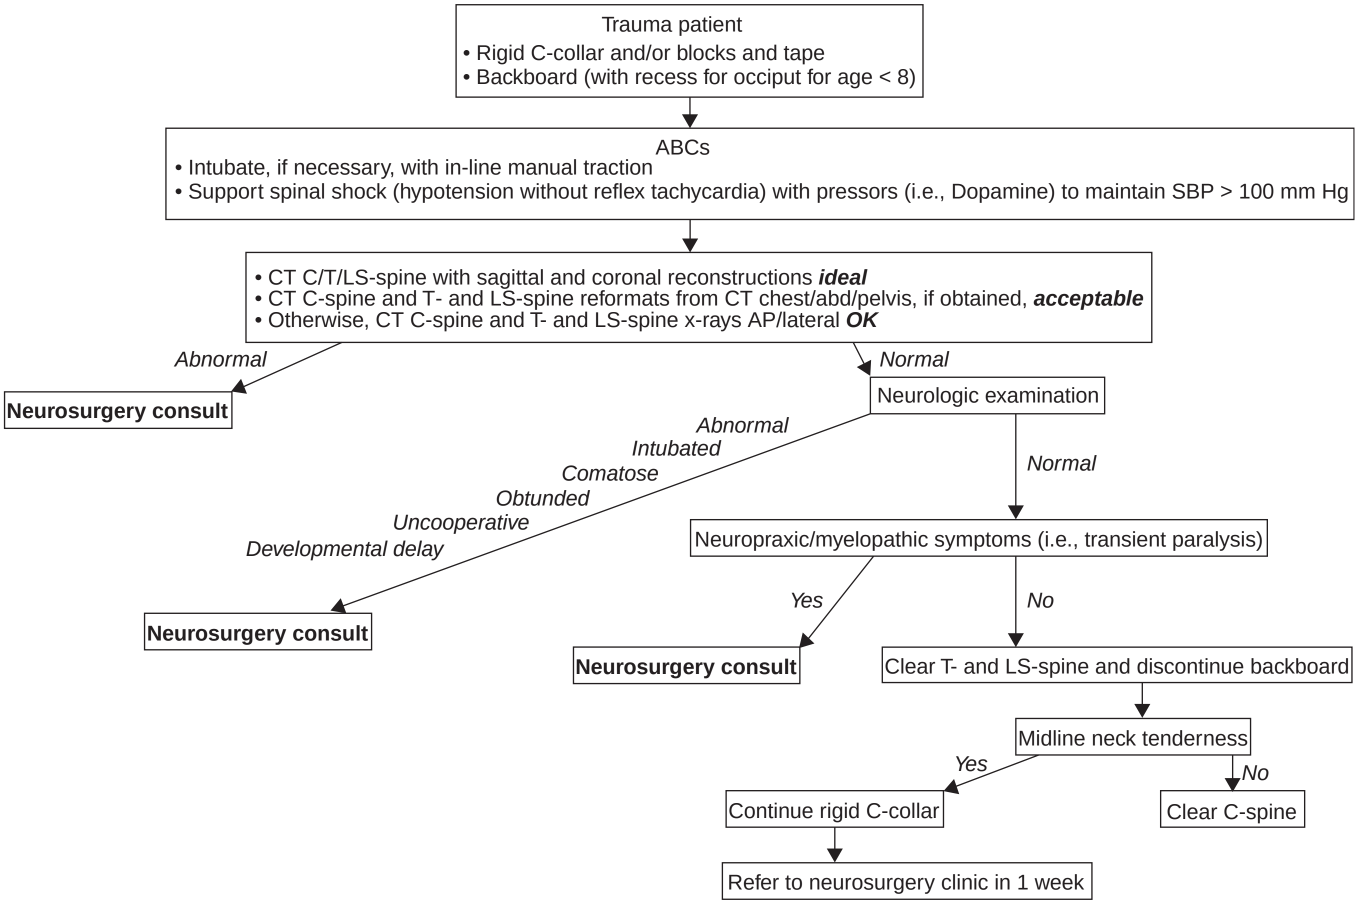

**FIGURE 24-11** A proposed computed tomography (CT)-based algorithm for the evaluation and treatment of pediatric spine trauma. Establishment of CT-based protocols to clear the pediatric spine of suspected injury has been shown to decrease the time required to accomplish clearance[178–181,201] and reduce the number of missed injuries.[174,175,178,181,202] ABC, airway, breathing, circulation; abd, abdomen; AP, anteroposterior; C-collar, cervical collar; C-spine, cervical spine; CT, computed tomography; LS-spine, lumbosacral spine; SBP, systolic blood pressure; T-spine, thoracic spine.

***Computed Tomography*** Computed tomography may suggest soft tissue, ligamentous injury, which most often occurs in the pediatric cervical spine. When using atlanto-occipital dislocation as a model for purely ligamentous injury, seen almost exclusively in the pediatric population, lateral cervical spine plain radiographs helped to make the diagnosis in 57% of patients; CT helped make 84% of diagnoses.[173] Another example of purely soft tissue injury in the pediatric population is atlantoaxial rotatory subluxation. Radiographic sensitivity during diagnosis was only 33%, whereas CT sensitivity reached 93% to 95%.[183]

Patients undergoing cervical spine and brain CT simultaneously had statistically significant less repeat or excessive radiographs than patients undergoing brain CT with cervical spine radiographs.[182] Children who underwent initial cervical spine CT did receive approximately 4 to 8 mSv of radiation; however, statistically significant increased risk of fatal cancer from low-dose radiation is in the range of 50 to 100 mSv.[184]

High-quality CT scans, perhaps, are most useful in identifying an occult and, possibly, surgically correctable vertebral fracture or dislocation.[166]

***Magnetic Resonance Imaging*** In the last decade, MRI has become the modality of choice for pediatric patients with apparent spinal cord injury but negative radiographic studies. MRI seems to be very sensitive at detecting ligamentous disruption and instability not seen on plain radiographs or CT.[185] MRI demonstrates the extent of actual damage to the spinal cord, ranging from mild hemorrhage and/or edema to cord transection.[186]

Magnetic resonance imaging findings are prognostic of patient outcome. A normal-appearing MRI suggests excellent recovery of function; major hemorrhage or cord transection on MRI is associated with permanent cord injury.

Magnetic resonance imaging is also useful in ruling out surgical lesions (i.e., those causing persistent cord compression, such as epidural hematoma or traumatic disc herniation).[187–189]

## EARLY MANAGEMENT OF SPINAL CORD INJURY

As with traumatic brain injury, it is extremely important to aggressively support systemic perfusion and oxygenation. Because children tend to have more rostral cervical cord injuries, impaired respiratory function is likely to be a concern. Furthermore, gastric dilatation commonly accompanies acute spinal injuries and can add a substantial mechanical barrier to effective respiration; therefore early nasogastric decompression of the stomach should be considered. For midlevel and higher cervical injuries, elective intubation may be needed to support respiration until a comprehensive assessment of the injury is completed. Because endotracheal intubation in a spinal-injured child is technically challenging, it should be performed by an expert who should not manipulate the relative position of the head and neck.

By restoring and supporting systemic blood pressure, one can maintain perfusion of the injured spinal cord. Patients with severe cord injuries, especially in the cervical cord, are most at risk for systemic hypotension. Although a patient can undergo initial resuscitation with intravascular volume loading, neurogenic hypotension should be treated with vasopressors. The resuscitation and maintenance of normal blood pressure in a patient with a spinal cord injury is complicated and may be aided by invasive monitoring of central venous pressure.

The pharmacotherapy of spinal cord injury has been the subject of active research and scientific controversy. The second National Spinal Cord Injury Study (NASCIS-II)[190] recommended that all patients with acute spinal cord injuries be administered high-dose methylprednisolone. Although the recommendations did not officially extend to pediatric patients, most centers applied these treatment recommendations to all age groups. Despite a subsequent study[191] that appeared to confirm the initial findings, the methodology and conclusions of these studies have been seriously questioned.[4,192] Current evidence suggests that administering high-dose steroids to spinal cord–injured patients, including children, is a listed treatment option, albeit one in which the harmful side effects may not justify clinical benefit.[4]

Early surgical therapy is rarely needed. Most pediatric fractures and dislocations can be reduced and maintained in anatomic alignment with a variety of orthotic devices, including a halo brace. Early surgical reduction and fusion is considered only for cases where there is clear neurologic deterioration occurring in the face of irreducible subluxation or compression from bone fragments, extruded disk material, or enlarging hematoma. These issues are unusual in young children. Adolescents suffer injuries similar to adults and can be treated using the surgical recommendations available for adult patients.[4] There is limited scientific information about the advisability and outcomes of operative management of spinal injury in young children, although recent reports indicate that surgical instrumentation is becoming more common.[193,194] Anatomic reduction of deformity, stabilization of clearly unstable injuries, and decompression of neural elements are indications cited for surgical treatment of spinal injury in children. Most of these goals can be accomplished nonoperatively. Current recommendations indicate that most vertebral injuries in young children should be initially treated nonoperatively, reserving surgical management for persistent or progressive deformity or ligamentous instability (see Fig. 24-8).[4]

## COMPLICATIONS

Children are subject to all of the complications associated with spine injury, which include skin breakdown, infections, deep venous thrombosis, autonomic dysreflexia, contractures, spasticity, neurogenic bladder and bowel, and progressive spine deformity.[195] However, the single major acute complication of spinal cord injury in children is respiratory; the most common cause of death in the acute phase of injury is respiratory failure.[196] Aggressive pulmonary care is essential, and ventilatory support may be necessary until accessory muscles of respiration can strengthen. Many of the other complications can be avoided or minimized by the early intervention of physiatrists and other rehabilitation specialists.

The incidence of venous thromboembolism in spinal-injured children has been reported, probably incorrectly, to be roughly similar to the incidence reported in adults.[195] However, series involving only pediatric patients indicate that this complication is extremely rare.[197] Therefore specific

recommendations for prophylaxis of this possible complication vary widely. For adults, and presumably, for older children and adolescents, thromboprophylaxis for up to 12 weeks after the injury is recommended, using low-molecular-weight or low-dose heparin in combination with rotating beds, pneumatic compression stockings, or electrical stimulation.[4,195]

## OUTCOMES

The mortality of spinal cord injury in childhood has been reported at 28%, which is significantly higher than the mortality rate for this injury reported for adults (approximately 15% at 10 years postinjury).[168,198] The majority of these deaths appeared to occur at the scene and would not be affected by current management strategies. For survivors of spine injury, outcomes are related to the level and severity of injury. Complete injuries remain complete, and although limited functional improvement may be seen over time, full recovery is not expected.[145,159,166,167] Children with incomplete spinal cord injuries have a good chance of showing significant functional improvement and even complete recovery.

The cost of long-term care for these injuries is staggering. The lifetime cost of care for a child with a spinal cord injury extends into the millions of dollars.[154,199,200] This cost must be added to the loss of productivity that accompanies these devastating injuries. The adult employment rate for individuals suffering childhood spinal cord injury is about 50%.[195] Factors associated with successful employment are younger age at injury, less severe neurologic impairment, better education, longer duration of living with the sequelae of the injury, and ability to drive independently.

# CHAPTER 25

# Vascular Injury

Joseph J. Tepas III and Danielle S. Walsh

In the century since Alexis Carrel was awarded the Nobel Prize for his work in devising the surgical technique of vascular transplantation and repair, management of the patient with multisystem injury has emerged as a constantly improving process of recognition, rescue, resuscitation, and repair. Recent combat casualty experience in Iraq and Afghanistan has validated the role of damage control surgery and has stimulated the emergence of increasingly sophisticated systems of care for the severely injured. Although this experience has been forged in the treatment of massive open wounds usually caused by explosive devices, the principles that have been developed are beginning to permeate the process of civilian trauma care. The treatment of vascular injury in particular has been advanced through the use of temporary vascular shunts, permitting the transfer of life- and limb-threatening injuries to centers able to perform reconstruction.[1] Sadly there are also a significant number of pediatric casualties about whom little is known because they were simply the collateral damage of civil war. Reports by pediatric specialists deployed to these theaters validate the incidence and intensity of these injuries and indicate that the same management approaches used in the adults have been equally effective in rescuing children. Also noted has been a significantly better outcome for those children managed by pediatric specialists. In short the war experience has taught us that the basic principles of management of vascular injuries are similar for children and adults.[2]

The pediatric surgeon must approach every injured child with an organized process of assessment based on thorough review of the mechanism of injury, a careful physical examination, and an appropriate strategy for imaging and intervention. The predictive accuracy of clinical examination and better definition of indications and techniques for arteriography have led to more timely operative intervention after effective resuscitation, assessment of associated injuries, and anticipation of reperfusion injury.[3,4] The emergence of endovascular technology has begun moving the acute management of some vascular injuries from the operating room to the angiography suite. At the heart of vascular injury management, however, remains restoration of peripheral perfusion and the technical repair of damaged blood vessels. Although these basic surgical skills are similar for patients of all ages, infants and children have unique characteristics, which can present significant challenges.[5–9]

## Epidemiology

As in the adult population, vascular trauma can be classified into torso injuries that involve major truncal vessels and extremity injuries that disrupt peripheral perfusion. Although blunt injury predominates in pediatric trauma overall, our young patients increasingly mirror the adult population as is evidenced by penetrating injury overtaking blunt injury as the cause of most vascular injury.[10,11] Fortunately the incidence of both remains relatively low, although the mortality rates are significant. Archival data in the National Pediatric Trauma Registry (NPTR), demonstrated an incidence of vascular trauma of only 1.3% of registry cases in a 13-year span. However the 13% crude mortality rate for this group was significantly higher than the 2.9% rate for the entire registry, demonstrating the lethality of these injuries. Table 25-1 lists mechanisms of injury and mortality in 1368 children with at least one vascular injury recorded in the registry. Table 25-2 further characterizes these injuries by variability of outcome with body region affected. Penetrating injury accounted for slightly more than half of reported cases and was more likely to require intervention. Blunt traumatic disruption of torso vessels, in contrast, was more likely to be fatal. Two institutional trauma databases from the Medical College of Wisconsin and the University of Miami similarly found a higher incidence of penetrating wounds at 68% and 53%, respectively, in children with vascular injury.[11,12]

A report by Allison and colleagues[13] reviewed management and outcome of 75 truncal vascular injuries encountered in 57 of 10,992 patients 17 years or younger treated at their regional pediatric trauma center between 1997 and 2006. The low incidence (0.7%) and high lethality associated with presenting hemodynamic instability is in accord with the NPTR experience as well as the experience at our University of Florida, Jacksonville regional trauma center with 38 of 3996 (1%) children younger than 14 years treated between 1995 and 2009. Our experience included a 47% incidence of penetrating extremity vascular injury; all these patients survived. Of epidemiologic significance in all these reports is that boys are more likely than girls to sustain vascular injuries of all types, by a margin of 2 or 3:1.[14,15]

**TABLE 25-1**
**Injury Mechanism in 1367 Children in the National Pediatric Trauma Registry II and III**

| | *Proportion* | *Mortality* |
|---|---|---|
| Penetrating | 52% | 10% |
| Blunt | 47% | 17% |
| Crush | 1% | 8% |

# Evaluation

General principles of assessment of acute vascular disruption are based on clinical evaluation. Regardless of cause, suspicion of vascular injury should prompt an organized clinical assessment based first on the patient's history. During initial clinical evaluation two immediate questions must be answered. First, is there evidence of disruption of integrity of the circulatory system, and second, is perfusion adequate? Despite the implied causal relationship of these two points, each can be deranged without immediate effect on the other. Prolonged spasm after injury, a common characteristic of childhood vascular trauma, may cause peripheral ischemia in an otherwise anatomically intact vascular tree. Conversely, effective collateral circulation, enhanced by the absence of obliterative vascular disease, may sustain distal circulation despite deranged proximal flow. Thus not every disruption of vascular flow produces immediate peripheral ischemia, and evidence of acute ischemia may not necessarily portend operative vascular injury. Regardless of circumstances, confirmation of restoration of cellular perfusion is the immediate priority in assessing any child with vascular injury.[8]

Children usually do not suffer from atherosclerotic vascular disease. Their vessels are more elastic and usually respond to application of force by stretch and transient deformity rather than rupture. The immediate result of this is an increased potential for intimal tears, which cause flow disruption in an otherwise anatomically intact vessel. The effect of this decreased flow may be acute ischemia or marginal insufficiency that stimulates increased collateralization. Although the former should be easily discernable on clinical examination, the latter can be subtle and clinically silent. The relevance of this is rooted in the mandate that functional and anatomic integrity of the circulation be clinically confirmed and documented in every injured child. Of equal importance is the understanding that unexplainable absence of palpable pulses, especially in the lower extremities, may be the result of preexisting rather than acute injury. If perfusion pressure is suddenly lowered because of other acute injuries, collateral circulation may become inadequate and symptoms of progressive ischemia may emerge.

Frykberg and associates demonstrated the predictive accuracy of "hard signs" of injury and recommended immediate operative intervention for any patient with active bleeding, an expanding hematoma, pulse deficit, or a bruit/thrill.[16] Nonexpanding hematoma, hypotension, peripheral nerve deficit, or a history of bleeding from the wound were considered "soft" signs, which required only clinical observation. Long-term follow-up of this population has confirmed the predictive accuracy of this approach and has validated the authors' initial recommendation that routine arteriography was not necessary for management of proximity injury.[4,17] Reichard and colleagues analyzed the predictive accuracy of clinical signs in their review of 75 children with vascular injury treated at the pediatric trauma service of Cook County Hospital.[18] Part of their report includes comparison to an additional 12 children managed by an "adult" protocol that required traditional arteriography. None of the studies performed for proximity injury alone was abnormal. All 10 children with vascular injury had hard signs. Four of 77 children with no vascular injury also manifested at least one hard sign, yielding a sensitivity of physical examination of 100% and a specificity of 95%. It is of note that these data validate similar recommendations published by Meagher and colleagues in 1979 and emphasize that arteriography for acute injury should be considered only if the risk of performance is outweighed by a threat of ischemia that cannot be defined by history and clinical signs.[16,19–21] Numerous investigators have validated the predictive accuracy of thorough clinical examination and in the process have refined indications for further imaging, particularly arteriography.[3,16] Although the emergence of multidetector computed tomography (CT) and magnetic resonance angiography (MRA)-based angiography has minimized the trauma of arterial vascular access, the additional radiation of CT, the lesser availability of MRA, and the risk of contrast toxicity still mandate a studied decision as to the appropriateness of these imaging studies.[22] Although CT and MRA do not require direct arterial puncture or manipulation of foreign bodies against arterial intima, they do require relatively large boluses of contrast medium and in the case of CT significant radiation exposure. The risk of inappropriate angiography has simply changed in characteristic rather than in magnitude or incidence.

Lineen and colleagues published their review of 78 pediatric patients with suspected vascular injury undergoing CT angiography for 41 penetrating and 37 blunt mechanisms.[12,23] Eleven injuries were identified from the penetrating trauma group, with 100% sensitivity and 93% specificity. Two normal veins were read as abnormal adjacent to missile tracts: one patient had ultrasonography to confirm the integrity of the adjacent vein and the other was observed because the physical

| Lower Extremity | 904-905 | 326 | 318 | 8 (3) | 36 |

examination was normal. Eight injures from blunt trauma were noted with 88% sensitivity and 100% specificity. One injury was listed as "indeterminate" but was confirmed on conventional arteriography as a subclavian artery injury. The authors therefore propose that CT angiography be used as the study of choice when the soft signs of vascular trauma are present on physical examination.

A recent report by Hsu and colleagues defined the clear benefit of CT angiography in assessment of pediatric extremity injuries both acutely and as an essential planning "road map" before definitive reconstruction.[24] In addition to avoiding problems with direct vessel injury, these authors cite the speed and accessibility of CT scanners and the ability of CT to define three-dimensional spatial anatomy as major advantages in assessing the injured child. Three-dimensional reconstructions precisely define level of injury and efficiency of collateral circulation (Fig. 25-1). However they may require a higher volume of contrast medium.

Duplex Doppler and B-mode ultrasonography are emerging, noninvasive, portable technologies that supplement clinical imaging with determination of flow and flow velocity. Their role in the diagnosis of acute injury, however, has not been well established. Because both CT and magnetic resonance imaging (MRI) are limited in accurate identification of spasm, Doppler flow studies can be extremely useful for both diagnosis and follow-up. Transesophageal echocardiography may also provide useful data in the evaluation of thoracic truncal injuries in particular.[25] "One-shot" emergency department arteriography, despite reports of safety and efficacy, has essentially been replaced by CT angiography.[26]

**FIGURE 25-1** Computed tomographic angiogram from a 5-year-old hit by a car. He underwent repair of transposition of the great vessels as an infant and was noted to have a pulseless right foot. Evaluation demonstrated a clinically silent femoral artery disruption.

## Traumatic Injuries

Traumatic injuries can be divided into those involving the torso (neck and trunk) and those involving the extremities (upper or lower). Each area presents unique challenges to accurate diagnosis and timely management.

### TORSO INJURIES

Torso injuries in the cervical region appear to be rare in childhood, although they are more common in metropolitan areas with a higher incidence of pediatric penetrating trauma from missile and stab wounds.[12,23] Cox and associates' review of the operative management of 36 children with vascular injury included 9 children with 11 carotid or jugular injuries.[13,27] Eight of these injuries were penetrating neck wounds. Mortality occurred in 2 of the 3 hemodynamically unstable children. Their updated publication of 2009 identified 14 patients with 20 head and neck vascular injuries, of which 53% were of a penetrating mechanism. Of the 8 children managed in our unit, 5 were victims of penetrating trauma, including all 3 fatalities, each of whom presented with nonsurvivable injuries. Rozycki and colleagues evaluated their proposed algorithm for diagnosis of blunt cervical vascular injury by reviewing injuries associated with a cervicothoracic seat belt sign in 797 motor vehicle accident victims treated over 17 months by the Grady Memorial Hospital Trauma Service.[28] The 3% of patients with carotid injury were all adults. No injuries were missed, and no injuries were noted in children. With the gradual increase in child restraint law compliance, this potential association between seatbelt marks and significant vascular injury will require continued close follow-up.

Thoracic and abdominal torso vascular injuries are also relatively rare in childhood. This is probably the result of the greater elasticity of young and healthy vessels. Although children are not immune to thoracic vascular disruption, most series that include pediatric patients demonstrate a low incidence compared with adults. The report by Cox and colleagues included abdominal vascular injuries in 39 children and thoracic vascular trauma in 13 patients.[27] Fifty-four percent of the abdominal injuries and 46% of the thoracic injuries stemmed from blunt trauma. A higher percentage of the injuries specific to the aorta were by blunt mechanism, whereas nonaortic injures—such as great vessel, mammary, and pulmonary vein injuries—were from traumatic missiles. In general, clinical reports of aortic injuries seen in children suggest a natural history no different from that of adults. Mortality is extremely high, especially for children with a presenting systolic blood pressure below 90 mm Hg and those with associated severe traumatic brain injuries.[13] Eddy and colleagues reviewed the King County Coroner's records over a 12-year period (1975–1987), and found 13 cases of aortic disruption in children.[29] Only 3 of these children reached a hospital alive, and just 1 child survived. Experience in the NPTR is somewhat more heartening in that 26 of 54 children with aortic ruptures (48%) survived to hospital discharge. This representative sample from multiple contributing hospitals in North America is similar to that reported from a single institution by Cox and colleagues, suggesting that outcome from this catastrophic injury may be better than what has been

consistently reported for adults.[27] Major thoracic venous injuries are even less common and are usually associated with major pulmonary disruption.

Because of the preponderance of blunt mechanisms of injury in the pediatric population, especially as the result of vehicular-related mishaps, abdominal vascular injuries can and do occur.[30] Arterial disruption is far less common than venous disruption. Hypotension progressing to frank shock is the most common associated finding, making the decision to explore the abdomen relatively straightforward, although usually there is the expectation of solid viscus derangement as the most likely cause. Fayiga and colleagues reviewed 18 years of experience in operative management of pediatric blunt vascular injury.[31]

Twenty-one major abdominal venous injuries were present in 17 patients and were lethal in 11 of them (65%). None of the abdominal venous injuries was recognized before laparotomy. As in numerous other series, survival was directly related to the presence of hemodynamic stability. Most complications were related to nonvascular injuries. The majority of vascular injuries were repaired directly, which parallels the experience from a similar series of 16 abdominal vascular injuries reported by Cox and colleagues.[27] Interposition grafts were required to repair only one aortic disruption and one superior mesenteric artery transection.

## EXTREMITY INJURIES

Vascular extremity injuries are uncommon in children. Most are associated with fractures, although the rising tide of violent crime is also driving an increase in penetrating mechanisms. As in the adult, careful and expeditious clinical examination is the critical starting point. Evidence of diminished peripheral flow may be the result of spasm (discussed in detail further on) with or without associated vascular disruption. In the absence of hard signs of disruption, imaging assessment using ultrasonography or CT angiography may be required to define the cause of distal ischemia. The use of stents for angiographically identified injuries is becoming more common in the adult population. However it is still rare and controversial in children.[32,33] Migration and stent impact on subsequent growth are still undefined, making formal operative repair the recommended option for vascular disruption. Chang's[33] report of use of a stent to treat an axillary arterial and venous stab wound includes follow-up that documents critical stenosis mitigated by adequate collateralization. The authors make a strong case, however, that this approach avoided dissection of a huge hematoma in an anatomic space that is difficult to approach safely. Future elective reconstruction, if required, will be much less difficult and dangerous than operative repair during the acute phase of injury. This experience implies a reasonable role for at least a temporizing if not definitive therapy for some vascular injuries.

Interposition of reversed contralateral saphenous vein remains the treatment of choice for all disrupted segments. Synthetic material should be considered only as a last resort when an autologous vessel cannot be harvested and fabricated into a patch or conduit.[7] Veins should be repaired before arteries. Anastomoses are constructed using monofilament simple sutures.[8] As the repair is being completed, the distal clamp is first released to confirm adequate backflow. The proximal clamp is then released to flush any residual air or clot before the final sutures are tied. Vasospasm if significant can usually be reduced by gentle mechanical dilation, using coronary artery dilators, topical 2% lidocaine, or papaverine. Investigators emphasize that the high proclivity for prolonged vasospasm can make arterial anastomosis in childhood especially challenging.[31] LaQuaglia and associates described experience in nine children with iatrogenic arterial injuries repaired using microsurgical technique using 9-0 to 11-0 nylon suture.[34] As microsurgical technique continues to evolve and better suture materials become available, this approach will become an increasingly valuable adjunct to the management of major injuries to tiny vessels. If ischemia time has been prolonged longer than 6 hours, the possibility of evolving compartment syndrome should spark consideration for fasciotomy.[35] Children who have undergone repair of injuries should undergo anticoagulation for 48 hours postoperatively. Some authors use heparin, whereas others simply use dextran solutions for 2 to 3 days postoperatively.

Although lower extremity vascular injuries are most commonly associated with fractures and soft tissue avulsions, the rising incidence of violence in our urban youth is increasing the frequency of disruption of groin and femoral vessels.[12] Popliteal injuries are often the result of sport and cycling mishaps associated with a skeletal fracture and warrant particular attention. Initial assessment must confirm the presence of palpable distal pulses and adequate capillary perfusion. Immediate reduction of displaced fracture fragments or subluxed joints will often result in restoration of palpable distal pulses. Reed and colleagues reported their experience with seven children with popliteal arterial injury who underwent immediate operative repair. Four had blunt trauma and three had penetrating injuries.[36] Associated morbidity included three fractures, four severe soft tissue wounds, and one nerve injury. All patients underwent angiography; three cases were intraoperative. Treatment included two primary repairs and four vein graft bypasses. One child required fasciotomy; there were no deaths, amputations, or reoperations. At the time of their report, follow-up ranged between 10 and 42 months. All patients had normal Doppler pressures or distal pulses, or both. These data illustrate the relationship between prompt, aggressive treatment and successful outcome. The potential for development of delayed pseudoaneurysm, which usually requires excision with vein grafting, mandates that every child with an extremity vascular injury be followed for at least 5 years.

Upper extremity vascular injury is most often associated with supracondylar fractures or penetrating trauma. Supracondylar fractures may disrupt brachial arterial flow by direct injury or by compression with or without prolonged spasm.[37] As with the lower extremity, definitive management begins with assessment of adequacy of perfusion and confirmation of integrity of the vessel. Of interest is a recent report that describes the use of the ipsilateral basilic vein as an ideal interposition graft for reconstruction of vessels in which segmental loss has occurred.[38] Axillary stretch injuries, especially when associated with high energy such as vehicular ejection, may disrupt arterial or venous structures, producing a hematoma that is not as precisely definable as those seen with more distal injuries. In addition to signs of obvious blood loss, diffuse edema of the axilla or shoulder region and diminution of peripheral pulses should prompt angiographic confirmation of both the existence and anatomic configuration of the

injury. Salvage from damage of upper extremity injuries is generally good, with return of functionality related to the nature of the associated musculoskeletal and neurologic disruption. The incidence of compartment syndrome as a result of prolonged ischemia in the upper extremity is reported to be significantly lower than that for lower extremity injuries. However careful follow-up for adequacy of perfusion and avoidance of potential postischemia muscular contracture must be part of long-term management.

### Mangled Extremity

The vast majority of extremity vascular injuries seen in children are associated with axial skeletal disruption. In its most severe form, this combination of bone and soft tissue destruction can result in what has been called the "mangled extremity." It is usually characterized by major soft tissue avulsion that can be associated with significant tissue loss. Initial assessment must consider tissue viability, anticipated limb function, and the need for amputation of a potential source of massive tissue necrosis and sepsis. The Mangled Extremity Severity Score (MESS) has been proposed as an accurate system of evaluation and prediction of limb salvage (Table 25-3). Although originally devised for adults, Fagelman and colleagues demonstrated a predictive accuracy of 93% when it was retrospectively applied to 36 injured children.[39]

Vascular disruption associated with fractures must be immediately addressed so that subsequent axial skeletal repair will produce a viable extremity. Restoration of flow may be achieved by temporary bypass until fracture fixation is achieved. When possible, venous repair should precede arterial repair. Devitalized tissue must be debrided and fasciotomy considered. Nerve function must be evaluated and documented before debating amputation. Although it is true that children do recover amazingly well from what initially appear to be devastating injuries, being permanently disabled by an insensate, immobile extremity is a poor alternative to an active life with a functional and properly fitted prosthesis. The decision to amputate is therefore based on assessment of limb viability and prediction of limb functionality. The Mangled Extremity Severity Score serves as a reasonable guideline, although the ultimate decision rests with the surgeon, the child's parents, and when possible the child.

**TABLE 25-3**
**Mangled Extremity Severity Score (MESS)**

| | |
|---|---|
| Skeletal/soft tissue injury | |
| Low energy (stab, simple fracture, pistol or gunshot wound) | 1 |
| Medium energy (open or multiple fractures, dislocation) | 2 |
| High energy (high-speed crash or rifle gunshot wound) | 3 |
| Very high energy (high-speed injury, gross contamination) | 4 |
| Limb ischemia | |
| Reduced/absent pulse, normal perfusion | 1* |
| Pulseless, paraesthesias, poor capillary refill | 2* |
| Cool, insensate, paralyzed, numb | 3* |
| Shock | |
| Systolic BP always >90 mm Hg | 1 |
| Transient hypotension | 2 |
| Persistent hypotension | 3 |
| Age (yr) | |
| <30 | 1 |
| 30-50 | 2 |
| >50 | 3 |

*Score doubled for ischemia >6 hours.
MESS >7 = 100% prediction for amputation
BP, blood pressure.

## Iatrogenic Injury

With continued evolution of increasingly sophisticated methods of imaging for infants and children, the potential for damage to the vascular integrity of a small child or tiny infant remains ever present. There have been numerous reports over the past decade describing this particular problem.[40–43] Many have been case reports of complications from some usually innocuous maneuver of routine care. Demircin and associates, for example, reported an infant with brachial arterial pseudoaneurysm resulting from inadvertent puncture during antecubital venipuncture.[10] The lesion was repaired by direct suture under proximal compression. Gamba and colleagues reviewed their experience with iatrogenic vascular lesions in low-birth-weight neonates. Of 335 infants encountered between 1987 and 1994, 9 (2.6%) were diagnosed with vascular injury.[44] Mean birth weight was 880 g (range 590-1450 g), although mean weight at diagnosis was 1825 g (range 1230-2730 g). Injuries were associated with venipuncture in seven of the nine cases and included six femoral arteriovenous fistulas, two of which were bilateral. One carotid lesion and five femoral arteriovenous fistulas were repaired using microvascular technique. Outcome as determined by follow-up clinical examination and Doppler flow was excellent, leading the authors to emphasize the role of aggressive medical and microsurgical management of these injuries. In 1981 O'Neill and colleagues reviewed their experience with surgical management of 41 infants with major thromboembolic problems associated with umbilical artery catheters.[45] Although the majority of complications were related to emboli distal to the femoral artery, 8 infants required emergency operative intervention for acute aortic obstruction. Four of these operations were transverse aortic thrombectomies; three patients recovered completely. As principles of umbilical artery catheter management have become better established, these problems appear to have become less frequent.

In their analysis of the predictive accuracy of clinical findings in pediatric vascular injury, Reichard and colleagues extolled the accuracy of the ankle-brachial index (ABI) as indicative of inadequate peripheral perfusion.[18] Their data suggest that an ABI less than 0.99 indicates clinically critical vascular injury and reinforce recent reports of intensive care nursery discharge data that suggest the true incidence of vascular injury is far more common than previously thought. In fact, findings reported by Seibert and colleagues suggest that assessment of the peripheral pulses and measurement of the ABI should be part of a routine postdischarge assessment of any infant treated with umbilical artery catheterization.[46]

The increasing use of complex endovascular diagnostic and therapeutic procedures in pediatric patients is also associated with a low but consistent incidence of unplanned iatrogenic damage to vascular structures.[9,42,47] However, with refinement of technique and improving technology, this also appears to be decreasing.[9,48] Morbidity from these iatrogenic

injuries occurs primarily in the neonatal period when small vessel diameter and vasospastic tendencies predispose to ischemia. Long-term consequences of such injuries include soft tissue loss, amputation, limb growth discrepancies, and the ultimate need for surgical reconstruction of these deformities. As CT and MRI-based angiography becomes more common and diagnostic, incidence of injuries directly related to vascular access for traditional angiography may be minimized.

Lin and associates analyzed 1674 diagnostic or therapeutic catheterizations performed in 1431 infants over a 15-year period.[49] Thirty-six procedures were required in 34 children. The authors stratified complications into nonischemic, acute femoral ischemia, and chronic femoral ischemia. Nonischemic lesions included pseudoaneurysms (n = 4), arteriovenous fistulas (n = 5), and groin hematoma (n = 5), and all underwent direct suture repair. Acute femoral ischemic lesions were most common and required a variety of procedures from thrombectomy to patch repair. Seven children presented with chronic femoral ischemia, defined as having evidence of flow disruption more than 30 days after the procedure, at an average of 193 days (range 31-842 days) after the index intervention. All seven children were symptomatic with claudication, leg length discrepancy, or gait disturbance. Operative repair consisted of revascularization using reversed saphenous vein for iliofemoral bypass in five children and femorofemoral bypass in one child. One child required patch only angioplasty. Risk factors for ischemia included age younger than 3 years, need for therapeutic or multiple catheterizations, and catheter size larger than 6 French. The value of this study lies not only in its identification of potentially predictive factors but also in its documentation of the relatively short time interval required for chronic ischemia to become symptomatic.

Children at risk of vascular injury with any abnormal clinical finding must be followed at least 5 years and preferably through at least the start of adolescence. The evolution of limb length discrepancy as a result of disruption of a major vascular structure may not become manifest until years after the precipitating event.[50] Recent reports have suggested that operative revascularization of iatrogenic injury before adolescence will correct some limb length discrepancy; however, these reports have been relatively small series and do not represent consensus.

The femoral artery remains the most common site of iatrogenic injury. As noted previously in the discussion of traumatic injury, efficient collateralization of the pelvis and gluteal region may result in these lesions remaining clinically silent throughout most of childhood. Mourot and colleagues reported their experience with ischemia after femoral arterial line placement in the pediatric burn population.[51] In a group of 234 children who underwent 745 femoral artery catheterizations, 8 patients developed loss of distal pulses, indicating occlusion or spasm of the femoral artery. Five children responded to nonsurgical treatment consisting of catheter removal and systemic heparinization. The other 3 patients required surgical thrombectomy.[51] The authors point out the importance of timely removal of foreign bodies from vessels in ischemic limbs with both vasospasm and occlusion for prevention of tissue loss.

Extracorporeal membrane oxygenation (ECMO) represents another area in which iatrogenic vascular injury may result in long-term consequences. Many authors advocate preferential use of venovenous ECMO over venoarterial ECMO because of uncertainty over the potential long-term consequences of neonatal carotid artery injury.[52] For patients requiring carotid artery cannulation, scientific inquiry continues to ensue over whether carotid artery reconstruction should be performed at decannulation, particularly in the neonatal population. Sarioglu and associates reported their experience in 61 infants with carotid artery cannulation for ECMO. End-to-end carotid artery repair was performed in 32 patients and simple ligation in 29 patients.[53] Early patency rate as evidenced by MRI and ultrasonography was 97%, although 12% appeared stenotic. These authors recommend routine carotid artery repair when technically feasible. Longer term patency after carotid artery reconstruction following ECMO for congenital diaphragmatic hernia was assessed by Buesing and associates in 18 infants.[54] All underwent three-dimensional MRA 2 years after the procedure and the common carotid artery was occluded or highly stenotic in 72% of the patients. All had patent internal carotid arteries and evidence of both intracranial and extracranial collateral vessel development. They also noted that unsuccessful repair of the artery was not predictive of a poor neurologic outcome. They concluded that the benefits of surgical repair are "doubtful" but that longer term assessment is still required. A recent report from Duncan and associates points out two cases of aneurysms at the site of carotid artery repair after ECMO, highlighting a potential complication of repair.[55]

## Vasospasm

As is the case with management of traumatic injury, the high proclivity for spasm and the need to differentiate prolonged spasm from arterial disruption remains one of the most challenging components of initial assessment. Prolonged spasm is felt to be the result of intimal injury, which causes derangement of nitric oxide production and disrupts control of arterial wall tension.[56,57] When endothelial-medial contact is lost, as can be caused by shearing friction from an oversized or overzealously placed catheter, underlying vascular smooth muscle is incapable of relaxation.[58] Angiographic confirmation of spasm requires the additional risk of the very mechanism suspected of causing the problem. CT or MRA may be the solution to this clinical conundrum, although dose and concentration of contrast medium must be carefully considered in comparing risk to benefit.

The role of spasm in causing gangrene is controversial despite case reports suggesting cause and effect.[59] From a clinical perspective once spasm has been confirmed to be the sole cause of diminished peripheral perfusion, management must focus on confirmation of evidence of tissue viability and absence of signs of evolving compartment syndrome or peripheral ischemia. Assuming that the basic cause of acute spasm is at least partly related to intimal injury, risk of thrombosis must be a primary consideration. Over the past few years, routine anticoagulation therapy has been supplemented by thrombolytic agents, especially urokinase.[60] Recommended doses of urokinase vary and tend to be empirical. Up to 6000 U/kg/hr have been used in infants with good success and no complications. Most recently, a report by Zenz and colleagues on the use of tissue plasminogen activator suggested that more rapid restoration of flow could be

achieved with this drug.[61,62] Some patients may still require operative intervention for thrombectomy after a period of time in a low-flow state.

## Digital Ischemia Syndrome

Intravenous catheter-related, ipsilateral digital ischemia may suddenly develop in acutely ill infants or small children with acute infectious disease. It is usually associated with dehydration and hypovolemia. In a review of 104 cases, Villavicencio and González Cerna reported primary involvement of the hand in 68.2% of patients and the foot in the remainder.[63] The age of the patients ranged from 29 days to 36 months; the mean age was 14 months. The infectious process was of respiratory origin in 27.8% of cases, localized to the gastrointestinal tract in 60.5%, and other areas in 11.5%. The most frequently cultured microorganisms were *Escherichia coli, Salmonella, Shigella, Streptococcus, Staphylococcus, Klebsiella*, and *Pseudomonas* species. Digital cyanosis usually occurs shortly after vessel cannulation and is probably the result of vasospasm provoked by the presence of an indwelling catheter. As described earlier, damaged endothelium may stimulate vasoconstriction. Immobilization causes constriction of the limbs and impairs the muscle action that is necessary to assist venous return. Persistence of these conditions increases extravascular pressure and gradually produces microcirculatory failure, leading to necrosis, which begins at the most distal areas of the digits.

Effective treatment requires prompt recognition of persistent cyanosis, correction of the underlying systemic disorder, and immediate removal of the catheter. Anticoagulation therapy should be initiated immediately. Application of nitroglycerin paste has been shown to improve local microcirculation and limit the extent of ischemic necrosis.[64,65] Lesions should be gently washed daily in warm water, and the involved limb should be actively and passively exercised through the full range of motion. Direct heating should be avoided because ischemic tissue burns at lower temperatures. Small pieces of cotton should be placed between fingers or toes; all lesions should be covered with sterile, dry dressings. Areas of dry gangrene do not require surgical removal. If there is concern whether infection is trapped under eschar, the area can be gently elevated at its corners to allow adequate drainage. As is the case with arterial lesions, amputation should not be considered until clear demarcation has occurred.

## Conclusion

In summary, although the epidemiology of vascular injury in the pediatric population is considerably different from that encountered in adults, treatment imperatives remain the same. Traumatic injury presents a unique set of characteristics that reflect the epidemiology of pediatric trauma. All vascular injuries, if carefully managed, can exploit the intrinsically healthy status of the child's vascular system and yield optimal results. Iatrogenic injury is the price of miniaturization. It is a recognized tradeoff for the dramatic advances that now make possible many lifesaving procedures. Attention to detail in those most at risk may not eliminate the problem but will at least reduce incidence and raise awareness. Accurate diagnosis, timely revascularization, and aggressive management of reperfusion are essential for complete recovery and normal long-term growth. The key to success is a high index of suspicion, recognition of the unique characteristics listed earlier, and operative intervention using the high level of precision that is the cornerstone of success in the surgical care of children.

CHAPTER 26

# Burns

Dai H. Chung, Nadja C. Colon, and David N. Herndon

The cornerstone of burn management stems from decades-long advances in the understanding of major burn sequelae. In 1944, Lund and Browder introduced a diagram to assess burned areas, allowing a quantifiable assessment of percentage of total body surface area (TBSA) burned.[1] While treating victims of the Coconut Grove fire in Boston in 1946, Oliver Cope and Francis Moore were able to quantitate the appropriate amount of fluid required to maintain the central electrolyte composition after "burn shock."[2] From there, the development of the Parkland formula transformed our approach to fluid resuscitation. In the 1960s, the discovery of efficacious topical antimicrobial agents, such as 0.5% silver nitrate,[3] mafenide acetate (Sulfamylon),[4] and silver sulfadiazine (Silvadene),[5] likewise revolutionized burn wound care, and when used adjunctively with early debridement and grafting, the rates of wound infection and graft failure decreased dramatically. In recent years, continued progress has been made in several areas of burn care. Early surgical excision of eschar and grafting has significantly lowered the incidence of burn wound sepsis and shortened length of hospital stay. The nutritional support with early enteral feeding has been found to blunt the hypermetabolic response that contributes to derangements in gut function and immunomodulation seen with severe burns. Treatment with anabolic agents restores net positive nitrogen balance during prolonged postburn hypermetabolic period. Acute recognition of inhalation injury and effective treatment have also improved overall burn patient outcome. These examples of significant recent advances made in burn care have led to a further decline in burn-related deaths.[6] Today, the overall increase in survival of major burn victims is most evident in the pediatric burn population, where mortality rate is 50% for 98% TBSA burns in children 14 years old and younger and 75% TBSA burns in other age groups.[7]

Hence, burn injuries that were once considered to be uniformly fatal are now survivable, in part because of vigorous efforts to promote evidence-based care of the burned patient. Despite implementation of aggressive prevention measures and legislation, nearly one million people sustain a total of 2 million burn injuries yearly in the United States alone, and one half of these require medical treatment. Approximately 60% of the 40,000 admissions for burn injury are now admitted to hospitals with specialized burn centers.[8] The majority of burns are minor and represent less than 10% TBSA, and although the mortality rate for all burns is 3.7%, mortality increases dramatically with larger TBSA burns (42% to 81% for 60% to greater than 90% TBSA). Although mortality from burn injury increases with advancing age and burn size, the presence of an inhalation injury in patients with a TBSA of less than 20% significantly increases the likelihood of death by 25 times (National Burn Repository 2010). Unfortunately, those at the extremes of age continue to have worse outcomes, likely related to their unique physiology. Burns in children, particularly those less than 5 years of age, represent 17% of total reported burn cases and constitute a large at-risk population in which burn injuries are responsible for nearly 2,500 deaths per year. The percentage of admissions accounting for child abuse–related burn injuries varies, but is estimated to be anywhere from 1% to 25%, with infants and toddlers comprising the majority of these cases.[9]

Accounting for more than 70% of reported instances, the most common etiologies of burn injuries are fire/flame and scalds. Scald burns remain the most common cause of burn injury in children younger than 5 years of age. The majority of scald burns in infants and toddlers are from hot foods and liquids. Hot grease spills are notorious for causing deep burns. Hot tap water burns frequently result in larger TBSA injuries in children and can easily be averted by installing faucet valves that prevent water from leaving the tap if its temperature is greater than 120° F (48.8° C). Children also frequently suffer contact burns to their hands and faces from curling irons, ovens, steam irons, and fireworks. In the adolescent age group, flame burns are more common, often occurring as a result of experimentation with fire and volatile agents. Particular consideration must be given to burn injuries secondary to child abuse, which also represents a significant cause of burns in children. Burns with a bilaterally symmetrical or stocking-glove distribution in conjunction with a delay in seeking medical attention should raise the suspicion of child abuse (Fig. 26-1).

## Pathophysiology

As the largest organ in the body, the skin guards against harmful environmental insults, prevents entry of microorganisms, maintains fluid and electrolyte homeostasis, and is critical for thermoregulation. Other important functions include

FIGURE 26-1 Scald burn from child abuse of an infant. Bilateral stocking-glove distribution with well-demarcated margins is consistent with a burn injury from abuse.

vitamin D metabolism and processing neurosensory inputs. The total surface area of skin ranges from 0.2 to 0.3 $m^2$ in an average newborn to 1.5 to 2.0 $m^2$ in an adult, making up nearly 15% of total body weight. The epidermis is composed primarily of epithelial cells, the most abundant of which are keratinocytes. Cells are generated at the stratum basale, from which they divide and migrate upwards through the strata spinosum, granulosum, lucidum, and finally, the stratum corneum. As they move through layers, the keratinocytes begin to flatten out, their nucleus degenerates, and they secrete a matrix made of lipids, cholesterol, and ceramides, which increases cohesion between the cells and is responsible for the barrier characteristic of skin. Once at the stratum corneum, the keratinocytes become corneocytes-anucleate cells that are filled with keratin, and the complete transformation is termed keratinization. Eventually, the corneocytes lose their cohesion and slough off. This entire process of epidermal maturation from the basal layer to desquamation generally takes 2 to 4 weeks.

The basement membrane at the dermoepidermal junction is composed of mucopolysaccharides rich in fibronectin, and the basement membrane functions as a barrier to the passage of macromolecules. The dermis, consisting of fibroblasts that produce collagen and elastin, is subdivided into a superficial papillary dermis and a deep reticular dermis. The papillary dermis is rather functionally active, and because it is this layer that is lost in deeper partial-thickness burns, such injuries tend to heal much more slowly than superficial partial-thickness burns.[10] A plexus of nerves and blood vessels separates the papillary and reticular dermis, and the reticular dermis and hypodermis (subcutaneous tissue) contain skin appendages, such as hair follicles, sweat glands, and sebaceous glands. Therefore burns involving the depth of deep dermis are generally insensate to touch and painful stimuli.

Thermal injury produces coagulation necrosis of the epidermis and a varying depth of injury to the underlying tissue. The extent of burn injury depends on the temperature, duration of exposure, skin thickness, tissue conductance, and specific heat of the causative agent. For example, the specific heat of lipid is higher than that of water, and therefore grease burns often result in much deeper burns than a scald burn from water with the same temperature and duration of exposure. Thermal energy is easily transferred from high-energy molecules to those of lower energy during contact through the process of heat conduction. The skin generally provides a barrier to the transfer of energy to the deeper tissues, and hence, much of the burn injury is confined to this layer. However, local tissue responses to the zone of the burn injury can lead to progression of the burn injury, with the result being a much deeper burn of the surrounding tissue than initially observed.

Classified according to the depth of injury, burns are described as superficial, superficial partial-thickness, deep partial-thickness, full-thickness, and subdermal (Fig. 26-2). Superficial (*first-degree*) burns, like sunburns, affect only the epidermis and are characterized by erythema, pain, and desquamation that resolve without scarring within 7 to 10 days. Superficial partial-thickness (*second-degree*) burns extend through the epidermis into the papillary dermis and are characterized by blisters, erythema, and edema. These burns blanch with pressure and have a brisk capillary refill. Deep partial-thickness (*second-degree*) burns involve the reticular dermis and exhibit a more sluggish capillary refill. The wound is very moist and edematous with diminished to complete loss of sensation. The tissue injury of full-thickness (*third-degree*) burns extends into the subcutaneous tissue and can have a leathery appearance, whereas that of subdermal (*fourth-degree*) burns extends into the fascia, muscles, and bone.

The early response to a burn can be described as local and systemic. The local phase response is characterized by three zones: coagulation, stasis, and hyperemia (Fig. 26-3). Representing the product of maximal insult, the zone of coagulation is identified by surface tissue necrosis as cells are irreversibly damaged secondary to denaturation and coagulation of constituent proteins and loss of plasma membrane integrity. The area immediately surrounding the necrotic area is called the zone of stasis. In this zone, most cells are initially viable, but tissue perfusion becomes progressively compromised because of the local release of inflammatory mediators, such

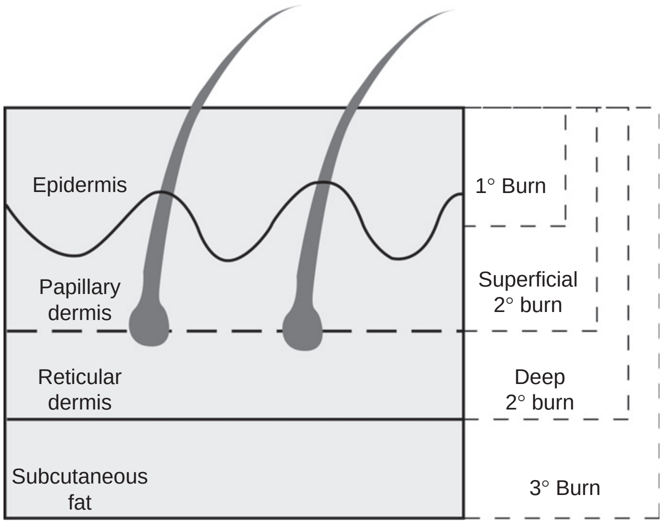

FIGURE 26-2 Depths of burn. First-degree burns are confined to the epidermis. Superficial second-degree burns involve the papillary dermis, and deep second-degree burns involve reticular dermis. Third-degree burns are full-thickness through the epidermis and dermis.

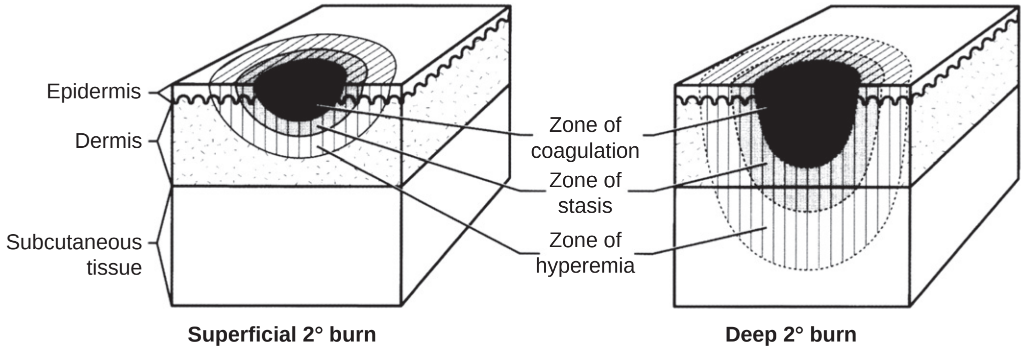

FIGURE 26-3 Three zones of burn injury: coagulation, stasis, and hyperemia.

as thromboxane $A_2$, arachidonic acid, histamine, oxidants, and cytokines. Their influence on the microcirculation results in the formation of platelet thrombus, neutrophil adherence, fibrin deposition, and vasoconstriction, all of which lead to cell necrosis and progression of the burn injury. However, adequate wound care and resuscitation may reverse this process and prevent extensive cell necrosis.

Thromboxane $A_2$ inhibitors, antioxidants (vitamins C and E), and bradykinin inhibitors can significantly improve dermal blood flow and thereby limit the expansion of the zone of stasis. Recently, activated protein C, a physiologic anticoagulant with antithrombotic and anti-inflammatory properties, was shown to improve perfusion in the zone of stasis and decrease the area of necrosis in animal models.[11] Similarly, statins are known to have multiple effects, such as decreasing oxidative stress while up-regulating endothelial nitric oxide synthesis, prostacyclins, and tissue-type plasminogen activator. In another animal model study, the administration of simvastatin was shown to increase blood flow and decrease intravascular coagulation, which resulted in salvage of the zone of stasis.[12] Finally, the zone of hyperemia lies peripheral to the zone of stasis and is characterized by vasodilatation with subsequent increased blood flow and edema resulting from the inflammatory response. Tissue within this zone frequently recovers unless affected by severe sepsis or prolonged hypoperfusion.[13]

The mechanisms involved in the response to burns are rather complicated but interconnected. The initial tissue loss sets off a chain of reactive processes, beginning with activation of toxic inflammatory mediators, such as oxidants and proteases, that not only further damages tissue and capillary endothelial cells but also potentiates further tissue necrosis. Both complement and neutrophil activation results in the production of cytotoxic reactive oxygen species and histamine, which mediates progressive vascular permeability.[14] Disruption of collagen cross-linking and loss of cell membrane integrity compromises osmotic and hydrostatic pressure gradients, resulting in local edema and exacerbation of marked fluid shifts.[10] Thus burn wound progression is compounded by the presence of edema, infection, and hypoperfusion.

The burn-induced inflammatory response is not limited to the local burn wound. A massive systemic release of thromboxane $A_2$, along with other inflammatory mediators (bradykinin, leukotrienes, catecholamines, activated complement, and vasoactive amines) induces a significant physiologic burden on multiple organ systems, particularly the cardiopulmonary, renal, and gastrointestinal systems. Decreased plasma volume resulting from increased capillary permeability with a subsequent plasma leak into the interstitial space can lead to depressed cardiac function. As a result of low cardiac output, renal blood flow can decrease, leading to a diminished glomerular filtration rate. Activation of other stress-induced hormones and mediators, such as angiotensin, aldosterone, and vasopressin, can further compromise renal blood flow, resulting in oliguria. If not promptly recognized and treated, this condition can progress to acute tubular necrosis and renal failure, which contributes to poor outcomes in burn patients.

Burn injury can also affect remote organ systems, such as the gastrointestinal tract. Splanchnic vasoconstriction can cause transient mesenteric ischemia and a rapid onset of atrophy of the small bowel mucosa resulting from increased epithelial apoptosis and decreased epithelial proliferation. Moreover, studies have found that intestinal permeability to macromolecules increases after burns, lending an explanation to how bacterial translocation and subsequent endotoxemia ensue. Burn injury also causes a global depression of immune function. Macrophage production and cytotoxic T-lymphocyte activity are decreased, and neutrophils become impaired in terms of diapedesis, chemotaxis, and phagocytosis. Taken together, these impairments in function contribute to an increased risk for infectious complications after burns.

# Acute Management

## INITIAL EVALUATION

The burn patient must be immediately removed from the source of burn injury and potential life-threatening injuries quickly assessed and addressed independent of the cutaneous burns, as in the case of a multiple-trauma victim. Burning clothing articles and metal jewelry are quickly removed. Immediate cooling, such as pouring cold water on the burn wound, can minimize the depth of burn injury but must be used with extreme caution in a small TBSA burn because doing so can result in systemic hypothermia. In the case of chemical burns, victims should be promptly removed from the continued exposure to the causative chemical agent(s) and the wounds irrigated with copious amounts of water, taking caution not to spread chemical on burn wounds to adjacent uninvolved skin areas. Attempts to neutralize chemicals

are contraindicated, because this process may produce additional heat and further add insult to the initial burn injury.

As with any trauma patient, burn patients are quickly assessed through primary and secondary surveys. Airway, breathing, and circulation status are assessed, and any potential life-threatening conditions should be promptly identified and managed as deemed appropriate. Respiratory symptoms, such as wheezing, tachypnea, or hoarseness, may signify an impending major airway problem. Therefore the airway should be rapidly secured with 100% oxygen support. Oxygen saturation is monitored using pulse oximetry, and chest expansion is observed to ensure adequate and equal air entry. Circumferential full-thickness burns to the chest can significantly impair respiratory function by constricting the chest wall and preventing adequate chest expansion. If necessary, escharotomy should be performed to allow for better chest expansion and subsequent ventilation. Blood pressure may be difficult to obtain in burned patients with charred extremities, and an arterial line may be necessary. One review of femoral artery catheterization in pediatric burn patients found that the complication rate was quite minimal and provided a more accurate measure of hemodynamics.[15] Nonetheless, a change in the pulse rate is a sensitive indicator for intravascular volume status, and therefore the presence of tachycardia should prompt aggressive fluid resuscitation.

The management of the burn patient depends on the depth of the injury. For superficial or first-degree burns, the treatment is focused on symptomatic relief and consists of a topical ointment containing *Aloe vera* along with a nonsteroidal anti-inflammatory agent. Superficial and deep partial thickness burns are also known as second-degree burns. The former heals spontaneously with re-epithelialization occurring within 10 to 14 days. Slight skin pigment discoloration is usually the only significant sequela. Deep partial thickness wounds, on the other hand, heal slowly over several weeks, usually with significant scarring, and generally require surgical debridement and skin grafting for a more rapid recovery and shorter hospitalization. Third-degree burns are synonymous with full-thickness injuries, and because there are no residual epidermal or dermal appendages, these burn wounds heal by re-epithelialization from the burn wound edges. As can be expected, this process is slow, requiring a prolonged hospitalization with an increased risk of burn wound infection. Fourth-degree burns, typically resulting from a profound thermal or electrical injury, involve organs beneath the layers of the skin, such as muscle and bone. The treatment for both third- and fourth-degree burns is similar in that they respond best to early debridement and grafting.

Accurate and rapid determination of burn depth is vital to the proper management of the injury. In particular, the distinction between superficial and deep dermal burns is critical because this can dictate whether the burn can be managed with or without excision and grafting. Early excision and grafting provides better results than nonoperative therapy even for so-called indeterminate burns. Because overall estimates report that clinical depth assessment is accurate in about two thirds of cases, more precise and objective methods to determine burn depth have been investigated.[16,17] One particular study examined the use of laser Doppler imaging in 48 children with burn injury and found that it could accurately predict whether a wound would need grafting or would re-epithelialize in less than 21 days.[18] A similar study reported that wounds healing within 14 days had a significantly higher perfusion on Doppler evaluation than late-healing wounds.[19] Thus laser Doppler flowmetry can be helpful in accurately predicting burn depth and wound healing capacity. Other less frequently used techniques include a punch biopsy with histologic confirmation, fluorescein fluorescence, indocyanine green video angiography, and high-frequency ultrasonography. Reflection-optical multispectral imaging and fiberoptic confocal imaging are two novel, noninvasive techniques that rely on the illumination characteristic of the tissue to determine the depth of the burn, and they may very well become the newest innovation in the field of diagnostics.[16] Ultimately, burn wound biopsy would seem to be the most precise diagnostic tool. However, this is not clinically useful, since it is invasive and can only provide static information of burn wound. It also requires an experienced pathologist to interpret histologic findings. Despite recent diagnostic advances, clinical observation still remains the standard and the most reliable method of determining the burn depth.

The size of the burn is generally assessed by the "rule of nines" in adolescents and adults. The upper extremities and head each represent 9% of the TBSA, and the lower extremities and the anterior and posterior trunks are 18% each. The perineum, genitalia, and neck each measure 1% of the TBSA. A quick rough estimate of the burn size can also be assessed by the use of the patient's palm, which represents 1% TBSA. However, the general use of this rule can be misleading in children, because of different body proportions. Children have a relatively larger portion of their body surface area (BSA) in the head and neck and a smaller surface area in the lower extremities. For instance, an infant's head constitutes 19% of TBSA compared with 9% in an adult. Thus the modified rule of nines takes into account the anthropomorphic differences of infancy and childhood, making it a more accurate assessment of pediatric burn size (Fig. 26-4). Table 26-1 also shows the chart used to estimate the percentage of TBSA burned based on age of patients and area of burns.

Full-thickness circumferential burns to the extremities produce a constricting eschar, which potentially can result in vascular compromise to the distal tissues including nerves. Accumulation of tissue edema beneath the nonelastic eschar impedes venous outflow, first resulting in a compartment syndrome and eventually affecting arterial flow. When distal pulses are absent by palpation or Doppler exam, which is not as a result of global hypoperfusion, escharotomies should be performed to avoid vascular compromise of the limb tissues. With the use of either the scalpel or electrocautery, escharotomies can be performed at bedside along the lateral and medial aspects of the involved extremities (Fig. 26-5). When the hands are involved, incisions are carried down onto the thenar and hypothenar eminences and along the dorsolateral aspects of the digits, taking care to avoid injury to the neurovascular bundle. Because burn wounds requiring escharotomies are typically full-thickness injuries, minimal bleeding is encountered. With prolonged vascular compromise, reperfusion after an escharotomy may cause reactive hyperemia and further edema formation in the muscle compartments. Ischemia-reperfusion injury also releases free oxygen radicals resulting in transient hypotension. If increased compartment pressures are noted, fasciotomy should be performed immediately to avoid permanent ischemic injuries to nerves and soft tissues.

Intravenous (IV) access should be established immediately to infuse lactated Ringer solution according to the

resuscitation guideline. Peripheral IV access is preferred, but femoral venous access is an ideal alternative in patients with massive burns, particularly those involving the extremities. When vascular access becomes problematic in small children with burned extremities, the intraosseous route is another alternative option in children less than 6 years of age. However, proper technique must be used to avoid potential injury to the bone growth plate. A nasogastric tube is placed in all patients with major burns in anticipation of a gastric ileus and potential vomiting. In addition, almost immediate implementation of enteral nutrition by either a gastric or transpyloric feeding tube can mitigate burn-induced small bowel ileus. A urinary catheter should likewise be inserted to accurately monitor urine output as a measure of end-organ perfusion. Initial laboratory tests should include complete blood count, type and

crossmatch for packed red blood cell, chemistry, urinalysis, coagulation profile, and chest radiograph. If inhalation injury is suspected, arterial blood gas with carboxyhemoglobin level should also be determined to guide respiratory therapy.

## FLUID RESUSCITATION

Appropriate fluid resuscitation should begin promptly upon securing IV access. Peripheral IV access is sufficient in the majority of small to moderate size burns. Saphenous vein cut-downs are useful in cases of difficult access in larger patients. In children, percutaneous femoral central venous access may be easier and more reliable when confronted with a difficult peripheral IV access situation. Many guidelines exist regarding fluid resuscitation, with the administration of varying concentrations of colloid and crystalloid solutions.[20] The Parkland formula (4 mL of lactated Ringer solution per kg of body weight per percentage of TBSA burned) is most widely used, but children's fluid resuscitation guideline should be based on BSA. Children have a greater BSA in relation to weight, and as a result, weight-based formulas can under-resuscitate children with minor burns and may grossly over-resuscitate with extensive burns. Nonetheless, fluid loss is also proportionally greater in children, and consequently, they may require more fluid per kilogram. TBSA can be assessed using standard nomograms based on height and weight or calculated using formulas (Table 26-2). The Galveston formula (Shriners Hospital for Children) uses 5000 mL/m$^2$ BSA burn plus 2000 mL/m$^2$ BSA of lactated Ringer solution given during the first 24 hours after burn, with half the volume administered during the first 8 hours and the remaining half during the following 16 hours (Table 26-3).

Regardless of which guidelines are used, the primary goal of fluid resuscitation is to achieve adequate organ tissue perfusion. Fluid administration should be titrated to maintain a urine output of greater than 1 mL/kg/hr. Approximately 50% of administered fluid is sequestered in nonburned tissues in 50% TBSA burns because of increased capillary permeability that occurs particularly in the first 6 to 8 hours after injury. During this period, large molecules leak into the interstitial space to increase extravascular colloid osmotic pressure. Therefore to maintain intravascular osmotic pressure, albumin is added 12 hours after the injury. Closely mirroring a similar study in adults, one retrospective study of fluid resuscitation in pediatric burn patients noted that patients requiring albumin supplementation took significantly longer to resuscitate (30.5 vs. 22.0 hr) and received significantly more fluid than patients receiving crystalloid only (9.7 vs. 6.2 mL/kg/%TBSA). Although their outcomes were the same, the nature of their injuries was more significant, however, given the greater percentage TBSA full-thickness burn and presence of inhalation injury.[21] After the first 24 hours, 3750 mL/m$^2$ BSA burned is given to replace evaporative fluid loss plus 1500 mL/m$^2$ BSA per 24 hours for maintenance requirement (Galveston formula). Dextrose containing solution, such as 5% dextrose with {1/4} to {1/2} normal saline is used as the primary solution. Children less than 2 years of age are susceptible to hypoglycemia because of limited glycogen stores, and therefore lactated Ringer solution with 5% dextrose is usually given during the first 24 hours after burns.

**TABLE 26-3**
**Acute Burn Fluid Resuscitation Guidelines**

| *Formula* | *First 24 Hours* | *Thereafter* |
|---|---|---|
| Parkland | Lactated Ringer solution; 4 mL/kg/% TBSA burn: 50% total volume during the first 8 hr after injury and the remaining during the subsequent 16 hr | 5% dextrose with $Na^+$, $K^+$ and albumin to maintain normal serum electrolytes and colloid oncotic pressure |
| Brooke | Lactated Ringer solution (with colloid 0.5 mL/kg/% TBSA burn); 2 mL/kg/% TBSA burn; 50% total volume during the first 8 hr after injury and the remaining during the subsequent 16 hr | Titrate to maintain urine output 0.5-1.0 mL/kg/hr |
| Shriners-Galveston | Lactated Ringer solution (12.5 g albumin/L added 12 hr after injury); 5000 mL/m$^2$ BSA burn + 2000 mL/m$^2$ TBSA; 50% total volume during the first 8 hr after injury and the remaining during the subsequent 16 hr | 3750 mL/m$^2$ BSA burn + 1500 mL/m$^2$ TBSA; substitute IV fluid volume with enteral formula |

IV, intravenous; TBSA, total body surface area.

Over-resuscitation during the first 24 hours postburn has been shown to be associated with an increased incidence of pneumonia, bloodstream infection, acute respiratory distress syndrome, multiple-organ failure, and death. "Permissive hypovolemia" during burn fluid resuscitation has been shown to improve multiple-organ dysfunction, further suggesting that this is a safe and beneficial approach during the acute burn resuscitation. One recent study reiterated the findings of a prospective clinical study, which reported that the use of high-dose ascorbic acid is associated with a decrease in fluid requirements and an increase in urine output during resuscitation after thermal injury without an increased risk of renal failure.[22] Some interest lies in the use of hypertonic saline as a resuscitative fluid in burn-induced shock and has been shown to be beneficial in treating burn-induced shock.[23] It theoretically should maintain intravascular volume more effectively by removing fluid from the interstitial space by osmosis, resulting in a decrease in generalized tissue edema. However, it is not widely used because of its potential risk for hypernatremia, hyperosmolarity, renal failure, and alkalosis. Importantly, no prospective randomized controlled studies have yet to confirm these end points.[24] Some favor the use of a modified hypertonic solution by adding one ampule of sodium bicarbonate to each liter of lactated Ringer solution during the first 24 hours of resuscitation.

Children often do not exhibit clinical signs of hypovolemia until more than 25% of the circulating volume is depleted and complete cardiovascular collapse is imminent. Thus

**TABLE 26-4**
**American Burn Association Criteria for Major Burn Injury**

| |
|---|
| Second- and third-degree burns > 10% TBSA in patients < 10 or > 50 years of age |

symptoms of hypovolemia, such as hypotension and oliguria, can be late signs of shock in such children. Tachycardia typically indicates an early sign of hypovolemia, but caution should be used not to overinterpret, because reflex tachycardia caused by postinjury catecholamine response is also common. A lethargic child with decreased capillary refill and cool, clammy extremities requires prompt attention. Measurement of arterial blood pH and base deficit values can also reflect adequacy of fluid resuscitation. Hyponatremia is also a frequent complication in pediatric burn patients after aggressive fluid resuscitation. Although rare, a serious complication, such as central pontine myelinolysis, can occur with rapid correction of hypernatremia.[25] Frequent monitoring of serum chemistry with appropriate correction is required to avoid severe electrolyte imbalance.

After initial first aid and start of appropriate fluid resuscitation, it must be determined whether a burn victim should be transferred to a tertiary burn center. Burn units with experienced multidisciplinary team members are best prepared and experienced to handle major burn patients. In addition to physicians and nurses, respiratory and rehabilitation therapists also play critical roles in the management of acute burn patients. As defined by the American Burn Association, any patients who sustain *major burn injury* should be transferred appropriately to a nearby burn center for further care (Table 26-4).

## INHALATION INJURY

Inhalation injury remains the major contributor to mortality in burn patients. The mortality rate of children with isolated cutaneous burns is 1% to 2%, but this can significantly increase to 16% in the presence of inhalation injury.[26] The initial assessment of patients with combined thermal and other traumatic injuries should, as always, center on airway, breathing, and circulation per advanced trauma life support (ATLS) guidelines. The treatment of inhalation injury begins at the scene of the burn accident. The administration of 100% oxygen rapidly decreases the half-life of carbon monoxide. If the respiratory distress is significant, intubation or a surgical airway may be required. Although hypoxemia is usually evident, the initial chest radiograph and arterial blood gas may be normal, but the inhalational injury can evolve for hours.

The diagnosis of an inhalation injury is usually made on the clinical history and physical findings at the initial evaluation. For instance, victims trapped in a house fire with excessive smoke and fumes are likely to have sustained a severe inhalation injury. Common signs include cough, stridor, singed nasal hair, carbonaceous sputum, and a hyperemic oropharynx. Although the immediate injury results in hyperemia, ulceration, and edema, these symptoms may not be obvious until the airway becomes significantly obstructed, in which case the time lapse can exceed 18 hours. Hoarseness and stridor should alert the surgeon to significant airway obstruction, and the airway should immediately be secured with endotracheal intubation. Patients who present with disorientation and obtundation are likely to have an elevated carbon monoxide level (carboxyhemoglobin > 10%). Cyanide toxicity as a result of the combustion of common household items may also contribute to unexplained metabolic collapse. Fiberoptic bronchoscopy remains the gold standard test to confirm a diagnosis of an inhalation injury by demonstrating inflammatory changes in the tracheal mucosa, such as edema, hyperemia, mucosal ulceration, and sloughing. A ventilation/perfusion scan can also identify regions of inhalation injury by assessing respiratory exchange and excretion of xenon gas by the lungs.[27] Together, these complementary diagnostic tools are more than 90% accurate in the diagnosis of inhalation injury.

Smoke inhalation injury can be divided into three different types of injury: thermal (usually restricted to the upper airway), chemical irritation of the respiratory tract, and systemic toxicity resulting from inhalation of fumes, gases, and mists. Although the supraglottic region can be injured by both thermal and chemical insults because of highly efficient heat exchange, tracheobronchial and lung parenchymal injuries rarely occur as a result of direct thermal damage, because the heat disperses so rapidly in the larynx. The heat destroys the epithelial layer, denatures proteins, and activates the complement cascade, leading to the release of histamine and the formation of xanthine oxidase to release reactive oxygen species (ROS) such as superoxide. At the same time, nitric oxide (NO) and reactive nitrogen species (RNS) formation by endothelial cells is propagated by histamine stimulation. Both ROS and RNS cause increased permeability to proteins, resulting in edema formation. In addition, interleukin-8 (IL-8) is also released after injury, leading to the recruitment of polymorphonuclear cells, which further amplify the inflammatory process.[28] Using an ovine model with combined thermal and inhalation injuries, one group found that infusion of 7-nitroindazole, a selective neuronal nitric oxide synthase inhibitor, blocks the inflammatory cascade, as demonstrated by a 40% and 30% respective decrease in IL-8 and myeloperoxidase activity in lung tissue concentrations compared with the injured control group. The treated group also saw a reduction in bronchial injury, peak pulmonary pressures, and shunting.[29] Thus 7-nitroindazole may represent an effective therapy in the management of inhalation injuries.

Hypoxia, increased airway resistance, decreased pulmonary compliance, increased alveolar epithelial permeability, and increased pulmonary vascular resistance may be triggered by the release of vasoactive substances (thromboxanes $A_2$, $C_{3a}$, and $C_{5a}$) from the damaged epithelium.[30] Neutrophil activation plays a critical role in this process, whereby pulmonary function has been shown to improve with the use of a ligand binding to E-selectins (inhibiting neutrophil adhesion) and

anti–IL-8 (inhibiting neutrophil chemotaxis). Sloughing of the respiratory cilia impairs the physiologic cleaning process of the airway, resulting in an increased risk of bacterial infections and pneumonia. This may be further complicated by increased bronchial secretions and mucous plugging, which may predispose to distal airway obstruction and atelectasis, thereby impairing pulmonary gas exchange. These exudates, consisting of lymph proteins, coalesce to form fibrin casts that can create a "ball-valve" effect in localized areas of lung, eventually causing barotrauma.

To reduce respiratory complications such as pneumonia, protocols have been instituted in an effort to improve the clearance of tracheobronchial secretions and decrease bronchospasm (Table 26-5). Aggressive pulmonary toilet with physiotherapy and frequent suctioning is an important adjunct. The patient is frequently turned side to side along with chest physiotherapy every 2 hours. In the critically ill patient, high-frequency percussive ventilation has been shown to reduce development of pneumonia through clearance of bronchial secretions. When physiologically stable, the patient is transferred out of bed to a chair, with progressive ambulation to prevent compressive atelectasis. Humidified air is delivered at high flow, while bronchodilators and racemic epinephrine are used to treat bronchospasm. The use of nebulized heparin has been shown to reduce tracheobronchial cast formation, improve minute ventilation, and lower peak inspiratory pressures after smoke inhalation. Inhalation treatments, such as 20% acetylcysteine nebulized solution (3 mL q4h) plus nebulized heparin (5,000 to 10,000 units with 3 mL normal saline q4h), are effective in improving the clearance of tracheobronchial secretion and minimizing bronchospasm, thereby significantly improving reintubation rates and decreasing mortality.[31,32]

The presence of inhalation injury generally requires an increased amount of fluid resuscitation, up to 2 mL/kg/% TBSA burn more than would be required for an equal-size burn without an inhalation injury. In fact, pulmonary edema that is associated with inhalation injury is not prevented by fluid restriction, but rather, inadequate resuscitation may increase the severity of pulmonary injury by sequestration of polymorphonuclear cells.[33] Corticosteroids have not been shown to be of any benefit in inhalation injury. Prophylactic IV antibiotics are not indicated unless there is clinical suspicion of pneumonia. Early pneumonia is usually the result of gram-positive organisms, such as methicillin-resistant *Staphylococcus aureus*, whereas gram-negative organisms, such as *Pseudomonas* and *Acinetobacter,* are responsible for later-onset infection. Antibiotic therapy should be guided by sensitivities and susceptibilities of serial cultures from sputum, tracheal aspirates, or bronchoalveolar lavages.

**TABLE 26-5**
**Inhalation Injury Treatment Protocol**

| *Treatment* | *Interval and Dosages* |
|---|---|
| Suction and lavage | q2h |
| Bronchodilators (Albuterol) | q2h |
| Nebulized heparin | 5000-10,000 units with 3 mL NS q4h |
| Nebulized acetylcysteine | 20%, 3 mL q4h |
| Hypertonic saline | Induce effective coughing |
| Racemic epinephrine | Reduce mucosal edema |

NS, normal saline.

# Burn Wound Care

The proper wound care is generally dictated by the accurate assessment of the burn depth and size. First-degree burns require no particular dressing, but the involved areas should be kept out of direct sunlight. They are generally treated with topical ointments for symptomatic pain relief. Superficial second-degree burns are treated with daily dressing changes with topical antimicrobial agents. They can also be treated with application of petroleum gauze or a synthetic dressing to allow for rapid re-epithelialization. Deep second- and third-degree burn wounds eventually require excision of the eschar with skin grafting. Table 26-6 describes various available antimicrobial, synthetic, and biologic dressing products for burn wound care.

## TOPICAL ANTIMICROBIALS

Various topical antimicrobial agents have been used for management of burn wounds. None of these agents effectively prevent colonization of organisms that are commonly harbored in the eschar, but instead promote bacteriostasis to limit bacterial burden to less than $10^2$ to $10^5$ colonies/g of tissue. Routine punch quantitative wound biopsy of burned areas can alert to impending burn wound sepsis and risk of failure of skin graft from infection. The National Burn Repository estimates that 4.4% of deaths after burn injury are attributable to burn wound sepsis. With evidence of multidrug-resistant organisms (MDROs), one study evaluated 47 MDROs and 27 non-MDRO controls versus 11 different topical agents, in which the topical agents were effective against 88% of the non-MDROs but only 80% of MDROs. Mafenide acetate, silver sulfadiazine, and silver nitrate were effective against both gram-negative and gram-positive bacteria, regardless of drug resistance status. Nonetheless, the results reinforce the concern that bacteria are becoming more resistant to antimicrobial regimens.[34]

Silver sulfadiazine (Silvadene; Monarch Pharmaceuticals, Bristol, Tenn.) is the most commonly used topical agent for burn wound dressings. Although it does not penetrate eschar, Silvadene has a broad spectrum of efficacy and mitigates the pain associated with second-degree burns. However, it frequently adheres to the wound surface, thereby traumatizing newly generated epithelial surfaces and delaying healing. Silvadene on fine mesh gauze can be used separately or in combination with other antimicrobial agents, such as nystatin. The combination of Silvadene with nystatin has significantly reduced the incidence of *Candida* infection in burned patients.[35] The most common side effect of Silvadene is leukopenia, which is likely related to margination of white blood cells and is only transient.[36] However, when the leukocyte count falls below 3000 cells/mm$^3$, changing to another topical antimicrobial agent is warranted.

Mafenide acetate (Sulfamylon; UDC Laboratories, Rockford, Ill.) is more effective in penetrating eschar, and therefore is frequently used in third-degree burns. Fine mesh gauze impregnated with Sulfamylon (10% water-soluble cream) is applied directly onto the burn wound. Sulfamylon has a much broader spectrum of antimicrobial efficacy, including against *Pseudomonas* and *Enterococcus*. It is also available in 5% solution to soak burn wounds, eliminating a need to perform

**TABLE 26-6**
**Burn Wound Dressings**

| *Dressings* | *Advantages* | *Disadvantages* |
|---|---|---|
| **Antimicrobial Salves** | | |
| Silver sulfadiazine (Silvadene) | Painless; broad spectrum; rare sensitivity | Leukopenia; some gram-negative resistance; does not penetrate eschar; inhibition of epithelialization |
| Mafenide acetate (Sulfamylon) | Broad-spectrum; penetrates eschar; effective against *Pseudomonas* | Painful; metabolic acidosis (carbonic anhydrase inhibitor); inhibition of epithelialization |
| Bacitracin/neomycin/polymyxin B | Ease of application, painless, useful on face | Limited antimicrobial property |
| Nystatin | Effective in inhibiting fungal growth; use in combination with Silvadene, Bacitracin | Cannot use in combination with mafenide acetate |
| Mupirocin (Bactroban) | Effective against *Staphylococcus,* including MRSA | Cost; poor eschar penetration |
| **Antimicrobial Soaks** | | |
| 0.5% Silver nitrate | Painless; broad-spectrum; rare sensitivity | No eschar penetration; discolor contacted areas; electrolyte imbalance; methemoglobinemia |
| Povidone-iodine | Broad-spectrum antimicrobial | Painful; potential systemic absorption; hypersensitivity |
| 5% Mafenide acetate | Broad-spectrum antimicrobial | Painful; no fungal coverage; metabolic acidosis |
| 0.025% Sodium hypochlorite (Dakin solution) | Effective against most organisms | Mildly inhibits epithelialization |
| 0.25% Acetic acid | Effective against most organisms | Mildly inhibits epithelialization |
| **Silver-Impregnated** | | |
| Aquacel, Acticoat | Broad-spectrum antimicrobial; no dressing changes | Cost |
| **Synthetic Dressings** | | |
| Biobrane | Provides wound barrier; minimizes pain; useful for outpatient burns, hands (gloves) | Exudate accumulation risks invasive wound infection; no antimicrobial property |
| Opsite, Tegaderm | Provides moisture barrier; minimizes pain; useful for outpatient burns; inexpensive | Exudate accumulation risks invasive wound infection; no antimicrobial property |
| Transcyte | Provides wound barrier; accelerates wound healing | Exudate accumulation risks invasive wound infection; no antimicrobial property |
| Integra, Alloderm | Complete wound closure, including dermal substitute | No antimicrobial property; expensive; requires training, experience |
| **Biologic Dressings** | | |
| Allograft (cadaver skin), Xenograft (pig skin) | Temporary biologic dressings | Requires access to skin bank; cost |
| Amniotic membrane | Minimizes dressing changes | Minimal experience; not widely used |

frequent dressing changes. Sulfamylon is a potent carbonic anhydrase inhibitor and can therefore cause metabolic acidosis. This side effect can usually be avoided by limiting its use to only 20% TBSA at any given time and rotating application sites every several hours with another topical antimicrobial agent. In addition, the application of Sulfamylon can be painful, which limits its practical use in an outpatient setting, especially with children.

Other agents, such as 0.5% silver nitrate and 0.025% sodium hypochlorite (Dakin solution), are also available as soak solutions. These soak solutions are generally poured onto gauze dressings, which minimizes dressing changes and the potential loss of grafts or healing keratinocytes. Silver nitrate is painless on application and has broad coverage, but its side effects include electrolyte imbalance (hyponatremia, hypochloremia) and dark gray or black stains. Dakin (0.025%) solution is effective against most microbes, including *Pseudomonas*. However, it requires frequent dosing because of inactivation of hypochlorite when coming in contact with protein and can also retard healing cells.[37] Petroleum-based antimicrobial ointments, such polymyxin B, bacitracin, and polysporin, are painless and transparent, allowing easier monitoring of applied burn wounds. These agents are mostly only effective against gram-positive organisms, and their use is limited to facial burns, small areas of partial-thickness burns, and healing donor sites. As with Silvadene, petroleum-based agents can also be used in combination with nystatin to suppress skin *Candida* colonization.

Commercially available dressings containing biologically active silver ions (Aquacel, ConvaTec, Skillman, NJ; Acticoat, Smith & Nephew, Auckland, NZ) hold promise for retaining the effectiveness of silver nitrate but without its side effects. Allowing it to adhere to the wound within 24 hours, the hydrocolloid properties of the Aquacel dressing make it absorbent and non-traumatic to the delicate tissues of the healing wound. Since it can be left without dressing changes for up to 2 weeks, it may be useful in the outpatient management of a burn injury. Similarly, Acticoat has been shown to have improved bacterial clearance, which is related to a sustained release of silver that allows for less frequent dressing changes.[38]

## BURN WOUND DRESSINGS

Superficial second-degree burns can be managed using various methods. A topical antimicrobial dressing using Silvadene is most commonly used, but synthetic dressings, such as Biobrane (UDL Laboratories, Rockford, Ill.) and Opsite (Smith & Nephew), offer unique advantages of eliminating frequent
